The diseases in which the change in the spleen seemed to be part of a general error in the hæmopoietic system were divided into an aplastic and a hæmolytic group, but there was no sharp line of division. True *aplastic anæmia* was chiefly found in young women and was rapidly fatal, so that splenectomy was not suitable. Many believed, however, that an aplastic condition might be a late stage of long-continued destruction, so that splenectomy in the early stage, before the marrow became aplastic, might diminish the strain on the marrow. The three cases operated on had all died. The hæmolytic group included pernicious anæmia, intestinal parasites, syphilis and carcimoma, puerperal lesions, chemical poisons, hæmolytic or acholuric jaundice, and purpura hæmorrhagica. Even if *pernicious anæmia* were originally due to excessive destruction of the red cells, the formation of new elements was undoubtedly at fault in the established condition. Even those who had advocated splenectomy had generally combined it with massive and repeated blood transfusion and the thorough treatment of all septic foci. Even with careful selection the surgical results were unsatisfactory. Since the introduction of liver treatment the operation was not justifiable. The profound hæmolytic jaundice found in the late stages of syphilis or carcinoma, as a complication of the puerperium, after the ingestion of chemical poison or during infestation with intestinal parasites, did not call for surgical interference. *Acholuric jaundice* might be compatible with active life, but in other cases the attacks of jaundice were associated with fever and malaise and with enlargement of the liver and spleen which might be painful. In the acquired type the attacks were more frequent and more severe and the patient soon showed a profound anæmia. The condition was often complicated by the formation of pure pigment gall-stones. The primary factor in the disease seemed to be an increased fragility of the red blood corpuscles—although this was not invariable—so that they were destroyed by the spleen and caused an increase of bile-pigment in the blood, though not in the urine or stools. In long-standing cases the anæmia might be increased by hæmorrhages. The enlargement of the spleen was moderate and variable, usually greater during the exacerbations. Splenectomy was followed by very good results and the mortality was low. *Purpura* might occur as a symptom of many conditions, but a very distinct type of the primary disease—thrombocytopenic purpura hæmorrhagica—had been differentiated. It was commoner in women and was essentially a disease of early life, though it might occur at any age. The diagnosis was made on the definite and distinct blood picture: a low platelet count, prolonged bleeding time, failure of blood-clot to retract, normal clotting time, and appearance of petechiæ below a tourniquet. Soon after splenectomy the number of platelets rose very considerably, so that an operation in the thrombocythæmic group of diseases (where the platelet count was normal or above) might cause widespread thrombosis, especially of the mesenteric vessels. Henoch's purpura was thrombocythæmic and purpura hæmorrhagica was thrombocytopenic. The diminution in platelets was an important but not the only factor in the production of hæmorrhage. H. L. Tidy had concluded that the underlying factor was an abnormal permeability of the vessel wall. The spleen was never greatly enlarged in purpura, but its size was some indication of its destructive action. A leucocytosis was evidence that the bone-marrow was still active. Acute types did not react well to surgical treatment, but for chronic relapsing cases there was no treatment but splenectomy. It was very difficult to distinguish one purpura from another and splenectomy should be reserved for the chronic relapsing cases, with typical blood characteristics, where it had a remarkable effect. The removal was usually easy and its mortality low, the platelet count rose almost immediately afterwards, and the bleeding diminished or ceased. If there was recurrence it was mild. This was the condition in which splenectomy gave the best results. *Gaucher's disease,* more common in women, was characterised by a considerable and progressive enlargement of the spleen and liver, by leucopenia, and sometimes by a secondary anæmia and browning of the exposed skin. The wedge-shaped thickenings in the conjunctiva were not absolutely constant. There was usually pain in the spleen and in the extremities, due to rarefaction of the bones, which might progress to deformity and fracture. The condition was familial but not hereditary, and was now generally regarded as a disturbance of metabolism. Some authorities nevertheless still believed that splenectomy had a place, though it could not prevent progress of the disease. Life was lengthened rather than shortened by operation, which might give considerable relief. In every case of splenomegaly a careful examination of the blood should be made; splenectomy for the leukæmias had been abandoned, although it could be performed with fair success after preliminary treatment with X rays and radium.

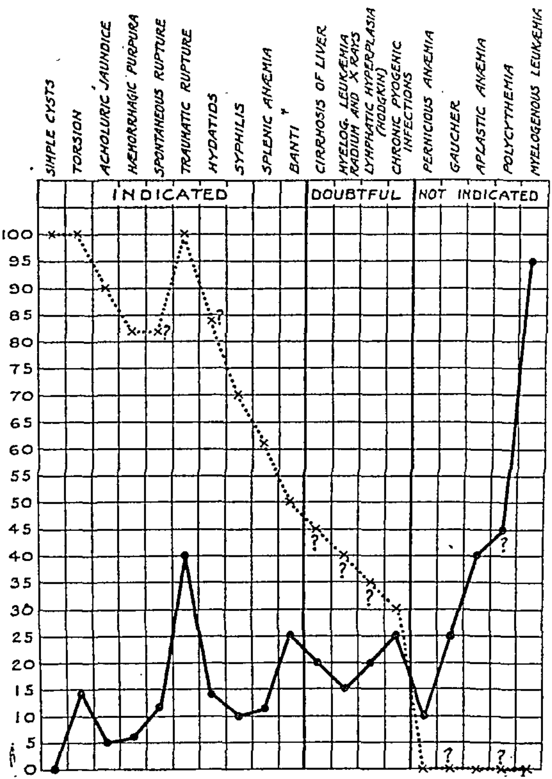

Chart showing operative mortality and end-results after splenectomy for different morbid states (Mr. A. J. Walton). Continuous line = operative mortality (percentage); interrupted line = post-operative recovery (percentage).

General Indications for Operation, and Technique.

The most important consideration was the platelet count, because of the danger of thrombosis if the platelets were many. A leucocytosis indicated that the bone-marrow was more active than if there were a leucopenia, and the degree of anæmia might indicate the extent of the hæmorrhage. In most cases the bigger the spleen the better the operative outlook. Free access was essential, especially in Banti's disease and inflammatory lesions, where there might be firm adhesions to the diaphragm. Mr. Walton preferred an incision running in the line of the intercostal nerves from the umbilicus to the left costal margin. From the lower end a left pararectal incision one inch from the midline passed up to the xiphoid. The oblique incision divided all the muscles in turn. The peritoneum was opened by a large triangular flap which was turned up over the left costal margin. This method caused no permanent harm to the abdominal wall, as it divided no motor nerves. The abdominal cavity was then surveyed rapidly, any change in mesenteric lymph glands being a bad prognostic sign. The stomach and intestines were packed off and the anterior peritoneal layer of the gastrosplenic omentum carefully divided. Ligature and division of the splenic vessels might be a delicate matter, for when the spleen was large the veins were often so friable that careful stripping with a gauze pad might cause furious hæmorrhage. If it satisfactory. *Tumours* of the spleen might be fibroma or fibro-sarcoma from the capsule and trabeculæ, lymphoma or lympho-sarcoma from the lymphoid elements, or angiomata or endotheliomata from the vascular and sinus endothelium. The first group usually caused a localised tumour diagnosed simply as splenomegaly and best treated by splenectomy. Lymphomata were often associated with general lymphoid enlargement, making distinction from Hodgkin's disease very difficult. Splenectomy was likely to be very unsatisfactory if there was general lymphatic enlargement. Great splenomegaly due to enormous enlargement of the Malpighian bodies, with general enlargement of lymphatic glands and a normal blood count constituted a syndrome which should be treated by X rays. The vascular endotheliomata were usually simple tumours, of pathological rather than of clinical interest. Gaucher had originally regarded his disease as an endothelioma, but it had now been removed from this group.

Acute inflammations could be provisionally grouped as localised (or abscess) and diffuse, either septic or specific. In all septic conditions the spleen tended to be large, soft, and flabby, but did not cause any symptoms. Abscess was rare and usually followed a localised necrosis, as in infarct. Drainage might be required for an abscess, but otherwise acute inflammations called for no surgical interference. *Chronic inflammations* occurred in: pyogenic conditions, splenic anæmia, cirrhosis of the liver, Hodgkin's disease, malaria, kala-azar, syphilis, tuberculosis, and secondary polycythæmia. The splenomegaly of chronic pyogenic inflammations might closely simulate that of splenic anæmia and could only be differentiated from it by finding the primary septic focus. It was very difficult to determine what part the spleen played in the clinical picture and secondary changes. A. G. Gibson stated that there might be hyperplasia, reduction of lymphoid elements, and infarcts due to local changes, and believed that embolism of the splenic vein sooner or later produced gross destructive and fibrotic changes in the liver. He believed that all forms of splenic inflammation tended to the destruction of blood-elements in varying degree. Splenectomy would not be suggested for enlargement of the spleen directly dependent on some septic focus. The pathology of *Banti's disease* was not understood, but the satisfactory results of splenectomy were best explained by classing it with the chronic inflammations. It was generally accepted that the disease had three stages: (1) splenomegaly and secondary anæmia which might last for ten years or more, and was generally described as splenic anæmia; (2) gradual enlargement of the liver; and (3) gradual cirrhosis and shrinking of the liver with ascites. There was a secondary anæmia with leucopenia and relative lymphocytosis and repeated hæmorrhages, especially from the stomach. There seemed to be no medical means of treatment; in the second stage operation was very satisfactory. The platelet count might be important even in this group. When there was ascites or jaundice the surgical outlook was not so good, and many died from post-operative gastric bleeding. A. G. Parsons said that if the cirrhosis were not too severe the liver might make a functional recovery. *Von Jaksch's anæmia* had such distinct differences from Banti's disease that it should be regarded as a separate clinical entity. It showed a familial tendency and was confined to the first three years of life. In addition to the splenic enlargement, the secondary anæmia, and the relative lymphocytosis, there was a constant myelæmia, the presence of nucleated red cells, and a tendency to spontaneous recovery. It was often associated with rickets, to which it might be partly due. With a recovery-rate of 65–70 per cent. and no tendency to persist, splenectomy was unnecessary. When it was certain that the spleen was affected before the liver, splenectomy might be useful for cirrhosis, but in common cirrhosis the operation was still in an experimental stage. Whatever the nature of *Hodgkin's disease,* the spleen formed only a small part of a general change and splenectomy was useless. The spleen acted as a storehouse for red blood cells and probably for this reason large numbers of parasites in *malaria, kala-azar,* and *syphilis* might find lodgment in it. In tuberculosis the spleen might show multiple miliary tubercles, or the foci in the rest of the body might be small or nearly cured while one or two areas in the spleen progressed to caseating masses. An enlargement of the spleen in children with anæmia should always suggest syphilis; there might be no improvement until the spleen was removed. There was always a risk of a later general infection if the spleen were removed for tuberculosis. Splenectomy in the protozoal and tuberculous group must be regarded as an exceptional measure, only to be carried out when all forms of medical treatment had been tried and it was certain that the spleen was the chief if not the only focus in the body. A secondary *polycythæmia* might occur with chronic non-suppurative thrombophlebitis of the spleen, and had been found in tuberculous children. On the assumption that polycythæmia was secondary to chronic inflammation splenectomy had been practised with success in one case. Primary polycythæmia would probably be classified with general blood disease when more was known about it; there were no indications for splenectomy, for more rather than less splenic tissue was needed to deal with the excess of red cells.

General Blood Diseases.

The diseases in which the change in the spleen seemed to be part of a general error in the hæmopoietic system were divided into an aplastic and a hæmolytic group, but there was no sharp line of division. True *aplastic anæmia* was chiefly found in young women and was rapidly fatal, so that splenectomy was not suitable. Many believed, however, that an aplastic condition might be a late stage of long-continued destruction, so that splenectomy in the early stage, before the marrow became aplastic, might diminish the strain on the marrow. The three cases operated on had all died. The hæmolytic group included pernicious anæmia, intestinal parasites, syphilis and carcinoma, puerperal lesions, chemical poisons, hæmolytic or acholuric jaundice, and purpura hæmorrhagica. Even if *pernicious anæmia* were originally due to excessive destruction of the red cells, the formation of new elements was undoubtedly at fault in the established condition. Even those who had advocated splenectomy had generally combined it with massive and repeated blood transfusion and the thorough treatment of all septic foci. Even with careful selection the surgical results were unsatisfactory. Since the introduction of liver treatment the operation was not justifiable. The profound hæmolytic jaundice found in the late stages of syphilis or carcinoma, as a complication of the puerperium, after the ingestion of chemical poison or during infestation with intestinal parasites, did not call for surgical interference. *Acholuric jaundice* might be compatible with active life, but in other cases the attacks of jaundice were associated with fever and malaise and with enlargement of the liver and spleen which might be painful. In the acquired type the attacks were more frequent and more severe and the patient soon showed a profound anæmia. The condition was often complicated by the formation of pure pigment gall-stones. The primary factor in the disease seemed to be an increased fragility of the red blood corpuscles—although this was not invariable—so that they were destroyed by the spleen and caused an increase of bile-pigment in the blood, though not in the urine or stools. In long-standing cases the anæmia might be increased by hæmorrhages. The enlargement of the spleen was moderate and variable, usually greater during the exacerbations. Splenectomy was followed by very good results and the mortality was low. *Purpura* might occur as a symptom of many conditions, but a very distinct type of the primary disease—thrombocytopenic purpura hæmorrhagica—had been differentiated. It was commoner in women and was essentially a disease of early life, though it might occur adhesions to the diaphragm very rapidly, then open the peritoneal cavity to the left of the stomach and tackle the vessels. This made it much easier to avoid the tail of the pancreas.

Dr. THURSFIELD and Mr. WALTON replied.

SECTION OF OTOLOGY.

AT a meeting of this Section held on May 3rd, the President, Mr. SOMERVILLE HASTINGS, being in the chair, three papers were read on

DEAFNESS AND ITS TREATMENT.

Mr. HAROLD KISCH dealt with non-suppurative *types of middle-ear deafness.* There were, he said, three clinical groups, but mixed forms might occur: (1) deafness due to the results of attacks of inflammation; (2) deafness due to Eustachian and tympanic catarrh; (3) cases of otosclerosis. In the first group the deafness was due to adhesions formed in the middle ear, which obstructed movements of ossicles. Two extra factors might add to the deafness in this group: (*a*) the functional element, (*b*) a concomitant nasal catarrh due to nasopharyngeal catarrh. The treatment of this group was to prevent the onset of deafness at the time of the acute attack. Massage and inflation were important. If the ossicles were much bound down, massage did not remove the trouble, and the effect of removing the incus should be tried. For this he preferred the mastoid route. The difficulty was to estimate the degree of fixation of the stapes. If it was firmly fixed no improvement in the hearing would take place.

The majority of cases of chronic deafness belonged to the second group. Most of them yielded to rational treatment. The chief cause was nasopharyngeal catarrh, and he had found great relief ensue from inflation and massage. He first treated the nasopharyngeal catarrh, then applied local measures to the middle ear. In a hospital clinic, observation extending over a large number of cases showed that 95 per cent. of adults who had not had their tonsils enucleated possessed septic tonsils. A minute amount of septic tonsil left behind at operation sufficed to cause continued catarrh. Chronic catarrh of the frontal sinus was more frequent than was usually supposed, while in some cases sphenoidal sinus disease was present. Rectification of nasal septum deflection sometimes gave rise to immediate improvement. Simple inflation of the ear was the only local measure required. He did not favour the use of hot air or vapour for the purpose, and in his hands ionisation had not been of value. Diathermy was still on trial; in some cases it helped to dissipate the tinnitus. He questioned whether, in a general way, sufficient attention was directed to the prevention of deafness. He thought that every case of catarrh should be looked upon as a potential case of deafness, and steps should be taken to deal with the catarrh, whatever it was due to. Contributory causes, such as a damp house and unsuitable climatic conditions, should be investigated.

Mr. W. S. THACKER NEVILLE dealt with chronic deafness. In his experience, chronic deafness had been due to chronic suppurative otitis media, chronic catarrhal otitis media, and otosclerosis. The catarrhal form he had treated with the inflation of hot air, by insufflations with oil of turpentine and balsam of Peru, by massage of the tympanic membrane with an electric motor, by diathermy and by ionisation. In chronic suppurative otitis media he had safeguarded the hearing with ionisation with zinc sulphate. For polypus he had used electrolysis with two needles, and crystals of chromic acid. Lipiodol he had recently used as a local application, as it was shown to enter the mastoid cells via a tympanic perforation. By these measures he had improved hearing without doing a mastoid operation. He [illegible] hearing was often improved by removing [illegible] operating on the nose for sinusitis, to [illegible] focus. Until this and such steps as [illegible] septal deviation to allow of catheterisation, removal of adenoids and dental sepsis had been carried out, the physical methods he had mentioned should not be considered. He had successfully used diathermy according to the technique of Lerroux-Robert, and Hollander and Cottle for what seemed to be hopeless deafness. One electrode was placed on the mastoid, the other on the cheek; this caused a rise of temperature amounting to 2° or 3° in the tympanic cavity within five minutes. Low voltage and low frequency were recommended so as to cause a deeper penetration of heat. This appeared to augment the blood-supply to the part and so hastened the absorption of effusions. Lerroux-Robert placed electrodes in the meatus as well as on the mastoid. The last-named *said that diathermy was indicated in cicatricial* otitis following suppuration and in adhesive otitis following an acute catarrhal otitis with calcareous deposits. For chronic deafness, but especially for improving tinnitus, he used the Zund-Burguet apparatus, and ionisation with sodium salicylate applied by means of the negative pole. He described the treatment and results in ten cases.

Dr. DAN MCKENZIE gave an account of his experiences with medical diathermy, and the intravenous use of collosol iodine. In the former, the amount of current passing rarely exceeded 500 milliampères; only that strength of current was used which caused a comfortable sensation of warmth. It was increased in strength from zero very slowly. If a deep aching was felt by the patient in the mastoid bone, it was probable that the temperature was too high. The cutaneous sensibility was the safest guide to the temperature of the deeper parts. The heating of the tissues in the path of the current was cumulative. Frequently an increase of the tinnitus was complained of directly after the sitting, but in most cases this was not an unfavourable sign. He gave an analysis of 46 cases which he had treated during the last 18 months, most of them being of the dry, progressive, middle-ear type. In five of them the deafness and tinnitus disappeared entirely after from two to six sittings. In another series of five great improvement followed the treatment, though they had been mostly long-standing cases—i.e., 2 and 9 months, and 5, 7, and 10 years. In general, 20 per cent. of these cases showed improvement. Of the remaining 36, 13 showed temporary improvement, but 21 did not show any, while in 2 the tinnitus was made much louder by the diathermy, and the patients declined to continue. He advised practitioners to watch for the onset of a continuance of deafness and tinnitus after colds in the head, influenza, &c., as well as after acute otitis media, and to submit these patients to diathermy in the early weeks of the symptoms. The intravenous injection of massive doses of collosol iodine was suggested to him 9 months ago by Dr. H. I. Shaheen Bey (Cairo), who had obtained good results from it in chronic dry deafness and tinnitus. From 6 to 13 ounces of collosol iodine was run into a vein once a week, as in blood transfusion. No shock, rigor, or pyrexia followed, neither did iodism. Patients could safely be allowed to return home after the injection. An objection to the treatment was that in two or three of the cases coagulation in the veins selected took place immediately after the injection. Until this could be avoided it must check any extensive trial of the remedy. Of the seven cases so treated, two were subsequently treated with diathermy also; one with definite and progressive improvement, the other with none. Of the other five, two showed improvement.

Discussion.

Mr. H. NORMAN BARNETT said the condition of the tympanum leading to middle-ear deafness might be due to: (1) long antecedent middle-ear suppuration; (2) infection from septic tonsils; (3) obstructed airway caused by deflection of nasal septum and enlargement of turbinals; [illegible] of the nasopharynx. He gave a [illegible] subject, contending that it was [illegible] to induce reabsorption of the products of chronic inflammation in the tympanum, and re-education of the dormant centre of hearing.

Mr. **ERIC WATSON-WILLIAMS** pleaded for a trial with parathyroid in the case of patients the subjects of otosclerosis. He had found grs. 1 to 2 of the dried extract very beneficial for them, though the dose recommended was usually only gr. 1/20, a quantity which was useless for this purpose. Some patients complained of an aching in the ears, others of flushing, following the treatment, but no serious disturbance had resulted.

Dr. **G. CATHCART** spoke of the success he had achieved with the electrophonoïde treatment.

Mr. **LOWNDES YATES** remarked that the vast majority of the cases of the kind under discussion showed an absence of wax. Patients having wax in the ears usually got well, but those without wax would require very prolonged treatment. Otosclerotics were found to be improved if their blood-clotting time could be brought down to normal.

The readers of the three opening papers replied, and the remainder of the meeting was devoted to the discussion of clinical cases.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

Report of the Cancer Research Committee.

AN open meeting was held at the House of the British Medical Association on May 3rd, when an account was given of the work of the Cancer Research Committee of the Marie Curie Hospital, which Committee, until the project of a special hospital materialised this year, has been working directly under the auspices of the Association.

Miss **F. HUXLEY**, the President, was in the chair, and said that the principal speakers would be: Miss Maud Chadburn, surgeon to the South London Hospital, to whose energy much of the success of the work was attributed; Dr. Elizabeth Hurdon, the research officer, working under a grant from the Medical Research Council; and Dr. Helen Chambers, who had long worked with radium at the Middlesex Hospital in association with Prof. Sidney Russ and had inspired the Association to organise a clinical research scheme on a scientific basis.

Miss **CHADBURN** said that the report to be submitted concerned the activities of the Cancer Research Committee and its clinical subcommittee between October, 1925, and March, 1929. Before work was started the Committee spent some time (1) in studying the radium treatment carried out in the Continental clinics; (2) in deciding on the technique to be adopted, and in designing applicators; (3) in collecting funds and obtaining the loan of radium. The clinical work had been carried on at four hospitals—the South London Hospital for Women, the Elizabeth Garrett Anderson Hospital, the New Sussex Hospital, and the Royal Free Hospital—by the women surgeons and gynæcologists on the honorary staffs of these hospitals. The actual clinicians working in coöperation numbered 18. Each hospital was allocated its day for the use of the radium and non-allocated days were shared as occasion demanded. The radium was conveyed to and from the hospitals by an officer appointed for the purpose, who also checked the amount of radium and number of containers. At all four hospitals the same technique, the same recording system, and the same follow-up system was used. This full collaboration and coöperation had been obtained by virtue of the facts: (1) that the technique was settled by the Cancer Research Committee of nine members, on which sat a representative of each hospital; (2) that all concerned met at frequent intervals to consider the results of treatment and the need of alterations in technique, and to receive reports of new work elsewhere; (3) that the research officer was an experienced gynæcologist, who gave her whole time to the work. She attended all radium insertions, had charge of the follow-up clinic, and kept the records. She also visited and reported on work in progress abroad. The research would have been impossible without this officer, whose salary was paid under a grant from the Medical Research Council, and who was in a position to place at the disposal of each member the experience gained at the other hospitals. At first (in 1925) only inoperable cases were treated, but the faith of the surgeons in radium treatment had gradually increased, and each year more operable cases had been treated. The desire to make the fullest use of the available radium led to the initiation of a scheme for centralising the work in one hospital. The Marie Curie Hospital, at 2, Fitzjohns-avenue, Swiss Cottage, would, it was hoped, be open to receive patients in August or September of this year. Here treatment of cancer in the rectum, breast, or other parts of the body, besides the uterus, would be undertaken. The hospital would be run (1) by its own board of management on which would sit representatives of the Boards of the coöperating hospitals; (2) by its medical staff, which would consist of a director and research officer, a pathologist, a radiologist, a physician from each of the four hospitals, and all the women surgeons and gynæcologists of the four hospitals. Miss Chadburn thought this would be the first example of a coöperating hospital. As to finance, the hospital would have to make its own way. There would be general and private wards, and public support was urgently required.

Results Obtained.

Dr. **E. HURDON** showed on the epidiascope coloured drawings, prepared from sketches and notes made by herself, of the lesions treated in some 20 healthy looking patients, who were present at the meeting; most of them had been under observation for more than three years after treatment for a growth deemed to be inoperable. She also showed statistics of the results obtained. Since five years had not elapsed since the clinic was started, these could not yet be compared with those obtained by other workers over this period. The total number of cases treated was 300, of which 266 were cancer of the cervix, 22 of the body of the uterus, and 12 of the vagina, vulva, or urethra. The immediate mortality was 0·3 per cent. Up to October, 1928, the total number of cases of cancer of the cervix treated was 191, of whom 130 were living. Recurrence was usually found to occur early, if at all, and patients who had remained well for three years were unlikely to relapse. Cancer of the body of the uterus was treated by radium only when operation was contra-indicated, technically impossible, or refused by the patient. Supplementary radiation by means of large amounts of radium (4 g.) or deep X ray therapy promised to give an increased percentage of cures. In conclusion, Dr. Hurdon said that in operable cases (early lesion limited to the cervix) the results of radium treatment were about equal to those obtained by surgery; in borderline cases (extension of disease beyond cervix, invading vagina or parametrium, but without fixation) radium appeared to be the best method; in inoperable cases (involvement of surrounding tissues with fixation) surgery had nothing to offer, while 40 per cent. or 50 per cent. of such cases were greatly benefited, and some even cured, by radium.

Technique.

Dr. **HELEN CHAMBERS** described the technique used, which was a modification of that adopted by Heyman in Stockholm. She explained the principles on which the radium tubes were arranged for cancer of the cervix; in the uteric cavity two tubes were placed in tandem, and in the vaginal vault three flat boxes, so that the walls of the vagina were stretched apart laterally. The experimental work done under the direction of Prof. Russ at the Middlesex Hospital had established the range of action of a definite quantity of radium, and this had made it possible to devise a scheme whereby in cancer of the body the tubes in the uterine cavity could be reinforced where required and the vaginal walls allowed to remain slack, whereas for cervical cancer where the parametrium might be involved a wider area of irradiation was needed at the base of the pelvic floor, and the walls must be stretched laterally by applicators of a suitable size. These must be packed into position by cotton-wool, since if they were allowed to slope towards rectum or bladder fistulæ might result. The range of action did not always extend to the glands in the parametrium. If these were affected their local application should be supplemented by radium at a distance, or by deep X ray therapy, which should not be postponed too long.

Discussion.

Dame **Louise McIlroy** praised the organisation of the clinic. In her view it was important for the surgeons to work with a radium officer like Dr. Hurdon, who could advise as to dosage and technique. Team-work was essential to success. Women were more likely to come early for advice if they expected to be treated by radium instead of by operation, and this was most encouraging.

In the absence of Miss E. Bolton, Miss **Morna Rawlins** gave some account of the relief given to advanced cases in the Elizabeth Garrett Anderson Hospital by radium.

Miss **Louisa Martindale** spoke of the X ray apparatus now installed at Geneva, Freiburg, and The Hague. At Frankfort 10 extensive X ray therapy plants were installed in connexion with surgical departments. It was becoming recognised that X ray therapy was needed to supplement radium therapy.

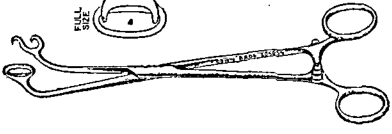
Mr. **Malcolm Donaldson** congratulated the Committee on the team-work and on the proposed new centre. More large centres were required, and he hoped that before long another would be established. The time of exposure was an important factor in the results obtained. At St. Bartholomew's Hospital glands were now being treated: (1) with X rays, (2) with intra-abdominal radium. The last-named technique had been started years ago, but discontinued owing to the production of ventral hernia in some cases. But since of 13 cases so treated in 1923–24 six cases were alive five years after treatment, and one case four years after, the technique was worth reconsidering.

Mr. A. **Palmer**, Dr. **Florence Stoney**, Dr. **Catherine Chisholm**, and Lady **Barrett** also spoke.

New Inventions.

A NEW TONSIL-HOLDING FORCEPS.

Many more enucleations of tonsils are now being performed, and with experience the surgeons find two varieties of tonsil which are hard to hold whilst enucleation is taking place. The first is the big, very soft, spongy, and friable tonsil; the second the retracted and buried tonsil, often very septic and adherent. The forceps here illustrated will, I hope, overcome both these difficulties. The length, the curve, the area of the grip, have all been carefully calculated in order to obtain a quick, firm hold.



The instrument is made by Messrs. Down Bros., Ltd., St. Thomas's street, London, S.E.

Harold E. Rawlence, M.D., F.R.C.S.

Reviews and Notices of Books.

Health, Disease, and Integration.

By **H. P. Newsholme**, M.D., F.R.C.P., D.P.H., M.O.H., City of Birmingham. London: George Allen and Unwin. 1929. Pp. 327. 12*s.* 6*d.*

The ancients did not doubt the importance of mind and spirit in causing diseases of the flesh, and long after demons had been discarded Lind's acute analysis of the data led him to look upon melancholy as a clear cause of scurvy. But with the progress of modern medicine these ill-defined ideas of ætiology gave way before the prim precision of theories of poisons and bacteria and such *like*; anything savouring of mysticism became abhorrent in the materialism of the nineteenth century. A good many people think that medicine still needs to be purged of much that is vague and indefinite, but, as usually happens, the pendulum probably swung too far and the psychological element in disease was undeservedly neglected in formal medicine. That some such element exists is, of course, plain to every observant man, and it plays a considerable part, unrecognised, in actual practice.

Dr. Newsholme has been so impressed by it that he has tried to imagine some scheme by which the materialistic causation of disease may be brought into line with the obvious fact that man consists of mind and spirit as well as body. He finally concludes that the education of the individual and the community should be directed at the spiritual and the material as one indivisible whole. With this few thoughtful sanitarians will want to disagree. But it is, we confess, a little difficult to follow the progressive steps of his argument or, indeed, to be sure that in places there is any coherent argument at all. Dr. Newsholme has a lively imagination and, as he confesses, only a moderate knowledge of the technical details of the many topics with which he engages. He lets his imagination loose at considerable length, and the result will, no doubt, irritate those who like hard facts. And some of his details are certainly open to criticism. The book opens where his own mental pilgrimage began—with three cases of lethargic encephalitis in the genesis of which violent emotional disturbances seem to have had some share. He bluntly says that he thinks it possible that some examples of this disease may actually be so caused, and he speculates on the possibility that the virus of encephalitis may be generated from nervous tissue by intense emotion de novo. It may be so. The critic will say that there are no controls dealing with the relation of emotion to other diseases and to health, that there is no certainty that the cases he quotes were encephalitis lethargica at all, and that if they were the facts are better explained as coincidences. His detailed discussion does not do much to strengthen his case. He accepts Levaditi's interpretation of the experimental aspect of the disease and writes as if it could readily be transmitted to animals: it is, in fact, not quite certain that this has ever been done, and the great majority of observers have certainly failed to do it. On pp. 57 and 212 he confuses labial herpes with herpes zoster (though it is true that Morris, whom he quotes as his authority, seems to do the same). A little later (p. 62) he says that the "introduction of a foreign colloid into the system is followed . . . by . . . a production of antibody to the colloid," and that antibodies act like enzymes—statements which are unintelligible or untrue.

Through the book anabolism and katabolism run about like a pair of goblins. Along such lines there is much that may be criticised, as we suspect the author would readily allow, and we think he would have been more convincing if he had not tried to find so much material basis for his idealism. But, taken as a whole, the book is worth while. It is quite time that the precise relation of parasites and especially viruses to diseases should be critically re-examined, that the question whether diseases are adequately defined by their ætiology should be further considered, and that pathology should recognise that man is something more than flesh. Dr. Newsholme preaches a doctrine which, in its application to hygiene, is perfectly sound, and he has raised a number of important and interesting problems; some of them are probably soluble.

SURGICAL RADIOLOGY.

By A. P. BERTWISTLE, M.B., Ch.B., F.R.C.S. Edin., late Resident Surgical Officer, General Infirmary, Leeds. London: J. and A. Churchill. 1929. Pp. 142. 8s. 6d.

THIS useful book gives outline descriptions of surgical diseases, summaries of such X ray examinations as may be carried out to elucidate diagnosis, and accounts of the appearances seen in the X ray photographs with their import. The book is of a size convenient to handle, though it deals with the whole field of surgery, and since the author has been at great pains to be accurate in his statements and is concise and informative there is every prospect of its success. The number of reproductions of radiograms is limited, but those interested can obtain abundant illustrations by procuring copies of the author's two atlases of radiography.

COLLOID CHEMISTRY OF PROTOPLASM.

Protoplasma-Monographien. Vol. I. By L. V. HEILBRUNN, Assistant Professor of Zoology, University of Michigan. Berlin: Gebrüder Borntraeger. 1928. Pp. 356. R.M.19.

THIS monograph constitutes Vol. I. of a series dealing very fully with the properties of protoplasm, and is an account of the colloid chemistry of protoplasm. The book is much more than a mere compilation. Prof. Heilbrunn, himself a distinguished worker in this field, states in his introduction that he has endeavoured to sift out the experimental evidence and where possible to indicate the lines of research which might prove profitable. As is to be expected with such a new branch of science, the volume consists mainly of an account of experimental work which throws some light on the behaviour of protoplasm. After some introductory chapters in which the microscopic appearance and morphology of protoplasm are considered, the author proceeds to give an account of methods of study. There follows a consideration of the physical properties of protoplasm, such as its viscosity, elasticity, and changes in its properties caused by differences of temperature, by various other physical factors, and salt solutions. The question of the electric charge of protoplasm is then discussed and the action on protoplasm of acids, alkalis, and fat solvents follows. The book concludes with a description of cell function and protoplasmic activity.

Prof. Heilbrunn writes in an interesting style and does not assume that the reader is already familiar with all the details leading up to the work described. The colloid chemistry of protoplasm is a subject which has only been developed during the last 10 or 12 years, but this book shows the remarkable amount of knowledge of the subject which has already been acquired. The author points out that the colloidal study of protoplasm is not easy. Observations must be made on tiny droplets of a material incompletely defined from a chemical standpoint, and probably consisting of a mixture of highly complex compounds. The results that can be obtained with such material must therefore be regarded leniently. The biologist cannot be expected to obtain data of the same degree of accuracy as those which the physical chemist can obtain with chemically pure compounds. But one must not be too lenient. If the colloid chemistry of protoplasm is to be a science, it must be based on firm facts and not on subjective impressions. The facts presented in this book, though they are not very numerous, show that a rational science of the colloid chemistry of protoplasm is possible and that it is now in the making. A bibliography of some 40 pages gives references of all the important papers dealing with this branch of the study of protoplasm.

SPASTIC CONTRACTURES.

Medizin in Einzeldarstellungen. Heft. 1: *Reflexmechanismus spastischer Lähmungen.* By Dr. Med. O. LEIBOWITZ. Bad Homburg v.d.H. Dr. H. Grossberger, Heidelberg. 1928. M.2.

THIS pamphlet of 40 pages represents the first instalment of a number of essays on Medicine.

In a short summary of the teachings of previous writers the author divides the numerous theories about spastic and especially hemiplegic contracture into two large groups, of central and peripheral centripetal origin. He points out the great differences as regards skin reflexes and contracture in the upper and lower extremities and discusses their significance.

ROENTGENOLOGY.

By G. W. C. KAYE, O.B.E., M.A., D.Sc.. F.Inst.P. London: William Heinemann, Ltd. 1928. Pp. 157. With 49 illustrations. 7s. 6d.

THIS small volume is essentially an expansion of the Caldwell lecture delivered by the author before the American Roentgen Ray Society in 1927. In this lecture the author dealt in detail with the various problems that arise in connexion with the protection of those who work with X rays. He has elaborated this thesis and now presents in a concise and permanent form a mass of information which is of great practical utility to all radiologists. In the appendix are included the recommendations of the British X Ray and Radium Protection Committee, which have now been accepted by the Second International Congress at Stockholm as the International Standard. The rest of the book is largely an explanation of how and why these recommendations were arrived at. The author gives a short historical summary of the development of radiology and two excellent chapters on the nature of radiations. These are followed by chapters showing the way in which the principles of protection can be turned to material account for the safety of workers. One criticism that we have to make of this small volume concerns its title, which is misleading, since the ground covered is only a small section of the physical side of this vast subject.

JOURNALS.

THE WORLD'S HEALTH.—The current number of this review, issued by the League of Red Cross Societies, appears this month in a new guise, for it is produced experimentally in an altered shape, and it is to come out quarterly (at 2s. each number), not monthly as hitherto. It deals with all the activities of the Red Cross, not only in war but in peace, when it prevents disease and in addition devotes itself to relieving great calamities. So the articles are concerned with a multitude of very various interests, the teeth of the school child, maternal mortality, nursing education in China and the Far East, with leprosy in the countries bordering on the Pacific Ocean, and with the communications between the Junior Red Cross societies of various nations. The photographs of Japanese leper asylums that are reproduced show how beautiful are their surroundings, and those of patients engaging with enthusiasm in organised games and recreations reveal the care and kindliness that are enlisted in their service to make segregation within the settlements as little irksome as may be. That is largely the purpose of the magazine, to show to all what is the best that other countries are doing. Thus standards are being raised all over the world.

THE LANCET.

LONDON: SATURDAY, MAY 11, 1929.

HEALTH OF THE MERCHANT SEAMAN.

A National Conference on the Health and Welfare of the British Merchant Navy at home and overseas was held at the Royal United Service Institution, Whitehall, on Friday last, May 3rd. The Conference was organised by the British Social Hygiene Council and the British Council for the Welfare of the Mercantile Marine, and should be useful in bringing before those who are immediately concerned the fact, often insisted upon in these columns, that the care of the mercantile marine in these directions has not been of the standard which is recognised as necessary among other sections of the population. It must be said, and with great pleasure, that the apathy, which was a marked feature in the situation until recently, has now disappeared, and that owners are wishful to follow in every direction where they can the opinions of medical and sanitary advisers. Further, their difficulties in doing so are now widely recognised, the necessary environment of seamen, whether on water or land, being one where the rules of health are exceedingly hard of application.

The principal discussion at the Conference turned upon the morals of the seamen, and it must have become apparent to the audience that the provision of suitable accommodation and chances of recreation at ports proved no sufficiently attractive alternatives with large sections of the men to diversions where the risks of venereal infection would be run. The sense of the meeting was that, while reading rooms, opportunities for indoor and outdoor sports, and the provision of instructional films were all to the good, they are not effective yet, if ever they will be, as measures for the prevention of venereal disease, so that practical attention must constantly be directed to the checking of dissemination and rapid treatment. As recently as April 5th of this year, at a meeting of the Medical Society for the Study of Venereal Diseases, reported fully in our columns on April 13th, a discussion on these questions was opened by Dr. H. M. HANSCHELL, medical superintendent and medical officer V.D. department of the Seamen's Hospital, London, and Dr. A. O. ROSS, V.D. officer of the City and Port of Liverpool. These observers pointed out from their large experience the risks run by seamen after promiscuous coitus, and at the same meeting Colonel L. W. HARRISON said that the only remedy lay in the equipment of ships for the modern treatment of venereal disease, with its implication that ships' doctors should be trained to use this equipment. At the Conference Dr. Ross stressed the point that chancroid was essentially an imported disease, and produced figures showing that quite one-third of all the venereal disease treated at the Liverpool clinics is imported from abroad. He pleaded for the examination of every seaman before every voyage, this examination being directed not only to the heart and hernial orifices but to the genitalia where simple examination would reveal acute disease if present. He testified to the impossibility of getting men on coastal trade to leave their employment in order to have treatment. Treatment of syphilis, he said, can usually be arranged for them, but in the case of gonorrhœa casual irregular treatment meant that cure remains for ever on the unattainable horizon.

The message which the Conference has delivered is that there must be facilities provided on shipboard for the treatment of venereal disease; preliminary examination, even if insisted upon, will not remove its incidence thoroughly. Nor is there any reason to suppose that owners would be otherwise than extremely eager to offer the full facilities demanded, but it must be pointed out that reforms along this line (which are already being introduced), while meeting the case in many prominent directions, could still leave out of count a large body of seamen whose avocations take them for extended periods away from land upon ships which carry no doctor. These men are deprived at the present of expert advice in the direction either of diagnosis or treatment. It is good that these things should be now commanding real attention, for publicity should pave the way to reform. And it would be better that there should be no more delay in the institution of working methods.

THE PROPOSED DIPLOMA IN PUBLIC DENTISTRY.

PUBLIC dental service has increased largely during the last decade. There is every reason to think that the future will see a still further increase of this branch of dentistry, and that a growing number of dentists will, at some period in their career, find employment in a whole-time or part-time capacity under public authorities. The dental treatment of school-children, while partly remedial, is concerned to an important extent with prophylaxis and prevention. Its value to the community, like that of the school medical service, is priceless, and it is essential for its officers to be highly trained and fully competent to carry out their responsible duties. There is at present keen competition for vacancies as school dentist and the appointing authorities have a wide range of candidates from whom to choose. Preference is naturally given to those who have had hospital experience, preferably as house surgeon in a dental hospital; but it must be remembered that dental hospitals are few and that only a minority of newly qualified practitioners can hope to obtain such experience. A large proportion of those appointed to the school dental service have had only a limited experience, and their knowledge of the particular problems involved in the dental treatment of children is necessarily meagre.

These considerations have spurred the British Dental Association to examine the case for the establishment of a diploma in public dentistry. The curriculum for qualification is already overloaded, but the student who does not propose to practise dentistry in private would surely welcome an opportunity of acquiring special training for public health work and would not grudge extra time devoted to this end. A well-planned post-graduate course leading up to an extra diploma gives not merely an academic hall-mark but a guarantee of such training as will enable technical skill to be used with the greatest advantage in connexion with the general health service of the community. The degrees in dentistry instituted by most universities do not meet the need, since the diplomate in dentistry who has not taken a university course from the beginning cannot proceed to a degree. The higher dental diplomas instituted by the examining bodies in Edinburgh and Glasgow are general in character and could scarcely be modified to provide a special course of the kind suitable for those engaged in public dentistry. A provisional syllabus for a diploma in public dentistry has therefore been framed by the British Dental Association and circulated to the various examining and licensing bodies for their consideration. It would seem a reasonable hope that, since the diplomas in ophthalmology and tropical diseases have admittedly been of service, a higher dental diploma would raise the standard of dental public health work and in the long run provide for a more efficient school dental service. So far, however, the response of the bodies to whom the proposal has been submitted, has not been propitious. The Dental Executive Committee of the General Medical Council consider that no sufficient case has been established for the institution of a diploma in public dentistry. A gleam of encouragement, however, comes from the University of St. Andrews, while other provincial universities are evidently giving the scheme sympathetic consideration. The provisional syllabus framed by the British Dental Association is, on the whole, well balanced. It provides for a period of study of not less than a year and includes courses in bacteriology, parasitology, the principles of public health and sanitation, epidemiology and vital statistics, oral hygiene, electrotherapy, and orthodontics. The practical syllabus provides for work under the supervision of a medical officer of health and a senior dental officer for not less than six months, and must include experience of the services organised for maternity and child welfare, venereal disease, and tuberculosis. Attendance at practical courses in orthodontics to be held at a recognised dental school is also necessary. The suggestion is that the examination, like that for the D.P.H., might conveniently be divided into two parts.

The scheme does not seem to us over-ambitious nor need the test be unduly severe. The objection that the dentist who does not possess a medical grounding might not be able to assimilate so miscellaneous a curriculum can be disregarded, since it is not intended to do more than to ensure that an officer concerned with one branch of public health should have a sufficient working knowledge of its other aspects. In two respects, however, the proposed curriculum might be strengthened. First, the practical instruction at a dental hospital should include not only orthodontics but also the general remedial treatment of dental disease in children, as contrasted with adults. Many special difficulties are encountered which the newly qualified rarely appreciate unless they have been warned. Secondly, since successful treatment of children requires not only a liking for them but also some knowledge of their psychology, the elements of child psychology might well form part of the course of study for a diploma in public dentistry. In private practice there is time to make friends with small patients, and most dentists soon acquire the art. But in school practice the difficult child may cause delay and disorganisation, and here some knowledge of modern ideas as to the probable causes of negativism and obstinacy may help the dentist to cope with an awkward situation. In our view the scheme outlined by the British Dental Association deserves consideration. It is designed to increase the efficiency of the school dental service and to make it easier to select suitable applicants for coveted posts. A properly planned diploma in public dentistry would not only enhance the prestige of the dental profession but would also strengthen the public health service of the country by promoting correlation between important branches of this service.

PELVIC DISPROPORTION.

AT the Congress of Obstetricians and Gynæcologists held in Dublin, reported on p. 999, interest in the first subject for discussion was well sustained throughout the day. Pelvic disproportion is indeed a subject of perennial interest and importance. It is doubtful, however, whether the practitioner will be able to disentangle from the views expressed any clear messages, apart from the vehement pronouncements against the use of forceps until the child's head is visible at the vulva. High-forceps and mid-forceps operations have been formally banished from obstetric practice and must not again figure in the obstetric literature and teaching of this country. Axis-traction forceps, with whose application and management the students of a generation only recently past were largely concerned, are to be regarded as obsolete instruments. Such an unequivocal and unqualified declaration of tactics, coming from many experienced obstetricians, and disclaimed by none, must certainly carry great weight. Probably more good than harm will result from this ban, and cases of "failed-forceps"—the nightmare of every obstetrician—will be less common. Still, we must bear in mind the fact, not sufficiently emphasised in the discussion, that malpresentations are a very common source of pelvic disproportion when both the pelvis and the child's head may be normal in size; and that of all the malpresentations of the head occipito-posteriors are the commonest. Indeed, in probably 35 per cent. of all cases the head of the child at the beginning of labour presents in this way. Spontaneous rectification usually occurs, but if it does not interference is desirable. Instrumental rotation is not now recommended by any responsible school, but most authorities agree that after manual rotation it is usually necessary to apply forceps to maintain the corrected position. This may be an unimportant exception to a sound general rule, but there are others of the same order, and they illustrate the danger in obstetrics of decrees that are too absolute. Undue dogmatism was exhibited also by certain speakers in regard to induction. Some agreed with the dictum of WHITRIDGE WILLIAMS that this procedure should never be performed; others were equally confident that it should be the method of choice in minor degrees of disproportion. But can the presence of minor disproportions be diagnosed with any certainty, and if so, by what criteria? It was argued that much depends on the moulding of the child's head, but too little was said about the chief factors concerned in this process—namely, the degree of ossification of the skull-bones, the force of the uterine contractions, and the strength of the accessory muscles employed during labour. In regard to the first of these factors, postmaturity is of the utmost importance, and is indeed a common cause of disproportion. It is the practice of one school to have an X ray picture taken of every patient who does not come into labour at the estimated date. If the child's skull is seen to be well ossified and if the centres of ossification of the lower end of the femur and head of the tibia are present, induction is immediately practised. It is likely that in this way a number of difficult labours are avoided. In the medicinal induction of labour—preferably by pituitary extract, since the efficacy and safety of quinine is in doubt—we have a safe method and one following which uterine contractions are likely to be augmented.

Another factor which may simulate disproportion or greatly complicate a difficult delivery is uterine inertia, of which little was said at the Congress.

Craniotomy and Cæsarean section have been performed for supposed disproportion on occasions when in reality uterine inertia was the cause of the trouble encountered, and many patients who have suffered a series of difficult labours have been found in later confinements to have inertia and have been relieved by the judicious use of pituitary extract. It emerged from the discussion that the procedure of choice in cases of pelvic disproportion is a "trial labour." It was generally agreed that in a well-equipped institution where the patient can be watched by experts, very little harm could result from a trial labour, and that many cases would be observed to terminate naturally, or at most after a low forceps delivery. But it was not stated with sufficient emphasis that a trial labour should never be allowed in a doubtful case in general practice. If the idea gets abroad that this is a proper method whereby to arrive at a decision as to the obstetrical possibilities of any given mother, the result will be a far larger number of emergency Cæsarean sections and craniotomies than at present. Moreover, the point of view of the prospective mother cannot be ignored, and it is unlikely that she would welcome expectant treatment which may involve distress of far longer duration than would induction or Cæsarean section. The avoidance of maternal injuries and disablement was not perhaps given enough prominence in last week's debates. Yet it is a subject of grave national importance as well as being the point where an obstetric case may be prevented from developing into a gynæcological one. In this connexion stress might have been laid on the association of the funnel-shaped pelvis (not at all an uncommon deformity) and perineal laceration. Owing to the narrowing of the transverse measurement of the outlet in this type of pelvis the head is compelled to shift backwards as far as possible towards the rectum and to be born with inevitable serious laceration. In most patients presenting complete perineal lacerations there is considerable narrowing of the transverse diameter of the outlet.

The subject of pelvic disproportion includes almost the whole of obstetrics, since nearly all difficulties are related to the primary one of delivering a living healthy child through a narrow passage without injury to the walls. It would have been impossible to touch on all its aspects in the time allotted, and the practitioner should be grateful for one piece of concrete teaching offered—the denunciation of high- and mid-forceps when used for traction alone. He is also likely to agree with the condemnation of the present method of conducting and staffing the antenatal clinics throughout the country. The general opinion was that supervision of pregnancy and antenatal examinations should be undertaken by the medical man or woman who is going to attend the labour. One of the first duties of the proposed College of Obstetricians and Gynæcologists might be the framing of an alternative scheme which would provide for this continuity of control.

THE OSLER CLUB.—On April 30th this club celebrated its first anniversary. Sir Farquhar Buzzard read a paper on the History of Neurology, in which he traced from their sources the different channels which have led up to the modern science, and prophesied a greater importance for neurology, in its widest sense, in the solution of social, and especially educational, problems. Mr. Falconer Madan spoke on Osler and Burton, and Dr. J. D. Rolleston gave a short sketch of the life and work of Theodor Billroth. Portraits and works of Burton and of Billroth and the club's collection of Osleriana were exhibited.

Annotations.

"Ne quid nimis."

THE PARATYPHOID OUTBREAK OF LAST SUMMER.

ABOUT the end of July last year five cases of paratyphoid fever were removed to St. James's Hospital, Balham, from a residential children's nursery in Streatham, and from there to one of the M.A.B. fever hospitals, when the infection had been identified by serological tests as paratyphoid B. A day or two later 15 cases of a similar illness were reported among well-to-do families in Kensington, and the London county health authority learned of an outbreak in Epsom somewhat earlier in which four children from two households had sickened within a few hours of one another after having consumed strawberries and cream. Many other cases occurred shortly after in the Western area of London and in the neighbouring parts of Surrey around Sutton, and inquiry revealed that most of the patients had partaken of cream purchased from retailers who obtained their supplies from one common source—namely, a large wholesale dairy. The circumstances of this outbreak were set out in our columns at the time, when it was pointed out that the outbreak showed no respect for age or class, was not closely localised to any one area, was characterised by abundant rose spots and a slightly enlarged spleen, and was not alarming in its severity although one death at least was reported. Dr. J. A. H. Brincker, senior medical officer to the London County Council, was deputed to collate all the available evidence so far as it concerned the County of London, and his report[1] to the Public Health Committee is now presented by Dr. Kay Menzies. From the first some article of diet such as cream was under grave suspicion of being responsible for the infection, and Dr. Menzies points out how the whole-hearted coöperation of all the medical officers concerned has solved the immense difficulty of tracking down the probable source of infection. The evidence for incriminating the cream of a particular wholesale dairy was cumulative. In London most of the proved cases (201 in number) of paratyphoid B developed their illness during the third and fourth weeks of July, and the same was true of the 219 proved cases in the home counties. It was clear therefore that the outbreak originated about the end of the first week in July, when, the weather being warm and fruit abundant, cream traced to this dairy had been freely supplied to the areas affected and had been consumed by the majority of the patients. In Kensington 41 out of 55 cases had certainly this cream, a proportion creating a high degree of presumption, for in investigations of this kind it is rare for more than half to be definitely ascribed to the suspected source of infection. A striking piece of corroboration was afforded by a Suffolk visitor who partook of strawberries and cream with a London friend on July 7th; both of them sickened of paratyphoid after a fortnight's interval. The evidence, however, remains presumptive only, for no paratyphoid organisms could be discovered in the cream when samples were taken three weeks after the infection had occurred; which does no more than suggest that the infection was of a transitory character such as would be produced by an intermittent carrier. The cream itself was derived from three principal sources, and definite evidence of contamination with the colon bacillus was obtained from two of these sources. The discovery of this gross contamination indicated that the cream must have been exposed to pollution at some stage of its production or in transit. No evidence of infection, after repasteurisation, by any employee of the firm could be discovered, and the explanation suggested is that contamination may have escaped the cordon of precautions during a rush period when there was an abnormal demand for cream. Although the evidence is thus incomplete the report is full of instruction as to the methods taken to track down the origin of an outbreak of this kind. The incidence of paratyphoid fever in London dates from the war period. It was anticipated that the return of overseas troops in 1918 and after would give rise to such outbreaks, for the micro-organisms of the Salmonella group may be carried by patients long after recovery and may be discharged by them intermittently over a long period of time. The previous outbreak of 1927 in Hertfordshire was traced to the infection of the milk-supply by two persons on a farm suffering from the disease in an unrecognised form. Modern sanitation and constant vigilance on the part of sanitary authorities have combined to keep in check the risks which are ever present. Happily the conditions favourable to the spread of the disease are generally absent when accidental infection by a carrier has occurred. An appendix to the report makes short work of the shameless capital made of this outbreak by some of those who wished to see the food regulations revoked, for it shows that the prohibited preservative could have had no effect whatever upon the growth of paratyphoid B; when the organism was implanted in cream even 4 per cent. of boric acid failed to prevent its growth.

---

[1] An Outbreak of Paratyphoid Fever. Report by the Medical Officer of Health, London County Council. No. 2643. London: P. S. King & Son, Ltd., 1929. 1s.

THE LEGAL ASPECT OF STERILISATION.

A RECENT episode at the Old-street police-court may some day be hailed as the first tentative step towards the sterilisation of mental defectives by magisterial direction. A young man having been charged with drunkenness and assault, Dr. Williams, a member of the medical staff of the London County Council, stated that he had examined him and was prepared to make an order concerning him under the Mental Deficiency Act, 1913. The London County Council, he said, was prepared to place the young man in an institution. Upon request being made on behalf of the relatives that the accused should be allowed to remain at large, Mr. Clarke Hall, the police-court magistrate, answered that, if set at liberty, the young man might propagate other mental defectives. A brother gave the court an assurance that the accused would not marry. Even so, rejoined the magistrate, he might have children. At this point the representative of the relatives is reported to have asked the brother if he was prepared to have the accused "medically treated"—"medical treatment" apparently meaning sterilisation. The brother is reported to have answered in the affirmative, Dr. Williams observing that "it would be rather a new process in this country." After an adjournment the relatives were still anxious that the defendant should remain at liberty, but his mother was not prepared to agree to the suggested operation. The magistrate therefore made an order for his detention in an institution; "I do not want," said Mr. Clarke Hall, "to turn out this mental defective of low grade to produce other mental defectives." Upon this incident a learned contemporary, the *Solicitors Journal*, makes the comment that the suggested operation would be entirely illegal. "A doctor who performed this operation on a person mentally incapable of giving assent would, at the very least, be guilty of a serious assault or unlawful wounding; it may also be laid down with some confidence that, even in the case of a person capable of giving assent and doing so, the operation would amount to an assault in a country where the law forbids consent to that minor form of battery, with temporary instead of permanent result, known as the "knock-out."

If sterilisation is volunteered on behalf of the defendant to the magistrate as an alternative to detention and as a basis on which a charge shall be disposed of, it may seem strange that there should be any element of illegality. Evidently, however, the law as it stands to-day has its complications. One high authority on criminal jurisprudence lays down the principle that people have a right to consent to the infliction upon themselves of bodily harm not amounting to maiming. He explains that injuries short of maiming are not criminal at common law unless they are assaults, and an assault is inconsistent with the idea of consent. Maiming (or, to use the old legal term, "mayhem") has a technical meaning. To maim a man, according to Coke upon Littleton, "signifieth a corporal hurt whereby he loseth a member by reason whereof he is less able to fight—as by putting out his eye, beating out his fore-teeth, breaking his skull, striking off his arm, hand, or finger, cutting off his leg or foot—or whereby he loseth the use of any of his said members." Hawkins' Pleas of the Crown specially mentions castration as a maiming. The element of diminishing the victim's value as a soldier is interesting if anachronistic. It can even be suggested, as an academic thesis, that the person who consents to sterilisation is guilty of the criminal offence of self-maiming, because, in the language of the *Solicitors Journal*, "it may be suggested that the Sovereign is entitled to rely on his subjects to ensure their continuance." There is a statutory offence of wounding with intent to maim; under Section 18 of the Offences against the Person Act, 1861, it is punishable with penal servitude for life. A surgical operation, if it breaks the continuity of the outer skin, comes within the definition of a wound; but, so far as Section 18 is concerned, the prosecution must prove that the wound was inflicted "unlawfully and maliciously." As for operations upon a person incapable of giving consent, it is clear that a parent has a right to consent to an operation upon a child who is too young to exercise a reasonable discretion. And if a patient is in such circumstances as to be incapable of giving consent to an operation—e.g., if he is rendered unconscious by a motoring accident which makes it necessary to amputate a limb—it is not a crime to operate without his consent. But these propositions seem to presuppose that the operation is reasonably necessary for the saving of life or the repairing of bodily injury. As we indicated last week, certain American States have experimented with the legalisation of sterilising the insane, and the Minister of Health has said lately in Parliament that he thinks a proper scientific inquiry into the subject will some day be necessary. At present, however, he seems not to regard the matter as urgent. Our mental defectives are, he says, broadly the product of one-tenth of the population, and, out of that one-tenth, only one-tenth (or 1 per cent. of the whole) are themselves definitely defectives. The others may be unrecognisable as defectives, and thus sterilisation can scarcely be an adequate and final solution of the problem.

THE CICATRISATION OF WOUNDS.

IN the *Presse Médicale* for April 3rd Prof. R. Leriche makes some suggestive observations on the processes which normally lead to the cicatrisation of a wound. Why, when an incision is made into the tissues, processes of repair should immediately be set in action and the wound should heal has always been unexplained. The question has a practical as well as a philosophical bearing on the everyday work of the surgeon, for if the inner nature of these processes were known it might be possible to hasten repair and thereby shorten convalescence after operations. The suggestions put forward from time to time, such as Weigert's theory of the release of restraining tissue tension and the idea of a stimulus by the products of the digestion of damaged cells, have none of them been really satisfactory. It is scarcely credible that a simple modification of tissue tension should be capable of making connective tissue, stabilised for many years, return to an embryonic state. And as for the second hypothesis, a wound heals all the quicker by first intention when disintegration is reduced to a minimum; moreover, the normal changes happen at once, whereas proteolytic digestion takes considerable time. The phenomena seen in aseptic wounds—namely, dilatation of vessels, margination of leucocytes, diapedesis, proliferation of fixed connective tissue cells, return to an embryonic state, and formation of new vessels—greatly resemble those of inflammation, so that it is correct to speak of the reaction as traumatic inflammation. The connective tissue takes the principal part in this. Regeneration may begin, but contraction of newly formed connective tissue slows it down and stops it, and eventually cicatrisation takes its place.

Leriche draws attention to the points of similarity between these phenomena and those which follow every sympathetic section, whether it concerns the large rami, the ganglionic centres, or the peripheral fibres. In each case there is active vaso-dilatation, hyperthermia, an increase in the amplitude of the pulse-wave, and a local leucocytosis. Indeed, every trauma, contusion, or wound can be regarded as a sympathetic injury which must be inevitably followed by an active vaso-dilatory action and an operative wound can be looked on as a series of sections of the sympathetic nerves which accompany the blood-vessels. In his view it is this hyperæmic reaction which leads to the changes in the connective tissue designated traumatic inflammation. In the hours which follow a surgical operation the local temperature is raised and it remains elevated for several days; Leriche has proved that this takes place after a radical cure of hernia, excision of the elbow-joint, a cold appendectomy, suture of a ruptured biceps muscle, and meniscotomy of the knee-joint. The hyperthermia is regional, but (particularly in the limbs) may spread for some distance from the site of operation. Locally he has been able to demonstrate a leucocytosis. Macroscopically the changes following surgical trauma are well known to all surgeons who have had occasion to intervene shortly after the first operation, for the wound is congested, there is a diffuse œdema, and a friability of the muscles. All these effects are seen after an operation upon the sympathetic, whilst Morpurgo has shown experimentally what a great influence the sympathetic innervation has upon the fate of wounds made in a rabbit's ear. After cervical sympathectomy he found that the wound will heal more quickly than a control wound on the opposite neurally intact ear. The hastening of repair after sympathectomy applies as much to epithelium and bone as to connective tissue. Another factor which plays an important part in the normal growth of tissues is the hydrogen-ion concentration in the tissue juice, the optimum pH lying between 7·4 and 7·8. Now sympathectomy and sympathetic section suppress the acidity of wounds and bring the pH back to the most favourable point.

These views on the healing processes, the result of a good deal of study, deserve careful consideration. Leriche has certainly formulated a hypothesis which suffices to explain, in some way at all events, the mysterious sequence of events after every surgical operation. There seems to be little doubt that section of sympathetic rami is one factor in the initiation of the healing process. More than this, he suggests that post-traumatic or post-operative hyperæmia may be the cause of the favourable results obtained by laparotomy in tuberculous peritonitis, or the curious amelioration of symptoms which explorative laparotomy so often brings about in cases of inoperable carcinoma of the stomach. On this hypothesis the gastric mucosa, formerly anæmic, hypopeptic and hypoacid, becomes congested for a few days, furnishing a gastric juice richer in pepsin and hydrochloric acid, and from this arises the subjective impression of cure.

THE FREQUENCY OF UNDETECTED CANCER.

THE accuracy of cancer statistics is considerably impaired by the still appreciable proportion of cases in which cancer is overlooked as a cause of death, and, on the other hand, by the cases wrongly diagnosed as malignant. An interesting contribution to this problem is made in *Norsk Magazin for Laegevidenskapen* for April by Dr. F. G. Gade, who prefaces an account of his own investigations with a summary of the observations of others. As he points out, Lubarsch's study of 86,216 necropsies in various German hospitals included 8557 cases of cancer, among which there were 1131 cases (13 per cent.) in which the correct diagnosis had not been made before death. In a still more recent work, dating from 1928, Kranzfeld, of Odessa, found that 15·8 per cent. of the cases found to be malignant post mortem had been overlooked. During the 20-year period 1908–27 the Norwegian Committee for Cancer Research, Dr. Gade's offspring, made a special study of the malignant post-mortem findings of the pathological laboratory of Ullevaal, Oslo's communal hospital. Among the 1618 necropsies on malignant cases (850 men, 768 women), which included 211 cases of sarcoma, there were 183 (11·4 per cent.) in which the malignant disease had hitherto been overlooked. This percentage of overlooked cases compares favourably with the German and Russian figures. But in 1915 it was as high as 29, and in 1926 as low as five, the average for the last half of the 20-year period being 8·4 per cent. A remarkable inequality in the sex distribution of these undetected cases was observed, as great a proportion as 67·8 per cent. being males, although the comparative incidence of malignant disease in males and females in Norway is as 52·5 to 47·5. The average age of the persons whose malignant disease had been overlooked was somewhat higher than that of the persons whose malignant disease had been detected before death. Curiously enough, there was only one case on record in which a diagnosis of cancer (of the rectum) was proved post mortem to be incorrect, but Dr. Gade assumes that several similar cases must have escaped record. The most common diagnosis in the cases of overlooked cancer was "debilitas senilis." Another category which must include many cases of cancer comes under the heading "deaths from unknown causes." In the north of Norway (Finnmark) 16·7 per cent. of all the deaths in 1925 were placed in this category. Assuming that the incidence of cancer is quite as high in this group as among all the deaths from known causes, Dr. Gade calculates that if the deaths from unknown causes be assumed to represent 2·7 per cent. of all the deaths in 1925, and an addition be made of 12 per cent. of the notified cases of cancer, to make good the proportion of overlooked cases, then the return of cancer deaths in this year ought to be increased by 489, from 3259 to 3748—i.e., a supplement of 14·7 per cent. Calculations such as these show that, high as are the figures indicating the mortality from cancer during recent years, it is still seriously underestimated.

THE CASE FOR OPEN-AIR SCHOOLS.

THE recent decision of the Hornsey Town Council to defer for two years a well thought-out scheme for establishing an open-air school has led to the public discussion of a matter which is of considerable importance to the educational and public health authorities as well as to the pockets of the ratepayer. Unable to reach unanimity last October the Council postponed its decision for its newly appointed medical officer of health, Dr. R. P. Garrow, to report on the scheme. Dr. Garrow was able to draw on his special experience in Chesterfield where much advanced work has been done in modern school construction along open-air lines, and his adverse report on the scheme as drawn up was based on the following considerations:—

(1) The rapid evolution of the open-air principle in general schools.

(2) The steadily diminishing incidence of the chief crippling diseases.

(3) The fact that bad orthopædic cases can only be dealt with in residential schools and hospitals.

(4) The undesirability of segregating cripples.

(5) The desirability of centring effort in the child's home.

(6) The inadequacy of the suggested accommodation (120 places) to deal with the whole number of delicate children.

(7) The good social, economic, and healthy position of Hornsey.

As an alternative method of dealing with the situation in Hornsey Dr. Garrow suggests (*a*) the establishment of a fully organised orthopædic scheme; (*b*) rest-hours for certain children in the elementary schools; (*c*) a campaign to improve the parental knowledge of proper diet for children and the supply of one-third of a pint of milk daily to each child in school; (*d*) charting the weights of children in school for monthly or quarterly periods; (*e*) extension of facilities for open-air education in playground classes, school camps, and the like. In his opinion the cost of these suggestions would be negligible, while their adoption would be followed by results far superior in health and educational progress to any which could be achieved by the provision of 120 places in a special open-air school. There will, we think, be general agreement that the alternative measures would go a long way to meet the needs of the elementary school population and would result in raising the general standard of health and reducing the sickness-rate. But as Dr. H. B. Brackenbury, chairman of the Hornsey Education Subcommittee, pointed out to the Council, there are at present in the borough a number of delicate children, estimated at 150, who on account of physical defects were unable to get proper education in the ordinary schools. It is the duty of the education authority to provide for their schooling, and in Dr. Brackenbury's view the argument for open air in all schools does not rule out the case for special open-air schools in a place like Hornsey, where the buildings are not of a modern type. It would, in fact, be an economy to provide locally for the Hornsey children now in attendance at special schools of other authorities. The differences between Dr. Garrow and Dr. Brackenbury are not in principle, but in its application. Dr. Garrow remarks in his report that no reasonable person could doubt the value of open-air education, and he would no doubt himself be the first advocate for a special open-air school in a smoke-clouded, foul-aired industrial town with extensive slum areas where crippling and other social diseases are rife. In such a milieu the only possible course would be to place the school in a healthy open suburb and to transport the delicate children there. The modern general school on open-air lines can hardly enjoy the special curriculum, dieting, resting, nursing, and supervising arrangements of a special school. Nor can the crippled or delicate child keep educational pace and even mix in safety with his normal fellows. While the incidence of crippling diseases is undoubtedly decreasing, it must still be long before we can afford to relax our efforts for the physically defective children who are still with us in large numbers. Their supply in the future will be cut off by Dr. Garrow's alternative suggestions.

LABOUR BEFORE MEAT.

"LET labour go before meat" said Hippocrates. In his "Haven of Health," written for the guidance of Oxford students in the sixteenth century, Thomas Cogan quotes Galen in support of this precept, which he says "is inadvisedly neglected in the Schooles of Germany. For there the Schollers never exercise but foorthwith after meate, eyther leaping, or running, or playing at the Ball, or coyting, or such like. And the same abuse is rife among us here in England, both in the universities and in the grammer Schooles." Cogan's idea that under these circumstances the "meate is conveyed into all the members before it be concocted or boyled sufficiently" may have been inaccurate, but his conclusion not to exercise immediately after meat has certainly been endorsed by many experimenters. Adair[1] tells us that Dr. Harwood, professor of anatomy at Cambridge, took two pointers and fed them equally. He allowed one "to follow his instinct and sleep," while the other was kept for about two hours in constant exercise. Both dogs were then killed and it was found that in the stomach of the first all the food was digested, while in the stomach of the dog that had exercised the process had hardly begun. A physiologist in the University of Wisconsin has improved on this experiment with the aid of the "gastric pouch" devised with so much profit by Pavlov. By this method both the work done and the juices secreted were accurately measured.[2] It was found that while the animals exercised their gastric secretion was depressed, and the conclusion is once more drawn that rest after meals is to be desired. Despite the weight of all this evidence, however, we are loth to agree without reserve that post-prandial exercise is harmful; for there is a contrary observation which must have been made, consciously or unconsciously, by almost everyone. The healthy child on release from table after a heavy meal is only too often gripped by an irresistible impulse to run, dance, and mishandle furniture, to the surprise and indignation of adult beholders, who at such times value peace above all things. The same phenomenon (pace Harwood) may be seen among dogs. These clinical facts would not, of course, command any attention in face of the laboratory opinions quoted did it not so happen that their lesson has been verified by test-meal analysis. A group of workers at Guy's Hospital[3] last year published an account of experiments going to show that exercise which does not produce discomfort of any sort actually increases the rate of digestion, and this suggests that the scholars of Germany knew their own business better than Thomas Cogan. While in young men moderate exercise such as running two or three miles slowly after a light meal was found to delay digestion—though hardly perhaps as much as might have been expected—lighter exercise such as walking did not disturb the secretion of gastric juice and increased the rate at which the stomach emptied itself. Walking with a friend and talking caused more rapid emptying than walking alone, which was held to show the importance of psychological factors. The effect of emotion on digestion is indeed beyond dispute. "Better is a dry morsel and quietness therewith," says the author of Proverbs, "than a house full of feasting with strife." Pædiatrists rightly insist on this truth in the case of small children whose digestions may easily be upset by the over-solicitous attentions of nagging parents, but it is still insufficiently realised perhaps how prevalent emotional indigestion is among adults. This is a subject considered in a recent paper[4] by Alvarez, of the Mayo Clinic, who says he has made it his study since the time when as a boy, helping in his father's practice, he was first struck by its practical importance. He relates that early one morning a girl fell out of a mango tree and broke her arm. The doctor's office was at some distance and it was nearly noon before the patient arrived. With the first whiffs of anæsthetic she vomited, and there were the mangoes unscarred by digestion with the marks of her teeth clearly chiselled on the surfaces. On another occasion he was called to see a young woman who, on receiving a menacing letter from an income-tax collector, had taken to her bed and vomited day and night for a week. The treatment consisted in appeasing the Federal authorities with $3.85, and it proved wholly successful. The effect of emotion, Alvarez points out, may be an inhibition of the psychic secretion (appetite juice) in any part of the tract; in neurotic persons there may be hypertonic constriction of the gastric and anal sphincters similar to that causing hysterical "globus"; or in the same individuals there may be reversed peristalsis. In normal people an inhibition of peristalsis may result from mental stress, or if this is greater an increase of peristalsis. Finally lack of normal psychic interest may be as injurious as excessive emotion, and patients, he suggests, should be warned against eating "when absent-minded, mentally upset, or greatly fatigued." This is advice which could be very generally applied with profit, and to the Hippocratic precept we may add a codicil to the effect that between labour and meat a short interval of rest should intervene—such a pause being desirable not only to get over the inhibitory effect of severe exercise (if any), but also to restore emotional harmony and allow the mind to settle down as it should to enjoy the pleasures of the table. After the meal is over it is reasonable to suppose that we may safely obey our own internal prompting, whether this is to jump up and down on sofas or recline on them at full length.

SEPTICÆMIA DUE TO BACILLUS FUNDULIFORMIS.

A GENERAL infection, due to an anaerobic organism hitherto supposed to be entirely saprophytic, is reported by Teissier, Reilly, Rivalier, and Layani.[1] The patient was a healthy male, aged 38, who was suspected of small-pox. He was taken suddenly ill with headache, backache, vomiting, and purpura. Later there was jaundice and generalised vesicular and pustular eruption. The coagulation time was prolonged—as was to be expected in the presence of jaundice—and there was no change in the blood picture. He died within a week. Lesions were almost confined to the liver which contained many abscesses; the biliary tract was nowhere involved, and the abscesses were confined to the parenchymatous tissues. Small abscesses were present in the kidneys. From the pustules during life, and from the blood, pure cultures of an anaerobic Gram-negative bacillus, recognised by the authors and by Veillon as *B. funduliformis*, were grown, and post mortem it was found in the hepatic abscesses. This organism was first identified by Hallé in the female genital tract, and has since been fairly widely found, but always saprophytically. It is not, as a rule, pathogenic to laboratory animals; but in this case it proved fatal to guinea-pigs and rabbits, always giving rise to hepatic abscesses on intravenous injection. The authors of this paper believe that the organism got through the intestinal tract into the portal blood, since it cannot live in the presence of bile, and did not infect the biliary passages. Their description is noteworthy, since cases of generalised infection with anaerobic organisms, whether of established virulence or not, are uncommon.

ENDEMIC AND EPIDEMIC MALARIA IN SOUTHERN RHODESIA.

Dr. J. Gordon Thomson has done notable work on malaria and blackwater fever in Southern Rhodesia, and in a paper read to the Epidemiological Section of the Royal Society of Medicine on April 26th he gave a further critical review of the malarial conditions in this attractive territory. The youngest of the self-governing Dominions, it is twice the size of Great Britain, and enjoys for the most part a climate well suited to white settlers. The census of 1926 showed an indigenous negro population of just under a million and about 39,000 Europeans. Since then some 10,000 new white settlers have probably been added. The country is a high plateau lying between latitudes 15° S. and 25° S.—i.e., within the tropics. Most of the whites live along the watershed running S.W. to N.E. at 5000 feet above sea-level. About a quarter of the entire area lies at 4000 feet, and there is much good agricultural land at 3000 feet above sea-level.

The work of Christophers has established that malarial hyperendemicity lies in the fact that while the adult indigenous inhabitant is tolerant to malaria and seldom suffers from an acute attack, the infants suffer for the first few years of life from acute malaria with numerous parasites in their blood, and a very high infantile mortality is the result. The survivors of this "acute infestation" gradually develop a tolerance to the parasite and acute attacks become progressively less frequent ("immune infestation"), till finally the adults are completely tolerant and seldom show parasites in the peripheral blood, although all are presumably infected with the parasite. In Southern Rhodesia hyperendemic malaria prevails with yearly seasonal epidemics among the non-immunes—namely, the indigenous negro children, and the whites of all ages. All these non-immunes live in a country where for about six months in the year the density of anopheline mosquitoes which bite man is high, and the atmospheric temperature and humidity are eminently suitable for the development of the malaria parasite in the common carrier *Anopheles gambiæ* (*A. costalis*). The hyperendemicity of malaria in Southern Rhodesia is shown by the fact that the enlarged-spleen rate in children is well over 50 per cent.; often over 90 per cent. in those between 2 and 10 years of age. Moreover, the parasite rate (endemic index) in the negro children is extremely high. The charted records of 1924–26 demonstrate that the amount of malaria varied from year to year directly with the rainfall; as the rains continue, so increases the number of cases of malaria and blackwater fever. The peak of the acute malaria incidence amongst the whites is in April; there is a quick drop in May and June with the onset of the cold weather, and it is interesting to note that Leeson reports that *A. gambiæ* appears first in late November and remains till early June, when it disappears.

Hyperendemic factors such as those operating now in Southern Rhodesia, and, moreover, associated almost entirely with the malignant tertian malaria parasite, make it plainly impossible for a non-immune white population to live there healthily unless they devote some intelligent, withal simple, effort to prevent malaria. But, in fact, carelessness and the stubbornness of ignorance lead to needless deaths and to much sickness from malaria among the white settlers, especially in the rural areas. Dr. Thomson, at first-hand experience, agrees heartily that "the attractions of Rhodesia are manifold and well-nigh irresistible, and to the right type of immigrant it offers a home well worth living in, and developing for future generations." But he emphasises that the settler must be of *the right type;* and clearly this means right-thinking about malaria and mosquitoes. He deplores the fact that to-day so many of the white settlers are as individuals apparently blind to the fact that prevention of malaria is for them a personal affair, and many of these blind resist enlightenment. No doubt in the process of development the disease will some day, in Rhodesia, be reduced to a minimum, where now it is of maximum importance. Meanwhile an intelligent settler in that country may protect himself and family from malaria by a well-constructed and screened house, with a strict and careful use of wide mosquito nets for the beds, by destroying mosquito larvæ in and around his living quarters, and especially by keeping negro children far away from his living quarters. Dr. Thomson points out that there are many white settlers in rural Southern Rhodesia to-day who live free from malaria by just these measures. These many might and should be many more.

MEDICAL DISPUTES AND LITIGATION.

"No practitioner is safe against becoming involved in very costly litigation arising out of his practice. This risk is one against which insurance should always be effected." So runs a sentence in the annual report of the Council of the London and Counties Medical Protection Society, and it may be taken as the moral of the many instructive stories which the report contains. No one would claim any novelty for the sentiment, since it is repeated monotonously every week or two in our own columns and elsewhere; yet a perpetual insistence on its truth is certainly justified by what the Society's solicitors describe as "the growing critical and litigious spirit of the general public." We are glad to say that the sensible plea for Safety First is having its effect, and that not far short of a thousand practitioners joined this particular defence society last year, bringing the total on Dec. 31st, 1928, to 11,492. That the subscription is a very small premium for the insurance afforded is an obvious commonplace, and no one can be blind to the advantage of belonging to such an organisation when faced with adverse damages of several thousand pounds. Not everyone, however, is aware of the large amount of assistance in everyday problems that the Society offers—an amount indicated by the fact that 1067 applications for advice were received from members last year alone. In considering the situations in which help is asked the solicitors, Messrs. Le Brasseur and Oakley, refer to the increase of cases arising under the National Health Insurance Acts and make the following outspoken comment:—

---

[1] Paris Méd., March 30th, p. 297.

> "Dental surgeons are now exposed, in much the same manner as general panel practitioners, to that form of private but statutory jurisdiction falling within the almost inexhaustible powers of the Minister of Health. It is a matter of surprise to us that those responsible for watching the interests of the medical and dental professions, and bodies concerned in matters pertinent to these professions, are so powerless to prevent the growth of bureaucratic power which can usurp jurisdiction designed to give citizens the fairest form of trial, and can vest in one man, who by virtue of his statutory powers of making regulations can pass what are virtually laws affecting so large a number without their having a word to say antecedent to such regulations becoming effective, a power of decision and sentence without right of appeal."

Addressing the Society's annual meeting on May 1st Sir John Rose Bradford, F.R.S., the President, spoke of the loss sustained by the death of Dr. G. W. Hill and Sir Anthony Bowlby, vice-president and trustee respectively, and of Mr. A. Neilson, K.C., who had been "a tower of strength to the Society." In the course of observations of the risks of practice he drew attention once more to the advantages of radiography in providing evidence of fractures, and insisted that members should "take every precaution to safeguard themselves and their interests" in this kind of case. A statement had been drawn up, he said, of the steps which ought to be taken where foreign bodies were alleged to have been left behind at operation. "So much," he added, "of the work of our Society, and of the expenditure also, could be diminished if quite simple methods of procedure were adopted by the individuals concerned in such cases," and few who study the report carefully will spurn the Society's good offices or imagine themselves qualified to play a lone hand in the game of law.

SIR RONALD ROSS.

A TESTIMONIAL has been started to Sir Ronald Ross, and we understand that subscriptions will be invited immediately. The object is to set free from financial anxiety Sir Ronald and Lady Ross in their declining years, and the appeal will be directed to the public generally, who may be expected promptly to recognise the claim on their generosity furnished by Ross's magnificent work alike in the ætiology and the prevention of malaria.

LONDON CLINIC AND NURSING HOME.—The share capital necessary for the prosecution of the scheme to erect an institution for paying patients containing 175 beds with full facilities for diagnosis and treatment on a site between Devonshire-place and Harley-street has now been acquired. Details of the organisation and an elevation of the proposed building were set out in THE LANCET, 1928, ii., p. 729, 783. The work of demolition of existing buildings on the site has commenced, and it is hoped that the Clinic will be ready for use early in 1931.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXX.—THE CLINICAL SIGNIFICANCE OF THE BLOOD-PLATELETS.

PART I.*

IN view of the great importance attached by clinicians and pathologists to blood examinations as an aid to diagnosis, it is a curious fact that so little attention has been paid to the blood-platelets. The explanation is partly that the technique of examining blood-platelets is more difficult than that of the other cellular constituents of the blood. The main reason, however, is that ever since their discovery 50 years ago, the majority of physiologists have, on quite inadequate grounds, dogmatically denied their existence as independent cellular elements, so that relatively little is known concerning their physiological and pathological significance. It is only during the last 15 years that interest in them has reawakened.

There are two processes of importance from the clinical and pathological standpoint in which the blood-platelets play a part of outstanding importance—blood coagulation and thrombus formation. In fact, these processes cannot be understood if the existence of the platelets is denied. The voluminous and confusing literature on blood coagulation bears eloquent witness to that statement. Recent work has shown that, in addition, platelets play a part in the defence against infection by micro-organisms.

It is impossible to understand the significance of changes in the platelets under pathological conditions or even the technique of investigating them without a knowledge of their physiological properties and functions. A very brief summary of our present knowledge on these points must therefore be given.

Properties of Platelets.

Platelets are minute discoidal particles of living protoplasm possessing a definite structure and amœboid movement. They vary slightly in size, their largest diameter being less than half that of a red corpuscle. They are present in normal blood in definite numbers which vary within certain limits in different individuals of the same species. In man their numbers vary between 250,000 and 400,000 per c.mm. They have a characteristic property which determines their function. When they come into contact with a water wettable surface larger than their own they attach themselves to it and spread out over it. In doing so they disintegrate in an explosive manner and shed into the blood a coagulating agent. This coagulating agent, which is not identical with either "thrombin" or "thrombokinase," is capable in the presence of calcium salts of transforming fibrinogen into fibrin with the formation of thrombin (fibrin ferment). If the water wettable surface is smaller than that of the platelets, as is the case, for instance, with colloids or many micro-organisms, they attach themselves to it without disintegrating, so that masses of agglutinated platelets are formed which settle in the liver, the spleen, and the bone-marrow. If removed from the body, even if allowed to remain in blood or plasma, the platelets eventually die. In doing so they contract and get agglutinated to one another. It is important to note that this manner of death of the platelets differs from the disintegration by expansion, referred to above, in this important point that the coagulating agent, liberated when the platelets disintegrate by expansion, is not liberated or liberated only in much smaller amounts when the platelets die in the contracted state. Another important point is that the characteristic disintegration of platelets on a water wettable surface is dependent inter alia on the presence of ionised calcium in the blood. In oxalated or citrated blood the platelets do not disintegrate when they come into contact with a water wettable surface. Lastly, the disintegration of platelets liberates a substance which has a very definite vaso-constrictor effect. These properties of the platelets give the clue to their function in blood coagulation, thrombosis, and in infections.

---

* Part II. will appear next week.

Pathological Significance of Platelets.

1. *Blood Coagulation.*—In the past a fundamental difficulty in explaining blood coagulation has been that blood keeps fluid as long as it remains in the blood-vessels and clots when it is shed. If one denies the existence of the platelets one is compelled to assume that blood when shed undergoes either a physical or a chemical change. Both views have been held. There exists a vast and confusing literature dealing with this point and involving many complicated hypotheses. The phenomenon is readily explained by the characteristic property of the platelets.

The endothelium of the blood-vessel walls owing to its richness in lipoids presents a surface which is not wetted by water, as one can readily verify. The platelets therefore remain unaltered in the intact blood-vessel. When a blood-vessel is cut, the blood flows over the water wettable surface of the wound-tissue to which the platelets attach themselves. This causes them to disintegrate and to shed into the blood their coagulating agent which, by the formation of fibrin from fibrinogen and the production of thrombi, causes the blood to clot. The same happens if blood is allowed to flow through a glass cannula into a glass vessel, even without coming into contact with the wound: the blood clots. In this case the glass presents the water wettable surface. A paraffined or oiled glass cannula or glass vessel is an imitation of the endothelial lining of the blood-vessel in so far as it presents a non-water wettable surface, and thus prevents the disintegration of platelets and the clotting of blood. If blood is removed from the body in such a way that the disintegration of platelets is completely prevented and if, then, by suitable manipulation the platelets are completely removed by filtration, no spontaneous clotting ensues even if ordinary glass vessels are used. If the removal of the platelets is only partial, as, for instance, by spinning, clotting is delayed roughly in proportion to the removal of the platelets.

If we restrict our attention to blood coagulation as it occurs in the body, which is after all that aspect of the problem which interests the clinician and the pathologist, the process is seen to be dependent *primarily on three main factors: the blood-platelets,* fibrinogen, and calcium salts. The relation of the platelets to blood coagulation can be summed up briefly in the following two laws of blood coagulation.

1st Law.—No coagulation of blood without disintegration of platelets.

2nd Law.—Everything that facilitates the disintegration of platelets facilitates the coagulation of blood. Everything that retards or prevents the disintegration of platelets retards or prevents the coagulation of blood.

This statement does not preclude the existence of other processes which may assist in the coagulation of blood such as the addition to the blood of coagulating substances by the tissues of the wound. Such processes are, however, subsidiary and not essential to blood coagulation, *since blood will coagulate even if every contact* with other tissues is carefully avoided.

2. *Thrombosis.*—Thrombosis begins, as a rule, as a mass of agglutinated platelets adhering to the damaged wall of a blood-vessel—usually a vein. It can be elicited by pathological changes in the endothelial cells, or by producing a slight injury to the endothelial lining of the blood-vessel, for instance, by pressure or by firmly tying a blood-vessel. As more and more platelets attach themselves to the original mass of agglutinated platelets, the thrombus *of platelets—a "white thrombus"—increases in* size, impeding the blood flow. If now some platelets, in attaching themselves to the white thrombus, are disintegrated and liberate their coagulating agent, there is a local formation of fibrin and a "red thrombus," which is actually a blood-clot, appears superimposed upon the "white thrombus" of agglutinated platelets. It is probable that an impeded blood flow plays an important part by preventing the liberated coagulating agent from being washed away.

Infections.—It has already been stated that the platelets attach themselves to certain types of bacteria when they are introduced into the blood stream and agglutinate them. This process is, therefore, one of the methods by which the blood tends to keep itself sterile.

Formation and Destruction of Platelets.

The view generally held is that the platelets are formed in the bone-marrow and are destroyed in the spleen. Their formation is believed by some to be referable to the megakariocytes alone. Their destruction is attributed by some to an action of the reticulo-endothelial system—generally including the spleen.

One of the writers (W. C.), working with A. H. Drew, has obtained evidence of the formation of platelets by the endothelial cells of the blood-vessels. Such a view would explain that an antiplatelet serum which on injection elicits purpura hæmorrhagica produces this effect not only by a lysis of the platelets, but also by damaging the capillary endothelium.

The formation of platelets is stimulated by irradiation with ultra-violet light and with small doses of X rays and radium. Animals kept in darkness for a long time show an abnormally low platelet count, which rises to the normal on irradiation with a mercury-vapour lamp. There is some evidence that excessive irradiation with light may have *a destructive effect, but this point requires further* study. Radiation with radium and X rays in large doses has a destructive effect on the platelets so that a thrombopenia is produced. Operative procedure is followed by a transient rise in the number of platelets which reaches its maximum in the second week after the operation and then falls again to the normal level. After removal of the spleen, an organ in which the platelets are believed to be destroyed, the post-operative rise persists for a longer period.

Technique of Platelet Count.

The following method of counting blood-platelets has been found satisfactory.

A syringe, of 1 c.cm. capacity, and preferably of the tuberculin type, is mounted with a needle whose bore is not too *narrow; it is sterilised by repeatedly drawing into it* and expelling liquid paraffin, heated well above the boiling point of water. Into this syringe is drawn 0·2 c.cm. of 3·8 per cent. solution of citrate of soda; then 0·8 c.cm. of blood are taken from a vein fairly rapidly. In this way the blood traverses an anticoagulating surface into an anticoagulating medium. *The blood is diluted in the proportion* of 4 parts to 1 part of citrate, and can be used not only for determining the ratio of platelets to red corpuscles, but also for making absolute counts of red and white corpuscles, the appropriate correction being made according to the dilution with citrate; the blood is also suitable for the sedimentation test. For *counting the platelets* a teated pipette is used to mix a small quantity of the blood on a paraffined slide with about 10 times its volume of the following solution:—

Sod. citrate	0·2 g.
Sod. chloride	0·8 g.
1 per cent. brilliant cresyl blue	1·0 c.cm.
Formalin	2·0 c.cm.
Dist. water to	100·0 c.cm.

A droplet of this mixture is placed on a clean microscope slide; this is inverted over a clean coverslip which it picks up, and the preparation is immediately sealed with hot liquid vaseline. With a 1/12 in. oil-immersion objective and an eyepiece containing a squared diaphragm, successive fields are examined until 50 platelets and the accompanying red corpuscles have been counted. An ideal field will contain about 30 red corpuscles; the normal red corpuscle-platelet ratio in man is about 16 : 1. The absolute number of platelets is obtained by dividing the ratio found into the number of red corpuscles per c.mm., as determined by a separate red cell count. In order to *conserve a uniform* relative distribution of red corpuscles and platelets it is essential to carry out the manipulations with rapidity. The presence of platelet clumps invalidates the count.

When a vein is not available the skin of the finger just behind the nail-bed is pricked through a droplet of diluent with the ragged end of a teated glass pipette whose interior is lined with paraffin. The blood-diluent mixture is transferred by the pipette to a paraffined slide where it is thoroughly mixed and if necessary further diluted; a droplet of this is placed on a slide and the red cell-platelet ratio determined as already described. The method is less good, and if there be any delay in obtaining the blood the platelet count is apt to be erroneously low.

Platelets in Disease.

The behaviour of platelets in disease is still an almost untilled field of clinical research. At present, therefore, a platelet count is more a piece of research than an aid to diagnosis and treatment. There are, however, several different groups of conditions in which a constant relationship with a change in the platelet count seems to have been definitely established, and these we propose to discuss next week.

W. CRAMER, Ph.D., D.Sc., M.R.C.S.,
Imperial Cancer Research Fund.
R. G. BANNERMAN, M.D., Ch.B.,
Pathologist, Miller General Hospital, London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. P. J. Maguire is placed on the Retd. List.

The following appointments are notified: Surg. Lts. J. P. Henderson to *Vivid*, for R.N. Barracks, Devonport; and H. A. Clarke to *Pembroke*, for R.N. Barracks, Chatham.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. D. C. Livingston to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. D. S. Buist is placed on the half-pay list on account of ill-health.

Temp. Lt. W. H. D. Priest resigns his commn.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. I. S. Thomson to be Capt.

TERRITORIAL ARMY.

Capt. A. C. MacDonald to be Maj.

Capt. J. W. Archibald relinquishes his commn. and retains his rank.

Lts. H. J. Curran and A. L. Moorby resign their commns.

A. H. Weston (late Offr. Cadet, Edinburgh Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

W. R. Sprunt to be Lt.

DEATHS IN THE SERVICES.

Surgeon-Commander James Walter Octavius Underhill, R.N., who died on April 29th, entered the Royal Navy in 1886, and two years later was appointed to the *Boadicea*, the flagship of Rear-Admiral the Hon. Sir Edmund Fremantle in the East Indies. Later he served in the Mediterranean, and in 1898 became staff surgeon. After serving in the North America and West Indies Station he was promoted to fleet surgeon, and subsequently retired in 1907. During the early part of the war he was P.M.O. of the *Excellent*, gunnery school, at Portsmouth. He was made surgeon-commander in 1918.

COLONIAL MEDICAL SERVICES.

Dr. G. H. Garlick has been appointed Physician and Radiologist, Johore; Mr. K. H. Uttley, M.O., Hong-Kong; Mr. J. W. Bowden, Mr. I. M. D. Grieve, Mr. P. G. Preston, and Mr. A. B. Swarbreck, M.O.'s, Kenya; Mr. W. C. V. Brothwood, M.O., Straits Settlements; Lieut. J. W. Walker, M.O., Tanganyika Territory: and Mr. J. McDaniel, M.O., Uganda. The following have been appointed M.O.'s to the West African Medical Staff: Mr. J. I. Lochhead, Mr. W. McLelland, and Mr. J. H. Young.

NAVAL VACCINATION ORDER.

In view of the prevalence of small-pox it has been decided to vaccinate all active service officers and ratings who have not been vaccinated within five years.

Special Articles.

MODERN CONCEPTIONS OF NUTRITION.

THE MAIN COMPONENTS OF THE NORMAL DIET.*

By STUART J. COWELL, M.B. CAMB., M.R.C.P. LOND.,
PROFESSOR OF DIETETICS IN THE UNIVERSITY OF LONDON.

THE foundation of our modern ideas of nutrition rests on the experimental work of the great French chemist Lavoisier, who first demonstrated, some 150 years ago, that the heat production of the body was due to the oxidation of food, and was in fact a phenonemon of the same order as combustion outside the body. He carried out a remarkable series of quantitative measurements of the variations of metabolic processes with the food eaten, the work performed, and the surrounding temperature, and was led to the then astounding conclusion that "life is a chemical function."

During the nineteenth century the chemical and physical aspects of nutrition were the subjects of laborious investigations at the hands of such masters as Magendie, Liebig, Voit, and Rubner on the Continent, and Atwater and Benedict in the United States. The crude chemical composition of foodstuffs was discovered, and elaborate determinations were made of the nutritive requirements of the individual in terms of the main components of foods—namely, proteins, fats, carbohydrates, and mineral salts—and in terms of the heat or energy exchange produced by the combustion of the several items within the body.

Towards the end of the last century it appeared almost as if the main problems of animal nutrition had been solved. Young animals could be successfully reared and maintained in good health when fed with nicely calculated quantities of apparently pure protein, fat, carbohydrate, and mineral salts, the chemical composition of all of which was more or less accurately known. What further great advances were possible? The man in the street began to talk about compressed foods, and cartoons were drawn illustrating dinner parties at which food was supplied in weighed blocks of pure foodstuffs. It is true that a word of warning was uttered by Pavlov, who pointed out the influence of the appetite-producing effect of food on its digestibility. Nevertheless it remained for one of the great biochemists of our own country to dispute successfully the proposition that protein, fats, carbohydrates, and salts were the sole essential constituents of a normal diet, and in so doing to pave the way to our modern views of nutrition which have done so much towards the prevention and treatment of human disease. I refer to the pioneer work of Sir Frederick Gowland Hopkins, who, by taking most careful precautions to purify all the constituents of the synthetic diets used by him, showed that young animals fed on such diets were unable to grow, although growth could be readily secured by adding to their diet a minute quantity of the natural food milk, which contained but negligible amounts of the then known food constituents. He postulated, therefore, the presence in milk of what he termed accessory factors in the diet. After a few years of controversy, his views were accepted universally and have led to enormous advances in the whole field of nutrition.

It would not be right to give the impression that all the recent advances in the science of nutrition had arisen from laboratory researches conducted by expert chemists. Careful observation, unaided by any facilities for strictly scientific experiment, had long ago led to such empirical discoveries as the protective influence of certain kinds of food against scurvy—though it was not until the disease had been experimentally produced and investigated in animals by Holst that anything like an adequate knowledge of the distribution of this protective factor was possible, and even then, neglect to take advantage of his experimental methods of investigation led during the Great War to the issuing as a scurvy-preventing agent of lime juice, which has virtually no protective effect against scurvy. Again, some 30 years ago, Eijkmann, who was then acting as medical officer to a prison in Java, observed that the fowls which were kept in the neighbourhood of his prison were frequently affected by peculiar paralytic symptoms which reminded him of those of the disease beri-beri which was common among the prisoners. The fact that these fowls and the prisoners were receiving the same kind of food led him to suspect a dietary origin for the disease, and subsequent careful studies by himself and his followers led eventually to the conception of diseases being produced by specific dietetic deficiencies.

---

* Being the substance of the Inaugural Lecture of the Chair of Dietetics, delivered at St. Thomas's Hospital on May 2nd, 1929.

In recent years our knowledge of the fundamental processes of nutrition has been progressing rapidly along each of these two paths—chemical and physiological analysis and clinical observation. Knowledge for its own sake may be a fitting motto for the chemist and the physiologist, whereas the prevention and cure of disease must be the first aim of the clinical observer. In spite of their diverse aims the exponents of the two methods find that each has something to learn from the other, and there is some justification for a feeling of elation that by their combined efforts it has already been made possible for us to control by dietetic methods alone many diseases which formerly baffled our best-intentioned efforts.

The Complete Diet.

In order to understand the ways in which the composition of a dietary can influence the health of the individual partaking of it, we should first find out as much as possible about the physiological action of every constituent known to be present in each item of food composing it. Our knowledge of the chemical composition of foods is still far from complete, but I intend in this and my next lecture of this series to describe briefly some of the more important attributes of the known food constituents; the sum total of all essential constituents chosen in the correct proportions should represent a complete or perfect diet, always assuming that the foods containing them are presented in a palatable and digestible form and free from harmful substances.

To begin with, let us consider the significance in human nutrition of those food elements which have been recognised for the longest period of time—namely, the proteins, fats, carbohydrates, and mineral salts. It is customary to consider protein and salts as the main tissue-building elements of the diet, fat and carbohydrate being considered as energy-providing constituents. This conception may be of some value in practical dietetics, but does not apply to the physiological processes that go on in the living cell. Certain parts of the protein molecule may be split off into compounds which are used for the supply of energy and may even be stored as fat. On the other hand, fats, as has been stressed by Leathes, form an indispensable part of all living protoplasm, and carbohydrates are believed to play an important part in synthetic processes that occur in normal tissues, as for example the calcification of bone. It must be remembered, furthermore, that these constituents very rarely occur in natural foods in a pure state. For example, lean meat, which is one of the richest common sources of protein, contains a considerable quantity of fat and mineral salts; some varieties of fat are associated with minute amounts of accessory food factors which may be of far greater importance for the nutrition of the consumer than the fats themselves; cereals from the main source of carbohydrates for the human race, but the presence or absence from this class of food of accessory food factors, or of certain toxic properties with which they may be endowed, may determine their nutritive value without relation to the pure carbohydrate they contain. It is therefore clear that the physiological action of any given type of food cannot be predicted from a chemical analysis of its main constituents, and must be studied by feeding experiments carried out on animals or by controlled observations on the human subject.

The Protein Fraction.

Protein from any source, whether animal or vegetable, is built up from a number of simpler chemical bodies known as amino-acids. During life there is a continuous destruction of the protein constituents of the cells which must be replaced by fresh protein constituents supplied in the food. There is every reason to believe that the protoplasm of the various cells belonging to different kinds of tissue must vary very considerably in its chemical make-up—that is to say, in terms of their protein constituents, that the groupings of the amino-acids in the cells of one kind of tissue will be quite different from the groupings in the cells of another tissue. Moreover, for each kind of cell of every species of living animal or plant we may expect a characteristic grouping of these amino-acids. Now, many of these amino-acids cannot be manufactured by animals from other materials and must be supplied ready made in food if the organism is to survive, which it can only do by making good the destruction of material that is continuously proceeding within its body. From the nutritional point of view, therefore, such amino-acids may be termed indispensable, and those proteins which do not contain them will not prove capable of supporting life. This fact was first demonstrated by Hopkins and was one of the earliest pieces of scientific evidence demonstrating the specific qualities of special varieties of foodstuffs. We may say, in general, that proteins of animal origin, with the notable exception of gelatin, are usually complete in the sense of containing all the essential amino-acids, whereas many of the vegetable proteins are deficient in this respect. If this deficiency is absolute the nutritive value of the protein can be restored by adding to the diet a source of the missing amino-acids—a process which is known as supplementing one protein by another, and which is commonly practised by a certain class of vegetarians who add the biologically valuable and complete proteins of milk and eggs to the less complete proteins of their main regimen. If, on the other hand, the deficiency is not absolute but relative—that is to say, if some essential amino-acid is present in a given protein in traces only—it may be possible to maintain the necessary supply to the body by ingesting very large quantities of the protein, a large proportion of which will then be eliminated from the body as useless material.

In any consideration, therefore, of the amount of protein that ought to be supplied to the ordinary individual, it is essential to pay some attention to the quality of the protein that is to be given, and this applies especially to the growing person who is constantly building up protein constituents into new tissue. It must be remembered that the metabolic processes concerned with the protein constituents of foods are so adjusted that a considerable variation in the total intake of protein is possible without affecting the total amount of protein retained within the body. Protein breakdown in the body is measured by the amount of nitrogen eliminated in the excreta, and it is possible for a man neither to gain or lose more nitrogen in his excreta than he takes in his food, whether he eats a large or a small amount of protein. This condition of so-called nitrogen equilibrium depends on many factors, including the nature and quantity of the other constituents of the diet, particularly the amount of carbohydrate eaten, for carbohydrate has a remarkable sparing action as regards loss of nitrogen from the body tissues. It is possible to determine experimentally the minimum amount of protein that will suffice to maintain a man in and the relatively low milk consumption of the population of England must indicate a widespread deficiency of calcium among a large section of the community. Eggs and green vegetables furnish moderate amounts of calcium, and the same is true of the whole cereal grains. In the case of the cereals, however, the amount of calcium in any particular variety gives no indication of its usefulness as an effective source of calcium to the tissues. In fact, the cereals which contain the greatest percentage of calcium may, under certain conditions, actually hinder the effective utilisation of calcium.

Phosphorus is another of the mineral elements which occurs in large amounts in the body. Most natural foods except the sugars contain easily recognisable quantities either in organic combination or as simple inorganic salts; there is no evidence that it is better utilised in the body when supplied in one form than the other. The ratio of the amount of phosphorus in a diet to the amount of calcium may be an important determining factor in the production of experimental rickets. We shall see, however, that this ratio can be varied enormously without the appearance of rickets if attention is paid to other factors in the diet and environment, and it is therefore probably not of very great practical significance in human nutrition. The growing child who receives a liberal daily allowance of milk is not likely to suffer from lack of phosphorus, and the mixed diet of the adult containing meat, fresh vegetables, and dairy produce will supply all the phosphorus he needs.

Iron and iodine are both liable to be deficient in the diet of mankind under certain conditions, symptoms of disease being thereby produced. Under ordinary conditions there is no likelihood of anyone in this country suffering from a deficiency of sodium chloride, but it has been found that men performing hard work under conditions of great heat may lose a great deal in their sweat, and, being very thirsty under these conditions, may drink excessive quantities of liquid so that their tissues cannot maintain their normal concentration of sodium chloride, and they suffer in consequence from the so-called miners' cramps. This condition can be prevented by the addition of sodium chloride to their drinking water. Potassium is usually present in large amounts in vegetables, and an excess of potassium in the food causes the elimination of extra amounts of sodium; this probably explains why herbivorous animals frequently display an intense desire for sodium chloride, travelling miles across country to visit "salt-licks." Sodium and potassium may be of practical importance from another point of view; they are potential alkali producers, while other elements such as chlorine, sulphur, and phosphorus may be regarded as acid-producers. The relative proportions of the two groups of elements in a food are spoken of as the acid-base ratio, and it has been claimed that this ratio may be of practical significance in the prevention and treatment of certain diseased conditions.

These are the main foodstuffs that compose the bulk of our diet, but the most ideal combinations of these substances in a diet will fail to support life without those essential accessory food factors or vitamins which are known to be required to complete the diet.

MEDICINE AND THE LAW.

A Breach of the Cremation Act.

PROSECUTIONS under the Cremation Act are rare; a recent instance was stated to be the first of its kind for over 20 years. Fortunately the facts negatived any suspicion of felonious intent, and it is reassuring to find that a breach of the Act did not escape detection. Proceedings were taken against a Camden Town firm of undertakers in the following circumstances. A man died in hospital and his relatives arranged for his body to be cremated. The defendant firm of undertakers was employed to carry out the arrangements and a shell was brought to the hospital for use in the cremation of the body. It happened that a child born in the hospital had recently died and that the mother, being in poor health, had left the burial to the hospital authorities. The authorities asked the undertakers to arrange for the burial of the child, and, no other provision having been made in advance, the child's body was placed in the shell which contained the man's body for removal from the hospital. By an oversight, which was not fully explained, the shell was taken to Golders Green Crematorium without the child's body being removed, and the two bodies were cremated. Subsequently the firm of undertakers seems to have discovered its mistake. It was stated that the ashes of the child were buried at St. Pancras. A double irregularity had occurred; the child had been cremated without compliance with the statutory conditions and the registrar was notified that the child had been buried when this was not the fact. The Hendon magistrates before whom the case came felt bound to take a serious view of the offence and imposed a fine of £20 with £5 5*s.* costs. Apart from certain vague prejudices which are slowly disappearing, the main attack which cremation has to meet is the criticism that it may be used to facilitate the concealment of crime. The reply to this criticism is a recital of the strict formalities and certificates which the Cremation Act and Regulations enjoin. If a child's body can nevertheless be cremated without compliance with these requirements, it becomes possible to destroy the evidence of infanticide or concealment of birth. Even where there is no suggestion of such a sinister purpose, an irregularity cannot be lightly passed over.

The Un-named Medicine Bottle: A Chemist at Fault.

Is a chemist obliged to write on a bottle of medicine, or on the wrapper which contains it, the name of the patient? Clearly, if he does not do so he omits a reasonable precaution and makes it easier for a jury to find that he has been negligent in the event of bottles being sent to the wrong patient. The point has arisen in the discussion of a complaint against a chemist at a meeting of the West Sussex Insurance Committee. The Pharmaceutical Service Subcommittee reported that a widow, an insured person, handed the chemist a prescription and received a bottle of medicine on which her name was written. Subsequently another bottle was obtained which, on being opened, indicated no name. The widow, afraid that she might be taking medicine not intended for her, sent the bottle back by the hand of her daughter. When it came back again it was found still to lack a name, and the daughter complained of the chemist's rude manner. It was said that he remarked, "We don't often put it on for panel patients." In the course of further evidence it appeared that the patient eventually sent the medicine to the prescribing doctor as she still had misgivings; he tasted it and reassured her. The Subcommittee reported its conclusion that the dispensing of the mixture was not complete till the chemist put the patient's name on the container. They declared that the regulations had been broken and they further found the chemist at fault for his attitude to the patient and to themselves. They recommended that he be censured and that the Minister be asked to withhold the sum of £1 from monies payable to the Committee for medical benefit, a like sum to be withheld from the remuneration payable to the respondent. Some members of the Committee thought this too lenient, one medical practitioner remarking that, if a doctor was at fault, the Ministry took severe measures. After discussion the Subcommittee's report and recommendation were adopted. The duty to write the patient's name on a medicine bottle would seem to be one which might well be expressly insisted upon in the regulations.

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

THE DUBLIN MEETING.

THIS Congress was held at Dublin from April 24th to 26th under the presidency of Dr. GIBBON FITZGIBBON. On the first day a discussion on the

MANAGEMENT OF CASES OF PELVIC DISPROPORTION

was opened with a paper on Diagnosis by Prof. MUNRO KERR (Glasgow). He pointed out that it was very difficult by any method to arrive at exact measurements of the pelvic inlet, whereas deformities of the outlet could be exactly determined. The selection of treatment for deformity of the pelvis at the inlet depended on exact estimation of the relative size of the head to the pelvis, but for the outlet treatment should be based on exact measurement of the outlet. It was important to recognise minor deformities, since failure to do so often resulted in unsuitable treatment; indeed, he believed that the largest proportion of disasters occurred in this group. The practical question was: Will the head pass? Among the factors which influenced spontaneous delivery were: (*a*) previous obstetric history, (*b*) irregularity in the pelvic brim, (*c*) size of the fœtal head, (*d*) degree of ossification, (*e*) variety of biparietal obliquity, and (*f*) strength of uterine contractions.

Prof. FLETCHER SHAW (Manchester) read a paper on the Immediate Results to Mother and Child of Labour with Contracted Pelvis. One of the most difficult tasks confronting an obstetrician, he said, was to decide what method of delivery to recommend to a woman with a moderately contracted pelvis. It was impossible to lay down hard-and-fast rules; nothing but experience and careful observation would allow of a correct decision. Analysing a series of 290 cases of contracted pelvis delivered in St. Mary's Hospitals, Manchester, in a period of nine months, he laid stress on the fact that among the 242 cases which were admitted from the antenatal department the maternal mortality was nil, the fœtal mortality being 5·7 per cent. The other 48 had been admitted as emergencies, and in these the maternal mortality was 10·4 and the fœtal mortality 56·2 per cent. Better proof of the importance of antenatal examination and subsequent treatment by experts could hardly be adduced. Prof. Shaw went on to describe the methods of delivery in detail, emphasising the importance of a trial labour in an institution under expert supervision. A history of previous stillbirths, he said, inclined him to advise Cæsarean section. This operation at term was preferable to induction before the thirty-sixth week, but he considered that medicinal induction after the thirty-eighth week could do no harm to the child and many cases so treated terminated naturally, which otherwise would have required Cæsarean section. He believed that none of the staff of St. Mary's Hospitals had found any marked advantage from section through the lower uterine segment. In his opinion one of the greatest blots upon modern obstetrical practice was the fact that the increased number of Cæsarean sections had not diminished the number of craniotomies. In concluding, Prof. Shaw emphasised the importance of antenatal supervision carried out by a skilled obstetrician who would attend the patient in her confinement and be responsible for the delivery.

Dr. JAMES YOUNG (Edinburgh) read a paper on the Factors Underlying Maternal Mortality in the Operative Treatment of Obstructed Labour. There was considerable variation, he said, in the published mortality figures of different hospitals in respect of the operative treatment of both clean and emergency cases of pelvic disproportion. He quoted figures from the reports of nine well-known hospitals totalling 1043 Cæsarean sections with a mortality of 3·6 per cent. However, on regrouping certain hospitals the maternal death-rate was shown to vary from 0·7 per cent. to 4·3 per cent. for similar cases. There was evidence that these variations were determined not so much by the type of operation selected and by the operative technique employed as by the success attending the efforts to prevent, on the one hand, contagion of the clean by the emergency case, and on the other hand, contagion transmitted from one emergency case to another. In general this risk of contagion sprang from the inadequacy of the machinery of segregation and this in turn might be dependent upon the difficulty of organising a satisfactory system because of the architectural unsuitability of the buildings. He outlined the general principles followed by the Edinburgh school for the treatment of labour with obstruction due to disproportion.

Dr. J. D. BARRIS (London) gave a contribution on the Results of Disproportion as Treated by Induction. Beginning with an outline of the history and origin of induction he showed how with the increasing safety of the Cæsarean operation it was encroaching more and more upon the time-honoured method of induction. The most difficult problem, he thought, was that of correctly estimating the time at which to induce. The best test of disproportion was the amount of moulding of the fœtal head, but this could only be ascertained after labour was completed. Before labour the sole known factor was the disproportion; it was only during labour that factors previously unknown came into play, such as the moulding and degree of flexion of the fœtal head and the character of the second stage. A floating head even in a primigravida in the later weeks of pregnancy did not of itself indicate disproportion, although it called for investigation. Dr. Barris thought that induction for disproportion had stood the test of time. It was easy to carry out, the labour was usually uncomplicated, it had a remarkably low maternal mortality, it avoided the risk of a difficult labour or Cæsarean section, and the fœtal mortality was not unduly high in suitable cases. Its use, however, should be limited to cases of moderate or slight disproportion after the thirty-sixth week, in which the vertex was presenting. Having regard to our social conditions it remained the best method for such cases.

Dr. BETHEL SOLOMONS (Dublin) read a joint paper with Dr. WENTWORTH TAYLOR (Dublin) on the Diagnosis of Disproportion, Antenatal and Intranatal, with a View to Treatment. It dealt with the material over a period of two years at the Rotunda Hospital, and 204 cases were considered. Among the questions discussed were: Does difficult labour depend on small external measurements? Is the outlet measurement of value? Should the Skutsch pelvimeter be used, and will X ray pelvimetry replace this method? A modification of the external Müller procedure was suggested and illustrated. The Kerr-Müller procedure must be carried out as a routine, and treatment would largely depend on the result of this examination, successful results being only obtainable after experience. In trial labour the details of making a rectal examination were important. The fact that a woman had been delivered of one or two infants normally did not exclude possible difficulty in subsequent confinements. Disproportion might be caused by factors other than the relation of the head to the pelvis; incoördinate uterine action was a typical example. Examples of this abnormality were given and the question was discussed. At the conclusion of the paper a summary of the varieties of contracted pelvis encountered in the investigation was given.

A paper by Prof. R. W. JOHNSTONE (Edinburgh) was devoted to Induction of Premature Labour in Disproportion. He did not agree with those who said that the fœtal head did not grow appreciably in the last four weeks of pregnancy, and pointed out that ossification of the bones of the vault of the skull went on rapidly during this period, the head becoming progressively less malleable. During the five years 1923–27 premature labour was induced on account of pelvic contraction in the Royal Maternity Hospital, Edinburgh, in 104 cases; a follow-up of these showed a combined fœtal and neonatal mortality of 6·7 per cent. Out of 72 babies traced a year after delivery 94·4 per cent. were alive, which compared favourably with the 90·5 per cent. who might be expected to be alive at the end of the first year according to the figures of the Registrar-General for Scotland. The speaker also quoted favourable figures for the second and third years of life. His figures did not bear out the statement that the earlier the induction the greater the fœtal mortality. In conclusion, he compared Cæsarean section at term with premature induction of labour, pointing out that with induction there was no maternal mortality and no uterine scar; the puerperal period was normal, and the fertility of the women, in his opinion, was better than after Cæsarean sections. He thought that induction was suitable for those cases of disproportion where there was just an element of doubt whether a full-sized child would pass through the pelvis (especially in a primipara), for the information so gained would be of great value in subsequent labours. Secondly, it seemed to be indicated for a woman who, in a previous labour, had been delivered naturally of a stillborn child of average or over average size, or in whom a test labour on a previous occasion had failed and necessitated a high forceps operation. Cases of slight contraction of the outlet also came within this category of suitability.

Discussion.

Prof. Osborn Polak (New York) said that in America they had to deal chiefly with generally contracted and high assimilation pelves; rachitic, simple, flat and scoliotic pelves were, he said, relatively rare. Induction of premature labour had received a good trial in America and was being abandoned. He thought that in cases of disproportion one thorough examination of the patient should be made under anæsthesia. He advised the use of oxygen in order to avoid asphyxia neonatorum for those patients that had been given morphia. After 25 years' experience of the upper incision and 11 years of the lower segment one for Cæsarean section, he had come to the conclusion that the latter was superior. In suspect cases he allowed the placenta to be extruded by the vagina in order to avoid contaminating the peritoneum.

Mr. Eardley Holland (London) said that it required much experience to know when to interfere in a trial labour, and therefore it was dangerous to adopt this as a general method. Nevertheless in safe hands trial labour was superior to induction. He thought that most of the antenatal work in England was mere eyewash, and laid stress on the necessity for those who would actually be responsible for the deliveries to supervise the antenatal period.

Prof. Ludwig Adler (Vienna) said that most of the confinements in his country were conducted in hospitals or nursing homes, but the methods were similar to those described by Kerr and Polak. He used pituitrin combined with thymus gland extract in order to induce labour.

Dame Louise McIlroy (London) thought that the age of the patient was more important than contraction of the pelvis and referred to work done in order to determine the amount of "give" in the pelvic ligaments. She did not think that radiographic examination helped much in cases of disproportion.

Prof. James Hendry (Glasgow) found that the fœtal heart-rate was valuable in estimating the degree of pressure on the fœtal head. He reviewed 25 cases of major pelvic contractions that had been under his care. He did not agree that a trial labour was justifiable in a multipara who had had vigorous interference in a previous labour, for he had seen cases where the uterus had not stood the strain.—Dr. J. S. Fairbairn (London) believed in premature induction of labour even in a primipara. He thought it preferable to err rather on the side of prematurity.—Dr. T. G. Stevens (London) also deprecated the general adoption of trial labour for disproportion. He advocated premature induction. He thought that the general maternal mortality from Cæsarean sections was probably in the neighbourhood of 10 per cent. as many cases were never reported. He did not think that the placental site was infected before the placenta was extruded, but that the infection subsequently ascended from the vagina. He therefore did not see why the placenta should not be brought out through the abdominal incision. The high forceps operation should never be done; forceps should only be applied when the head could be seen on separation of the labia.

Dr. W. R. MacKenzie (Belfast) did not agree with those who said that X rays were of no use in measuring the pelvis.—Dr. F. H. Lacey (Manchester) referred to a paper he had read in 1918 on 75 cases of induction at the thirty-seventh and thirty-eighth weeks of pregnancy with no maternal mortality and morbidity, and 95 per cent. of the children surviving.—Dr. A. L. Mudaliar said that cases of immature pelvis were not uncommon in India, where many primipara were only 13 to 16 years of age. He did not induce in these cases except just before term; he thought the pelvis stretched considerably. The speaker described his technique for symphysiotomy, which he had carried out successfully in 34 cases during the last 15 years.—Prof. Miles Phillips (Sheffield) hoped that induction would be generally approved by the Congress, and referred to sluggish uterus as an indication for Cæsarean section during a trial labour.—Mr. R. H. Paramore (Rugby) said that pubiotomy was the only resort when the child was alive and the patient had been in labour some considerable time with a good deal of interference.

Many of the speakers emphasised the fact that antenatal clinics should only be conducted by skilled obstetricians who would supervise the deliveries.

The Chairman for the afternoon session, Dr. Haig Ferguson, referred to three points that had arisen from the papers and discussion: (1) Antenatal care was not the be all and end all, and those conducting the antenatal supervision should follow up the cases and be responsible for the conduct of labour. (2) Forceps should be applied only when the head was low down. (3) Nature induced prematurely in nearly all primigravidæ, for the head sank down in the latter weeks of pregnancy. By giving quinine and castor oil with a small dose of pituitrin the head would pass down into the pelvis and stay there.

FIFTH INTERNATIONAL CONGRESS OF MILITARY MEDICINE AND PHARMACY.

(LONDON, MAY 6TH–11TH.)

The International Congress of Military Medicine and Pharmacy, which meets in London for the first time, is being attended by some 750 delegates representing 40 nations.

INAUGURAL MEETING.

The inaugural meeting was opened on Monday afternoon by Sir Laming Worthington-Evans, Secretary of State for War. Before this meeting the Permanent Committee of the Congress held their session and the delegates paid a visit to Westminster Abbey where General Lanne, representing France, and General Rouppert, representing Poland, headed a procession to the tomb of the Unknown Warrior, upon which they laid wreaths bearing the colours of all the countries represented. The opening ceremony in the Great Hall of the British Medical Association House was brilliant with the uniforms of many foreign armies, in contrast with which the Service dress of our army officers appeared dull, although display of naval uniforms did not lack distinction.

Among those present at the opening ceremony were Lieutenant-General Sir Matthew Fell, Director-General Army Medical Services, President of the Congress, Surgeon Vice-Admiral A. Gaskell, Medical Director-General of the Navy, Air Vice-Marshal

D. Munro, Director of R.A.F. Medical Services, Sir Ewen Maclean, President of the British Medical Association, Sir Lisle Webb, Director-General of Medical Services Ministry of Pensions, Surgeon-General H. S. Cummings, Surgeon-General of U.S. Public Health Service, Commander W. Seaman Bainbridge of the U.S. Naval Reserve, Surgeon-General S. Rouppert (Poland), Major-General Riva (Italy), General Lanne (France), Sir Humphry Rolleston, Sir John Rose Bradford, General Sir A. Blenkinsop, and Sir Wilmot Herringham.

Sir Laming Worthington-Evans said that to a Minister of War it was an inspiring thought that in the field of medicine, at any rate, the nations of the world had reached that unity of aim and endeavour that was still sought from afar in the realm of international politics. What was the secret of this success? Was it not that the medical services were all ranged on the same side against the common enemies of mankind, disease and pain?

Sir Matthew Fell also welcomed the delegates in a graceful speech.

Response was made by Médecin-Général Inspecteur Lanne, Director of the Military Medical School at Lyons, who (speaking in French) said that in attending this Congress he and his colleagues were pooling their knowledge of the medical services of the armies of all the countries represented and were thus rendering a great service to humanity. Surgeon-General Rouppert also responded.

On Monday afternoon the delegates were received in the Throne Room of St. James's Palace, being presented by the Secretary for War.

In the evening a dinner was given, at the Hotel Cecil, to the principal official delegates by His Majesty's Government. Sir Laming Worthington-Evans was in the chair, and among the guests were General Lanne (France), Mr. W. C. Bridgeman (First Lord of the Admiralty), General P. Demolder (Belgium), Field-Marshal Sir George Milne, Major-General Umberto Riva (Italy), Vice-Admiral Sir Michael Hodges, General Sir Walter Braithwaite, Major-General F. J. Bauer, Major-General Lord Moynihan, Lieutenant-General Sir Matthew Fell, General Sniker (Lettonia), Air Vice-Marshal David Munro, Sir Herbert Creedy, Surgeon-General H. S. Cumming (United States), Sir Oswyn Murray, General Stanislaw Rouppert (Poland), Surgeon Vice-Admiral Gaskell, Major-General Saccane, General Stefan Hubicki (Poland), Sir John Rose Bradford, F.R.S., Sir Ewen Maclean, Major J. C. Diehl, Major-General Sir George Makins, Surgeon Rear-Admiral J. F. Hall, Sir James Berry, Surgeon-Commander W. S. Bainbridge (United States), and Lieutenant-Colonel Basha. Sir Laming Worthington-Evans, in proposing the health of the guests, said that it was difficult for a layman to keep pace with the advances in medical science. Experience in the war had shown that the risk of death from disease on the Western Front was much less than the risk of death from enemy action, whereas in all former wars the balance of risk was the reverse. General Demolder and General Rouppert responded to the toast.

A SCIENTIFIC SESSION.

On Tuesday morning the chair was taken by Surgeon Vice-Admiral A. GASKELL, and later by Air Vice-Marshal D. MUNRO. A paper on the

Evacuation of Sick and Wounded by Sea

was read by Surgeon-Commander A. V. ELDER. He said that two points were essential: the maximum speed compatible with efficiency, and the maximum comfort and safety. *The administrative and clinical* aspects of the problem were distinct but equally important. No fixed routine could be laid down for water transport, which was subject to local and weather conditions. For general purposes the best hoisting apparatus was a wooden cot tray—a lidless box suspended by wire slings and hooked on to a single-fall winch wire from a derrick in the receiving ship. This took up too much room when ships' boats were used, and then a bridle with wooden *spreader* was useful. Military stretchers were best dealt with by Lieut.-Colonel Faulkner's canvas sling. Surgeon-Commander Elder recommended the use of a standard stretcher for all services. By this means patient and cot would travel together from the "front" to the base hospital ward, each link in the transport chain having its complement of clean empty cots or stretchers to exchange for loaded ones. The ideal method of transfer was by gangway, which was no more serious than removal from ward to ward; it saved time and did not alarm the patient. Hospital ships should be provided with entry ports on both sides of each deck and rubber-tyred two-wheeled stretcher bogies should be supplied to all ships. Clinically it was important to remember to alleviate pain, heat, cold, thirst, and hunger, and the sedative effects of tobacco must be remembered, although it was contra-indicated for gas cases. Pain might be due to tight dressings. Morphia could not be administered by unqualified persons, but more lives had been lost from shock than from morphia, and anodyne tablets should be present in every medical valise. Every unit ought to have ample supplies of lime-juice and water, hot coffee and cocoa in thermos flasks, and blankets and tarpaulins. Purely surgical cases generally had healthy appetites and their dietary scale should be generous. If the Geneva Convention were to have any value or meaning, it was most important to adhere strictly to the regulations governing the Red Cross.

Group Captain H. V. WELLS dealt with

Evacuation by Aeroplane.

This, he said, had been much used overseas and was the normal method in Iraq. Some aeroplanes could carry several cases and a medical orderly, others took one case each and were useful for small landing grounds. *Aircraft for ambulance carriage* must be constructed on the hoop system and avoid cross-bracing wires, but in emergency a special stretcher could be carried on the upper surface of the fuselage of other types of machine. Air evacuation was the *quickest and easiest means*, serious cases could be treated early, wounded could be removed from a besieged force, and hospitals could be centralised, thus economising equipment and staff. The limitations of the method were weather conditions and the necessity of providing landing grounds near the hospitals. A standard stretcher suitable for all services was desirable, but a light metal stretcher had many advantages for air work. In combined operations the responsibility for evacuation should be clearly understood in advance and the line of demarcation of the naval, military, and air responsibility must be defined on the spot. All ambulance aircraft should be under the control of those responsible for the removal of casualties and under Red Cross protection. Identification by day was difficult, but special lights made it easier at night.

MM. P. OUDARD and A. SCHICKELE presented a

Report from France on Evacuation by Water and Air.

Evacuation *by inland waterways*, they stated, was little used at present, but might be more extensively employed with the *improvement in mechanical* towing. It was suitable for seriously wounded persons who had received treatment. Operations would come under the general scheme for the use of waterways by armies. In the early stages of evacuation *by sea from an expeditionary force hospital ships* might take the place of medical formations not yet landed or not in working order; for this purpose the ships should be small, swift, and surgically equipped so that the wounded could be treated en route for their base. *Naval warfare afforded little opportunity* for the use of a hospital ship, except for helping a damaged vessel which had taken refuge in calm waters.

In distant colonial expeditions the hospital ship was needed for medical rather than surgical cases. The hospital ship must be very seaworthy, strongly built, stable, silent, with a minimum of vibration, and an average size of 8000 tons and speed of 15 knots. Three types were necessary—surgical, medical, and combined. Wards should have from 25 to 100 beds with a minimum of 6 cubic metres of air per person, and beds should be isolated and movable. Isolation wards and padded cabins should be provided and all gangways kept clear. The surgical service should be on deck and general services, salvage, signals, and safety devices should be ample. An amphibious seaplane was useful to have on board. The tanker was a particularly convenient construction for a hospital ship. The senior medical officer must be in charge, the captain being responsible only for navigation and crew, and the medical personnel must be accustomed to seafaring. There must be a complete and close connexion between medical services on sea and land, and there ought to be a military as well as a naval medical base at each port. The two bases coöperated, the former selecting the patients to be embarked and having authority up to the quay. Evacuation of wounded by sea raised several problems of international law which would justify a revision of The Hague Convention of 1907.

The *ambulance aeroplane* must henceforth be considered a routine method of evacuation. It gave swift and comfortable transport, especially suitable for serious cases. Its fitting must chiefly be concerned with giving the best facilities for embarking and disembarking and for comfort and safety during transport of stretcher cases. The small carrier was sufficient for urgent cases in peace time or for colonial use and to take wounded from the front to landing grounds in war, but the medium carrier would prove most useful for military operations in general, transporting patients from the landing grounds to the hospitals. The helicopter should give new facilities in the front area, but it did not seem possible for the aeroplane to get beyond the army corps area. The value of the *ambulance seaplane* in naval warfare was very problematical; it would never be as seaworthy as a boat. It would have to be a large amphibious type with twin engines and careened hull. The ambulance aeroplane raised several points of international law which called for solution. In mountain warfare a *rope way* facilitated evacuation; it consisted of one or more cables, fixed at each end and supported between by pylons, with special trucks for stretchers. Safety depended only on the soundness of the cables; an emergency brake system should be devised to avoid the danger of a traction cable breaking.

Colonel A. Vaudremer briefly discussed the papers.

Visit to Aldershot.

On Tuesday afternoon a visit was paid to the Army Establishments at Aldershot, where one-half of the 500 visitors inspected the R.A.M.C. headquarters and the remainder the Institute of Hygiene. At the Institute bakery a demonstration was given of the production of bread on strictly hygienic lines. A staff of 20 can here turn out, with the aid of modern machinery and draw-plate ovens, 48,990 lb. of bread in ten hours. In the slaughter-house of the butchery a squad of six butchers can kill and dress 20 bullocks and 120 sheep in eight hours. In the meat shop a class of ten men, picked from all arms, was being trained to joint and cut up quarters of sheep. The whole of the quarters in which cooking is done have been newly built, and the soldier at Aldershot is well served, both as regards quality and quantity. He has meat twice a day, and his menu is diversified in accordance with the teaching of modern dietetics. Evidence of abstemiousness was seen in the canteen which provides beer but no spirits; the present-day soldier seems to prefer coffee and tea, supplied in the excellent restaurant. Ample facilities for bathing are to be found in the bath-houses, tub and shower baths, which are provided with hot and cold water. Tubs are still preferred to showers by the rank and file. Every kind of field-kitchen was on view. Demonstrations on disinfestation touched on modes for killing flies and purifying water, with addresses (in French) by the officers in charge. The final visit was to the Chief Command. Refreshments were provided on the sports ground, where a magnificent display was given of physical drill and gymnastics. The foreign guests appeared delighted with the afternoon's fare. The day was fine, the scenery was engaging, the roads were good, and the char-a-bancs travelled fast and smoothly.

Receptions at the Royal Colleges.

Sir John Rose Bradford and Lady Bradford received a large gathering at an evening reception held at the Royal College of Physicians of London on Tuesday evening, when a large number of members of the International Congress of Military Medicine and Pharmacy and British guests were given an opportunity of seeing the splendid portraits hanging on the College walls, and of inspecting an interesting collection of books illustrative of naval and military medicine. The librarian of the College, Dr. Arnold Chaplin, discoursed with pleasant learning on the various exhibits. A programme of music was provided by musicians from the band of the Welsh Guards, and the discussion of a generous stand-up supper filled the intervals of the evening. The musical programme was distinctly light and gay, and the party did not break up till a late hour.

Lord and Lady Moynihan received the guests at a brilliant gathering at the Royal College of Surgeons of England on Tuesday evening, when Sir Arthur Keith gave an admirable demonstration with the epidiascope of museum specimens illustrating design in nature. Afterwards the very numerous guests, of whom a large proportion were French and Belgian, distributed themselves over the exhibits set out for their delectation in the spacious galleries. In the War Museum was an army medical collection with apt examples of reconstructive surgery. The conservator's office contained selected specimens from the museum on which learned members of the Council were present to assist interpretation. The Council room contained Hunterian relics, and there were, of course, the portraits by Reynolds, Lawrence, Romney, and Hogarth to satisfy the artistic sense. Refreshments were served in the library, and an admirable programme of music was rendered in the inner hall by the Royal Artillery Band.

PARIS.

(From our own Correspondent.)

Malariotherapy in France.

The treatment of general paralysis by malaria has been widely practised in France since 1923, when it was introduced into this country by Dr. Auguste Marie. Dr. Henri Claude, who is professor for mental diseases in the Faculty of Paris, has had the method tried on a large scale at the St. Anne Asylum and, like many other French authorities, has come to the conclusion that it is the only form of treatment that can claim anything resembling cures of general paralysis—that is to say, remissions of such length that they may be looked on as due to the remedy rather than to natural causes.

In view of these favourable results Prof. Claude, in a paper read before the Academy of Medicine, urges the necessity of creating special centres for malariotherapy. The method is not one to be applied by any one anywhere and in any way. Without precautions it is certain that accidents will happen and that the treatment will be discredited. Among the reasons for setting up special centres is the necessity of having a suitable source of malarial organisms so as to get attacks mild enough to be harmless to the patient, yet of sufficient virulence to give him the necessary febrile reactions. A well-trained biologist seems to be required at these centres, as well as a competent resident physician who can follow the evolution of the induced malaria.

Another advantage of special centres is the gathering together of many patients in a place where there are special services and opportunities for the thorough study of the disease and its treatment. Of course patients could be sent back to their usual medical advisers if social conditions permitted. Prof. Claude believes that the centres should not be in closed asylums but in open-door institutions; for in this way, he thinks, people will come earlier for treatment and thus have more chance of recovery.

Small-pox in Paris.

There is a large public demand for vaccination both at hospitals and in private practice, this demand following naturally from the attitude of French people towards what they regard as a frightful disease, as I said in my recent letter. Three cases of small-pox have been registered in Paris during the past fortnight. One of the patients was an English lady recently arrived from London, who died some days ago; of the two others I have no special news.

Syphilis by Blood Transfusion.

Cases have several times been reported in which syphilis has been given to a patient by blood transfusion; but hitherto it seems that the Wassermann of the donor has always been frankly positive. A case reported by Dr. Dufour, a leading member of the Paris hospitals' staff, to the Société Médicale des Hôpitaux, puts a new aspect on the situation so far as France is concerned, for the donor had a negative reaction. The recipient of his blood nevertheless developed roseola with a positive W.R. six weeks after the transfusion, so the question now arises whether blood can be contagious though its reaction is negative. If this proves to be so, it will not simplify the preliminaries of transfusion.

Speaking about this case Dr. Tzanck reported one of his own which seems to be the first of its kind. A woman who had had several miscarriages previously was exsanguinated by the last of them and treatment by transfusion was adopted. The blood donor was the husband, who had been responsible for procreating the aborted fœtuses, which seemed, on clinical inquiry, to have been really syphilitic ones. Forty days later the wife had a rash with a positive blood reaction, which leads us to admit anew the possibility that a woman can conceive a syphilitic fœtus by a syphilitic man without herself contracting the disease —a view which has been considered very doubtful for many years.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT).

Medical Ethics and the Lay Press.

AT the present moment the Chicago Medical Society finds itself at odds with the local newspapers and in particular with the *Chicago Tribune*, a somewhat influential journal that has not been unfriendly to the medical profession in the past. The immediate occasion of this quarrel is the dropping of a physician from the Chicago Medical Society because of his connexion with the Public Health Institute of that city. The real dispute lies deeper and involves difficult though important issues.

The Public Health Institute was founded some years ago through the interest of public-spirited and influential citizens who were concerned about the city's venereal disease problem. This institution was not to bring any profit to its founders, and presumably has not done so. The physicians working for it have not been recognised by the Medical Society because of the advertising campaign which the Institute has conducted. This advertising, on the one hand, has undoubtedly contributed largely to the success of the institution, and it may perhaps be inferred has therefor been of benefit to the public health in Chicago. It may also be supposed that the advertising has reacted unfavourably upon the private practices of venereologists in the city and that it has bought some goodwill from the owners of Chicago newspapers. It is this latter aspect of the problem that is insisted upon by the American Medical Association which warmly supports the local society. However, the newspapers insist that another problem is involved—namely, the cost of medical care. It is claimed that by using large scale and efficient methods adequate treatment can be given at moderate cost. To do this was certainly one of the objects of the institute, and it appears to have been achieved. It is, of course, not possible to determine without a full investigation to what extent thoroughness of treatment may have been sacrificed to economy of operation. If, however, price-cutting is added to the unfair advantage of advertising it is clear that such a state of things makes private practice in the same field a risky adventure. Moreover it is obvious that if the Public Health Institute were being conducted by the City Health Department instead of by a philanthropic body the effect on private practice would be no less injurious.

This reflection cannot help but arise in connexion with the resignation from the Medical Society, in protest against its action, of Dr. Bundesen, who, until recently replaced by Mayor Thompson, was the City Commissioner of Health and who is also a past-President of the American Public Health Association. However, it must be said that Dr. Bundesen was a personal friend and political associate of the doctor who has been dismissed, and that these facts may have influenced his decision.

Munificent Gift for Child Welfare.

Senator James Couzens announces a gift of $10,000,000 as a trust fund, to be known as the Children's Fund of Michigan. In spite of its name the fund is not to be limited to work in Michigan alone, the powers vested in the trustees enabling them to take research work into any part of the world. Dr. Hugo Freund, who besides being a trustee is also the Senator's personal physician, is reported to have said: "It is too early to state all the lines of activity contemplated. Mental hygiene and child guidance clinics will be encouraged; vocational and educational problems will receive attention; plans for properly supervised group recreation will be assisted; dietetic, hygienic, nutritional, and other subjects bearing upon the health of children will be investigated whenever and wherever the indication for their study arises." The fund, including principal and interest, is to be disbursed in its entirety in the next 20 years. The total amount that will thus be available is estimated at $17,500,000. It is reported that a New York millionaire is also anxious to dispose of $10,000,000, but is unable to find a method that will help people in need, since every method that he has yet heard of is against natural law and in the end hinders more than it helps. In his perplexity he seems to have offered a reward of $1000 to the person who solves his difficulty.

Farm Centres for Addicts.

The last congress has authorised the establishment of two federal farms for the supervision and treatment of narcotic addicts. Only prisoners committed by federal courts will be eligible to the farms, one being for men and the other for women. Besides custody of the prisoners and treatment of their drug habit the farms will serve as centres of research under the direction of prominent specialists. The separation of addicts from other criminals is a change that reformers have for some years been anxious to bring about.

INSTRUCTION IN SMALL-POX.

To the Editor of THE LANCET.

SIR,—The Metropolitan Asylums Board is to be heartily congratulated in having arranged a special course of instruction in the diagnosis and treatment of small-pox. The treatment of small-pox, of course, is a minor matter for most practitioners of medicine, but there is probably no disease in the whole range of medicine where diagnosis is a more vital matter so far at least as the safety of the community is concerned. It is well known amongst all who have had to deal with the control of small-pox how large a part is played in the spread of the disease by errors in diagnosis, and this deficiency is largely accounted for by the fact that so many practitioners have had little, if any, practical instruction in the subject.

Such a course as has now been arranged by the Board, as announced in your issue last week, will be of a great value to those who attend it, but the pity is that attendance on such a course is not made compulsory on all medical students before qualifying. It is a curious anomaly, a survival, no doubt, of a bygone age, that whilst every student must take out a special course of instruction in vaccination, which now plays only a comparatively subsidiary part in the effective control of small-pox, the subject of the diagnosis of small-pox, which is the keystone of modern methods of control, is largely left to look after itself. I am, Sir, yours faithfully,

C. KILLICK MILLARD,
Medical Officer of Health.

Health Office, Grey Friars, Leicester, May 6th, 1929.

*** The Deputy Clerk to the Metropolitan Asylums Board informs us that the holding by the Board of courses of instruction in small-pox is not a new departure. The lack of sufficient clinical material has, however, rendered it impracticable to organise courses for some considerable time past, though it has been possible, from time to time, for parties of medical students attending fever courses at the Board's hospitals, to attend single demonstrations at the small-pox hospitals.—ED. L.

FLOGGING IN SOUTHERN RHODESIA.

To the Editor of THE LANCET.

SIR,—Under the existing Government of Southern Rhodesia, adult natives may, by law, be flogged. The law, in authorising flogging, shelters itself behind medicine, and medicine sanctions the practice. Government medical officers in Southern Rhodesia are controlled by a Medical Director, and all of them come under his decrees. He sanctions flogging. At the gaols there is a book which has to be signed by the Government Medical Officer certifying that the prisoner is physically fit to undergo punishment, the certificate being manifestly designed to protect the flogger as well as the flogged. The term "boys" is, of course, misleading—it means adults from 17 to 70 years of age. A punishment may be described as "cuts with the cane" and this, to the ordinary Englishman with scholastic experience, sounds innocent enough. It is not so. The prisoner is stripped naked and is then fastened with straps to the triangle which stands in the prison yard. The "cuts" are administered with a long, stout cane upon the bare buttocks. The cane wielded with two arms by a muscular person can, and does, inflict cruel punishment. Not only must the Government Medical Officer certify to the fitness of the prisoner, he must also be present at, and witness to, the flogging. This is a degrading and revolting duty for one medical officer to impose upon a colleague, and not calculated to exalt the professional status of the practitioner of medicine.—I am, Sir, yours faithfully,

R. F. RAND, M.D.

Hartley, Southern Rhodesia, April 8th, 1929.

THE MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—The annual meeting of Fellows and Members will soon take place. The same resolutions will be passed, the same answers given in different form; all of which concerns management, a trifling claim, and a trifling refusal.

This letter is to plead that the College, Fellows and Members should put on a higher plane the demands and refusals. The Council should cease to act as if they were only an examining body to grant surgical diplomas, and cease to resist all claims to professional distinction by their Members; the gift of two Fellowships each year is no stimulus to special work. Members should claim recognition of skill in their profession, and not only of ability to assist in the internal economy of the College.

No examination ever created a genius (I heard the late Prof. Huxley speak on this subject). The College can easily encourage good work, and make it possible for a Member to become a Fellow other than by the method of examination, which comes easy to a class of brain that is not the most useful in the world. A Fellow has knowledge, but he is not always a surgeon, a Member may not have such technical learning, and he may have failed to absorb text-book information, yet many Members are first-class surgeons and diagnosticians. It is here that the College takes up the position "you cannot enter the honours list of our profession unless you go to school again and cram"—a procedure that is often impossible, and waste of time. The body of Fellows should not be a scientific "pocket borough," with a high commercial value attached to their honours examinations.

I am, Sir, yours faithfully,

W. B. COSENS, M.R.C.S.

Oakley-street, Chelsea, S.W., May 1st, 1929.

BLOOD STANDARDS.

To the Editor of THE LANCET.

SIR,—Dr. Goodhart's vigorous defence of the Haldane instrument and of the makers thereof is based on a misconception of my remarks, for which I fear the brevity of my phraseology is somewhat responsible. I did not mean to imply that there was necessarily an error in the standardisation of different specimens of Haldane's apparatus, but that there was a variation in the hæmoglobin value as estimated by different methods and observers. I hasten to assure Dr. Goodhart that when specimens from the same patient are estimated by such an experienced observer as himself, it would not be possible to question the accuracy of his comparative tests on the same apparatus. This, however, is not always what happens. Observers who do not do much blood work are, in my view, hampered by the *tint* of methods where the colour is red. This always contains proportions of blue and yellow. By taking a monochromatic reading through green glass this error is reduced to a considerable extent.

In regard to Haldane's colour-scale I have found the personal error of different observers to vary within rather wide limits. By using Tallquist's scale in the manner I suggested errors in dilution of the blood are also avoided. For these reasons I consider it preferable to Haldane's or other dilution methods for use in general practice or in cases where the blood of the patient cannot always be estimated by the same observer.

I am, Sir, yours faithfully,

A. KNYVETT GORDON.

Bedford-square, W.C., May 3rd, 1929.

Obituary.

HERBERT JONES, L.R.C.S. IREL., D.P.H.

Dr. Herbert Jones, who died on May 1st at the age of 71 years, had spent a life of rare usefulness as medical officer of health for rural Herefordshire, resigning in 1926 when his health failed. His death occurred at Welwyn Heath, Herts, where he was living in retirement.

Herbert Jones was born at Hanley, Staffs, in 1857, was educated privately, and studied medicine at the Middlesex Hospital, from which he qualified L.S.A. in 1886. After a period of residence in America he returned to this country and began to practise at Shipley, Yorks. About this time he took his triple Dublin qualification and the Cambridge Diploma in Public Health, leading up to his first appointment as whole-time medical officer for the borough of Crewe in 1891. From there he went on to the Rhondda Urban District and finally to the Combined Rural Districts of Herefordshire, which included Leominster, Ledbury, Bromyard, Weobley, and Dore. Later on he was appointed to the newly created county medical officership but he soon reverted, at his own wish, to his former charge. His sure grasp of public health problems, combined with a collossal industry, made him master, as few have been, of the intricacies of public health administration in a rural area. On occasion he would be his own ambulance-driver or serve in any capacity where need lay. Part of his time he was medical superintendent of the rural isolation hospital, and his faithful committee work brought him on to the Council of the Society of Medical Officers of Health, of which at length he became President in 1914. This year saw him seconded for war service, and he rose to be Lieut.-Colonel in the R.A.M.C. (T.), and as such commanded the 2nd line Field Ambulance of the Welsh Brigade, and was responsible for recruiting and training a third unit. He then commanded the 326th Field Ambulance on the East Coast and in Ireland until the end of the war. Writing came easily to him, his first publication of note being a Guide to Examination in Sanitary Science; a text-book of School Hygiene ran into several editions. He edited the *Sanitary News* for some years and was for a while acting editor of *Public Health*. Locally there were few medical institutions which were not revivified by his touch. He was largely responsible for resuscitating the Herefordshire Medical Society, of which he was secretary for many years; he was hon. secretary of the Hereford Division of the British Medical Association and its chairman in 1913, and the popular Speaker of a City Parliament which gave his townsmen the opportunity of practising the difficult art of effective public speaking. For a while, too, he was a member of the National Insurance Advisory Committee, a post which he surrendered in deference to local medical feeling. The public health service will not forget his untiring exertions in the pursuit of security of tenure and adequate superannuation for all grades, partially satisfied in the Sanitary Officers Order of 1922.

A colleague, who enjoyed the intimate friendship of Dr. Herbert Jones during the last ten years of his life, writes of him: "He had inherited from a long line of Quaker ancestors a certain reserve which casual acquaintances failed to penetrate. Within the barrier he was one of the most lovable of men, generous-hearted and broad-minded. A keen power of critical observation, combined with an ease of expression and a wide and varied experience of men and affairs, made his conversation at once entertaining and instructive. There was no end to his interests and activities; he was never happier than when championing a feeble cause, or helping a lame dog over a stile. He was one of the busiest and most energetic men in public affairs, but in spite of his multitudinous duties he would undertake a little office for a friend with as much thoroughness and attention to detail as he would expend on the most important professional urgency. His bearing was dignified, his manner to strangers mild and unassuming; to his inferiors he was courteous at all times and in every circumstance. He was completely free from petty jealousy, and never bore a grudge. Although the last few years of his life were passed in suffering and seclusion he endured to the end with a quiet fortitude and patient resignation."

Dr. Jones was a keen Freemason and held the office of Master of the Vaga Lodge, Hereford, of which he was also a Founder. He was a Founder of the Dean Leigh Masters Lodge in the same Province, as well as Senior Warden of the Hereford Provincial Grand Lodge in 1925. His wife, who survives him, was a daughter of Mark Spencer, of Coventry.

HENRY RUTHERFURD, M.B., F.R.F.P.S. GLASG.

We have already recorded the death of Mr. Henry Rutherfurd which occurred at Glasgow on April 14th at the age of 68. The accounts of him which follow bear witness to qualities, both professional and personal, of a kind that can ill be spared.

"Henry Rutherfurd," writes a colleague, "was the son of a Glasgow linen merchant and was educated at the old High School, and in the University of Glasgow, where he graduated M.A. in 1881, and M.B., C.M. with distinction in 1884. He filled house appointments in the Western Infirmary with the late Sir William Gairdner and the late Sir Hector Cameron, and it is probable that the influence of the latter played a large part in moulding his future surgical career. He maintained his great and intimate friendship with Sir Hector Cameron to the end of his chief's life. He visited the continental schools of Jena and Vienna, and returned to Glasgow to join the staff of the late Prof. Coats as demonstrator in pathology. After filling various junior surgical posts he became extra surgeon to the Royal Hospital for Sick Children, and in 1906 was appointed surgeon to the Royal Infirmary of Glasgow, holding that position till 1921, when he became consulting surgeon to the Royal Infirmary, shortly afterwards joining the board of managers as one of the three members of the board appointed by the Royal Faculty of Physicians and Surgeons. He was also surgeon to the Royal Cancer Hospital, Glasgow, where he early recognised the potentialities of radium as a curative agent, and encouraged the younger members of the staff to carry out original research. He was appointed Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow in 1890, and filled various offices, including those of councillor, examiner, and representative on the Conjoint Board.

"He was extremely happy in his work in the Royal Infirmary, devoting far more time than was commonly allotted to such public work. He had an extraordinarily accurate and full knowledge of the science of surgery, and was renowned for his extreme interest in surgical pathology. His contributions to surgical literature were, however, comparatively few. In his earlier surgical career, in 1898, he was one of the editors of three volumes of Glasgow Hospital Reports, to which he contributed two excellent monographs on the Management of Rupture of the Urethra, and Tumour in the Sacro-Coccygeal Region. Other papers were Nephrectomy for Transverse Rupture, Downward Dislocation of the Patella, and Irreducible Intussusception in the Infant.

"Rutherfurd was a man of interesting personality. He was not gifted with fluent speech; indeed, his speech was well known for its staccato jerky style. But it was remarked that when he did speak, as, for example, in meetings of the Royal Faculty, every word could have been taken down *verbatim* and not a single phrase or word would have required correction. He was a man of keen wit, with a kindly but not cynical eye on his fellow men. It was characteristic of his sense of duty and of his sporting quality that he volunteered for foreign service during the war at the age of 56, being attached to a hospital in Salonika with Serbian soldiers as patients. He was a gentleman of the highest sense of honour with no thought of personal advancement behind any of his actions. He had, essentially, a gift for friendship, and there are many of his time in Glasgow who feel sorely grieved by the loss of Harry Rutherfurd."

Another colleague has sent us the following personal note: "To those of us who were privileged to know and work with Mr. Henry Rutherfurd, his death comes as a personal loss, and there must be many of his former students and house surgeons who will recall their time with him in the Royal Infirmary, Glasgow. A man of wide culture, full of historical and classical knowledge, his conversation during a ward visit might begin with the ancient Persian wars and end on the correct interpretation of a sonnet of Keats. It was perhaps this wide general knowledge that was responsible for the clarity of thought and the almost whimsical outlook on people and things, which were typical of him. Well versed in the surgical literature of the day, he had a humorous eye for the gusty theories which enliven or entwine the surgical wayfarer, and his advice was always to trust clinical experience before anything. His ward journals must have been models of what records should be, and his meticulous care in dealing with patients was, at times, the despair of a house surgeon with a golf appointment. Once beneath his reserve one found a simple, kindly gentleman of the old school, with a wide knowledge of men and things, an honesty of thought and directness of speech which expressed itself sometimes forcibly but always fairly, and a very high sense of duty."

PERCY ROBERTS WILDE, M.D. ABERD.

Dr. Percy Wilde, who died at Bath on April 23rd at the age of 72, was the son of Dr. John Wilde, and was educated at the Universities of Aberdeen and Edinburgh. Even before graduating in 1880 he had already won a prize from the Royal College of Surgeons of Edinburgh for an essay on Public Abattoirs, and in the first few years of professional life, when he was assistant to the Professor of Physiology at Aberdeen and ophthalmic assistant at the Royal Infirmary, he was already writing suggestively on a variety of subjects. Rather more than 40 years ago he settled at Bath, devoting much of his time to the study of physical remedies, especially in relation to rheumatism. A colleague writes of him that he was "a man of striking personality, with an original and independent mind. He was largely responsible for the foundation and progress of the Lansdown Hospital, and was thus a pioneer in the establishment of the self-supporting hospital that lives entirely on the fees paid by its patients. He was also the founder and for many years editor of Wright's 'Medical Annual,' and in its earliest days helped to nurse the little book that it was then into the portly volume that has for years been familiar to readers all over the world." Dr. Wilde also wrote a number of books on spa treatment, therapeutics, and rheumatic disorders, on the ætiology and treatment of which he held original views. He leaves a widow, and one son and one daughter by his former wife, who died some years ago. One son was lost in the South African War, another went down in the *Indefatigable* at Jutland, and a third died about a year ago.

ROBERT EDWARD SARE.

MANAGER OF THE LANCET.

THOSE responsible for the production and publication of THE LANCET have sustained a sad blow by the death of the Manager, Robert Edward Sare, after a severe and painful illness of some three months' duration.

Robert Sare was born on July 5th, 1878, at Bradenstoke, Somerset, the son of Mr. Frederick Sare, received his early education at King Edward Grammar School, Bath, and manifested at the close of his school time the desire to follow the medical profession. Eventually, however, he elected to enter the business side of journalism, and was for several years employed by the *Studio* when, by his work in coöperation with the production of some of the well-known pictorial supplements of our contemporary, he greatly contributed to the success of the periodical. In 1904 he became connected with Messrs. Hodder and Stoughton, and three years later was appointed Manager of the Oxford Medical Publications, which was then a joint undertaking of the Oxford University Press and the former firm.

MR. SARE.

In 1920, when the interests of Wakley and Son, Ltd., the then proprietors of THE LANCET, were acquired by Messrs. Hodder and Stoughton, Sare became Manager of THE LANCET, and in that capacity was well known to all supporters of the paper both on the business and on the literary side, while he added greatly to the personal intimacies which he already enjoyed with many members of the medical profession, owing to his connexion with the Oxford Medical Publications. He worked unceasingly in the exacting and sometimes delicate duties which fall upon the shoulders of the business manager of a journal, who has to recognise at every step the claims, sometimes divergent, of the literary and publication departments. Speaking both for the editorial and managerial sides of the paper, those in the office of THE LANCET wish to record the conscientiousness and courtesy which marked his dealings with them, while they feel certain that they are here expressing the sentiments of all the external staff. Similarly, the chairman and directors of the Board of Management of the paper wish to add their public testimony to his enthusiasm, kindness, and loyalty.

Robert Sare was married to Beatrice, daughter of Mr. E. Richens, of Olney, Bucks, by whom he had five children, of whom the eldest son has followed his father's footsteps into the employ of Messrs. Hodder and Stoughton. Apart from his strong domestic interests, Sare was an extremely keen Mason. He had been Worshipful Master of St. Bride's Lodge, was Senior Warden of the Alliance Lodge, and was a great believer in the influence for good that was diffused by Masonic organisation.

After the funeral service at Coulsdon, where he had his home, a cremation service followed at West Norwood.

ST. THOMAS'S BABIES' HOSTEL.—This Dietetic Hospital for Sick Babies and Mothers, at Kennington, S.E., does specialised work in dietetics, for which it is not possible to find accommodation in a general hospital. A large proportion of the cases are referred from the general hospitals and are of a more severe nature than those usually sent from infant welfare centres, and last year's results are stated to have been very satisfactory, 89 sick babies out of 101 having completely recovered. The hostel trains nursery nurses and gives instruction to public health students, and 300 or 400 requests for the small number trained are received every year. The out-patient department is at present an Army hut which it is hoped to displace by a permanent building together with a nurses' home, but at present only £610 is available for the purpose.

Parliamentary Intelligence.

HOUSE OF LORDS.

THURSDAY, MAY 2ND.

THE RECONSTITUTED CREAM BILL.

The Earl of CRANBROOK moved the second reading of the Reconstituted Cream Bill. After a debate in which Lord STRACHIE, Lord BLEDISLOE, and the Marquess of SALISBURY took part, a motion for the rejection of the Bill was negatived, and the Bill was read a second time.

TUESDAY, MAY 7TH.

The House went into Committee on the Reconstituted Cream Bill, the Earl of DONOUGHMORE in the chair.

Lord CLINTON moved an amendment to substitute the word "artificial" before the word cream instead of the word "reconstituted."

The Earl of ONSLOW, speaking for the Ministry of Health, said the Department preferred the word "reconstituted" to the proposed alternative.

After considerable debate, in which general dissatisfaction was expressed with the Bill as drafted,

The Marquess of SALISBURY (Lord Privy Seal) said that the Government would leave the decision to the judgment of the House.

Lord CLINTON'S amendment was carried, and the title of the Bill was accordingly altered to "The Artificial Cream Bill."

The Bill passed through Committee and was reported to the House.

HOUSE OF COMMONS.

WEDNESDAY, MAY 1ST.

MINISTRY OF HEALTH VOTE.

Mr. Chamberlain's Statement.

The House went into Committee on the Civil Service Estimates. Mr. JAMES HOPE, Chairman of Committees, was in the chair.

On a vote of £14,228,664 for the salaries and expenses of the Ministry of Health,

Mr. CHAMBERLAIN (Minister of Health) said that the policy of a reduction in the housing subsidy had been absolutely justified by the results, and had brought about what was most necessary to-day in housing—namely, a reduction in building costs, which would allow houses to be let at lower rents. Referring to the Widows' and Orphans' Pensions section of the work of the Ministry, Mr. Chamberlain said that since the Pensions Act came into force he had made some inquiry to see how far the relief afforded by the new system to old people and to widows was reflected in the reduced number of those who found it necessary to apply to the poor-law authorities. He was pleased to find that no less than 88,560 persons, including dependent children, who were before in receipt of poor-law relief, had been able to free themselves entirely from dependence on the guardians. That was not really the whole measure of the relief that was being made, because they had to add the number of those who would have applied if they had not received the pension. Turning to the other side of health insurance, the feature of last year had been the coming into force of the new Act. The provisions of that Act had proved to be very beneficial. With regard to the administration of the poor-law, he thought that they had now passed the worst period, and during the last year there had been a substantial reduction in the numbers of those who were in receipt of relief on account of unemployment.

Review of Health Services: Treatment of the Insane.

On the last occasion, said Mr. Chamberlain, he did not touch upon the work of the Board of Control, who were responsible for the treatment of insane persons and mental deficients, and he would like to take that opportunity of saying something about it, because it was very important work. It was not work which was very attractive, but it was very valuable in the general interests of the community. As to the magnitude of the problem there were at present about 141,000 insane persons under care in England and Wales, and that number showed a fairly regular increase of about 2000 a year. That might sound at first rather disquieting, but the increase must not be taken necessarily to mean that the number of insane persons in proportion to the population was increasing at that rate. Insanity was a disease which affected adults and not children, and, of course, as the expectation of life continually increased so a larger and larger proportion of the population reached the later ages and became susceptible to this particular form of disease. The recovery figure was less satisfactory. They must distinguish between insanity and mental deficiency. Insanity was a disease from which people might recover; mental deficiency was an arrest of mental development from which there could not possibly be recovery. But it was a little disquieting that the rate of recovery among insane persons seemed always to remain about the same point—namely, about 30 per cent. He thought, however, that they might perhaps assume safely that with the greater knowledge they had to-day medical superintendents were more careful in classifying cases as cases of recovery than they used to be, and that there might be an increase which was not accurately reflected in the figures at their disposal. There was one class of case, however, in which there was a definite improvement in the matter of recovery, and that was the general paralysis of the insane, which was for a long time considered incurable. It was very often fatal. The new treatment of the general paralysis of the insane was to give the patient another disease, and that was malaria. It was a discovery which he believed came from Vienna. It had been found that by introducing malaria a patient suffering from general paralysis of the insane was now in many cases capable of very considerable improvement, and possibly of cure. In going round a mental hospital to-day one might see as part of the equipment a portion of the ward shut off and surrounded by mosquito curtains, with perhaps one or two beds in it. The patient was brought into this place, the infected mosquito was brought down from London, introduced into the mosquito curtains, and after that the matter worked itself out in its own way. He wished they could make further progress in the matter of research. At present local authorities had no power to devote money to research.

Mental Deficiency.

This matter might well arise out of the Report of the Royal Commission which he hoped would form part of the work of another Parliament. As regarded mental deficiency, some misunderstanding seemed to have arisen as to the attitude of the Ministry of Health towards what was known as the Wood Report. That Report was a report of a committee which inquired into various matters connected with mental deficiency. The Committee issued two very long reports. One of them had been published, and he had been frequently asked when he was prepared to publish the part of the Report which dealt with adults. It was a very long and complex Report, and he must have time to consider it. But he had no intention to withhold from local authorities anything which they ought to know which was contained in this Report. Probably the most important part of it to them consisted of the figures of Dr. Lewis's investigation into mental deficiency which had already been published. As to the rest it was having his personal consideration, and he hoped to be able to make a decision before very long.

The serious aspect of the figures was that Dr. Lewis estimated that there were 300,000 mental deficients in this country, which was about double the number estimated by the Royal Commission in 1908. That must give rise to serious anxiety and apprehension among all who cared about the future physical and mental condition of the people of this country. Naturally it had been asked whether it would not be possible to take some steps to prevent the propagation of a class of people who would never take their proper place in society. They were told that in some countries a system of sterilisation was practised, and they were asked why they should not follow that example. Personally he thought that some day there would have to be a proper scientific inquiry into this matter, because undoubtedly up to the present they had not sufficient data to enable them to come to any satisfactory and definite conclusion. But the mental deficients in this country to-day were, broadly speaking, the product of one-tenth of the population—that was to say, that it was only 10 per cent. of the population who were responsible for the production of mental deficients, and out of that one-tenth only one-tenth—or 1 per cent. of the whole—were themselves definitely defective. The others might be indefinitely defective, unrecognisable as such, and, therefore, it must be clear that any process of sterilisation could not possibly deal satisfactorily with the problem. The ideal method of dealing with these people in the light of present knowledge was in colonies, which should consist probably of not less than 1000 persons if they were to be carried on with the greatest efficiency. These colonies must be considered not as places in which mental deficients should be kept for the rest of their lives, but rather as places where they should be as far as possible trained up to a point at which they could be released and allowed to go out on license and under supervision. But, of course, it was not possible to carry out an ideal of that kind at a single step. It was a costly matter to provide one of these colonies; they had to have some regard to the financial limitations of the country, and they would have to proceed slowly, bearing in mind that they could even now do a great deal to mitigate the lot of these unfortunate people, and to render them less dangerous to society and to themselves. He believed that under the Local Government Act, by which a large number of institutions were placed in the hands of the county and county borough authorities, it would be possible to devote some of those institutions to the reception of certain types both of mental deficients and of insane persons, and seeing that the cost of a bed in a mental hospital was about twice that in a mental deficiency colony, perhaps local authorities would make the best bargain for themselves if they allotted some of these institutions to the treatment of insanity.

Miss WILKINSON asked whether the Minister proposed to do anything to make further provision for the treatment of border-line cases which were not yet certified.

Mr. CHAMBERLAIN said that as far as the present administration was concerned that was the case. It was part of the general policy pursued by the Board of Control all over the country at the present time.

The Four State-aided Services.

The four State-aided health services which came under the Ministry of Health were tuberculosis, venereal disease, the welfare of the blind, and maternity and child welfare. Last year, 1928, there was the lowest death-rate on record both for pulmonary and non-pulmonary tuberculosis. He would call particular attention to the non-pulmonary cases, because 80 per cent. of the decline had occurred among children, and whereas the death-rate among these cases in the ten years from 1901 to 1910 was 500 per 1,000,000, last year it came down to 173. That was due to the greater care taken and the greater knowledge which now existed as to the best method of treating these cripples, as they generally were in the case of children. They had also to bear in mind that the condition of those who survived was very much better than it used to be. Many a child was to-day going about with straight limbs who formerly would have been a permanent cripple. Blind persons, too, were better looked after to-day than they ever were before. Most of them had come under the attention of the local authorities, and there were more and better means of making their sad lot tolerable. He would draw attention in particular to the cases of ophthalmia neonatorum, which in the past had given rise to so many cases of permanent blindness. In 1922 there were 8000 patients of this most distressing disease. In 1927, the latest year for which he had figures, the number had fallen to 5000.

Child Welfare.

The maternity and child welfare work had produced the most striking results of all their health services in the last generation. Last year the infant mortality-rate came down from 70 per 1000, as it was in the year before, to 65. In the five years since he had been at the Ministry of Health the figure had declined 10 points from 75 to 65 per 1000. In other words, in 1928, 6500 babies survived who would have died if they had been born under the conditions existing in 1924. They must, however, not only look at the lives saved; they were, so to speak, a barometer of the general rise in the standard of health among young children, and they might be quite certain that for everyone whose life had been saved there were half a dozen others who were stronger and healthier than they would have been. This wonderful fall in the death-rate in a single year was the product of a number of causes, all combining to work in the same direction, but the expenditure in grants showed that there was a steadily expanding service, and they might claim for that service at least a major share in the very satisfactory results. In 1924–25 the total amount spent by way of Exchequer grants on maternity and child welfare services was £814,000. In 1928–29 the sum was £1,072,000, and in the present Estimates the amount set aside for this purpose was £1,163,000.

Maternal Mortality.

Last year when presenting these Estimates he had referred to the fact that the figures of maternal mortality—deaths of mothers in childbirth—had practically not moved for the last 20 years. He said then that he felt the time had come when it was necessary to make some new and vigorous attempt to deal with this very distressing problem. He set up two committees, one to inquire into the whole conditions affecting the practice and profession of midwifery. That committee had nearly completed its labours, and he hoped that in a few weeks he would have its report. The other committee was one which was directed to trying to throw more light upon the causes of these deaths. Even now they were to a large extent ignorant of the causes of this persistent maternal mortality. He set on foot an investigation with the help of the general practitioners of the British Medical Association and the local authorities, with a view to getting a report on every case of maternal death right through the country. That work had been going on. The committee began to function in the latter part of last year, and 311 deaths formed the subject of reports. This year already they had had reports of 448 more cases. It was too soon to be able to say what conclusions they would be able to draw from this evidence, but already the focusing of the evidence upon these cases and the concentration of attention upon the whole subject had begun to show indications from which they believed they could see some of the flaws and weaknesses in their system which would enable them presently to direct their efforts to the weak spots. The general arousing of public interest, the fixing of attention upon this particular set of circumstances, upon the lamentable results to the health and life of the nation which came from this persistent mortality, in itself had meant that greater care had been given to these matters before and after birth, and although he did not prophesy as a rule he said with some confidence that from the mere fact of this attention being given without any special steps having been taken, they would see a large reduction in this figure which had persisted for so many years.

Small-pox.

There had been a good deal of discussion on the question of small-pox within the last few weeks, and some very embarrassing restrictions had been placed upon the entry of British nationals into another country. That had arisen partly owing to the presence of certain cases of virulent small-pox which had come to this country on a ship. He did not think that this state of affairs would have arisen at all had it not been that the attention of other countries had been drawn to the mounting figures of cases of small-pox of a mild character which had been so remarkable a feature of the last few years. In 1927 there were upwards of 14,000 such cases. Last year there were not quite so many. Although the very fact of these cases being mild had tended to prevent anxiety, he felt that so long as a large part of the population were unvaccinated the country was running a risk which might seem to be small to-day, but which, if there was any spread of a really virulent type of the disease, might cause something like a panic.

Cancer and Radium.

The other matter to which he wished to refer was cancer. Unfortunately the number of cases of that disease was still on the increase in this country, nor had they been able so far, in spite of much research, to say that they had got down to the real cause of cancer or of the agencies which encouraged its development in the human body. What they could say was that after many experiments and some mistakes they had obtained a fairly practical working knowledge of the method of treatment which had been singularly successful, and had, in fact, quite superseded the older methods of surgery—he meant treatment by radium in one form or another. So established was the practice now of the treatment of cancer in many cases by radium that the demands for that substance had become pressing and urgent. It was a substance only found in workable quantities in very few spots in the world, and owing to its powerful character it required most careful handling in its preparation. It was, therefore, a very costly substance, but a subcommittee appointed by the Committee of Civil Research examined into this matter, and informed the Government that 20 grammes of radium were all that could be properly and efficiently used at this moment. Twenty grammes could be obtained at a cost of £200,000, and in the opinion of the subcommittee it was desirable that the Government should offer pound for pound for any sums raised for this purpose by the public. The Government felt that they must at once accept that recommendation, and they undertook to find their share of the necessary money. It was very satisfactory that as a result of appeals which had been made in the Press a very large share of the sum required was already forthcoming. Many generous donors had come forward, and he believed that this was an appeal which was likely to have the sympathy of many people, for who knew which of them might not presently require the very treatment made available by this substance, and which of them, if that were so, would not be prepared to find any sum within his means to escape the anguish, the torture, and possibly death which might follow? It was a great satisfaction to him at the end of this period of his office to find that something had been done to bring relief to many sufferers in the future from this most terrible and terrifying of diseases. He was confident that in a few days they would find that the necessary money had been secured, and that they would be able to proceed to the use of this most beneficent discovery.

Criticisms of Ministerial Policy.

Mr. A. GREENWOOD moved the reduction of the vote by £100. He said that with most of what Mr. Chamberlain had said the Committee would be in general sympathy, but the opposition contended that the country was still faced with a serious housing problem, and the Government had hindered the building of new houses by their policy of a reduced subsidy.

Mr. HOPKIN MORRIS said that he had been hoping that Mr. Chamberlain would give an assurance that the Report of the Wood Committee on Mental Deficiency would now be issued. Why should he appoint a Committee of such distinction and spend public money unless the results of its investigations were to be placed before the country?

A Medical View.

Dr. VERNON DAVIES said that while bearing in mind all that had been done during the past four and a half years in connexion with the health services, and particularly the marked progress in housing, pensions, and national insurance, he was appalled by the amount of work which still remained to be done. It could not be denied that there was a certain amount of apprehension or anxiety as to the non-publication of the adult part of the Wood Report on Mental Deficiency. Although he was convinced that the Minister must have good reasons for his action in this matter, he hoped that he would give the subject his immediate attention and remove unnecessary apprehension. As regarded insanity, it was important to bear in mind that there was a large number of people on the border-line who by proper treatment in mental hospitals could be prevented from going over the line, or could be brought back to normal. That was one of the urgent and vital tasks of the Ministry of Health. The main essential was that they might have a class of patient who could be treated mentally without certification. For years in this country there had been a feeling that any poor individual who suffered mentally was suffering from an affliction inherited from the parents, or that the affliction was from God. If a patient suffered from the heart, chest, or lungs he was regarded as suffering from one of the ordinary afflictions of human life, and there was no discredit attached to it. Why should people try to attach discredit to a poor person who happened to be suffering from mental illness which might be temporary or permanent? Until the Ministry of Health took their courage in both hands and dealt with the Report of the Royal Commission on Lunacy, and brought in legislation for that purpose, this awful feeling towards people suffering from mental affliction would continue. A great work lay before them in that respect. Another important question was that of small-pox. This country, the home of Jenner, the country which first discovered the principle of vaccination and dealt with small-pox, was held up to the ridicule and horror of the world. A neighbourly and friendly country like France, acting in a moment of panic or irresponsibility, issued a very drastic Order against this country in regard to small-pox. At the other end of the world Brazil was taking the same action, and objecting to the importation of people from Great Britain unless they had been vaccinated. He thought that he had read in a publication of the International Labour Office of the Health Commission that this country was the worst vaccinated country in the world. The Minister had powers to enforce the administration of the law. The Rolleston Committee suggested various alterations in regard to vaccination, and he hoped that the Minister of Health would take this matter in hand and see that there was really efficient administration so as to get rid of the curse of small-pox. As regarded the question of cancer, he would draw the attention of the Committee and of the country to the fact that although in radium they had a substance which had proved, and was proving, of enormous value in the treatment of certain forms of cancer, it must not be forgotten that they were dealing with an extremely dangerous element, which ought only to be handled by experts. In the hands of people who did not know how to use it, it was likely to do more harm than good. The essential thing, having obtained radium, was to see that it was used only by people who thoroughly understood it; by medical men who were thoroughly expert in its use. What he was afraid of in this country was not that they would not get a sufficiency of radium, but that for some time they would not have a sufficient number of experts to deal with it.

The Minister of Health took a great interest in the question of maternal health and maternal mortality, and they appreciated the fact that these committees had been set up. They had great hopes that they would lead to a diminution in the maternal death-rate, but he was convinced that the secret of the matter was efficient midwives, properly trained, and, above all, that babies should be born in satisfactory surroundings. It was extremely difficult to say that there was no risk to a mother or baby born in a slum area, but there was a possibility that there was a certain amount, or had been a certain amount, of carelessness. The Minister of Health had said that the fact that he had made inquiries from medical men in the country as to the causes of death had already led to an improvement. That could only be the result of a little extra care taken by the doctor or nurse or the attendants, and a little more cleanliness. If that extra care and attention was going to add to the number of lives saved that alone would more than justify the right hon. gentleman for the work he had done. Very little had been said by Mr. Chamberlain about tuberculosis. Unfortunately they had not had the report for last year. This was a subject in which he (Dr. Davies) took the greatest possible interest, and he would like to know whether there had been any improvement in the compulsory notification of phthisis? Were they getting better results? Was the dispensary system functioning properly? Were they coöperating with the medical men, the sanatoria, and the hospitals? Were they all working as one efficient unit? Would the right hon. gentleman take care to see that under the Local Government Act the tuberculosis system was worked as a complete unit? If it was necessary to have a full-time medical officer for health services, it was ten times more important to have a full-time tuberculosis officer. The one essential thing in tuberculosis was early diagnosis, and that was a matter for the expert. They could not expect the ordinary general medical practitioner, who had not the latest means at his disposal such as X rays, to diagnose the early case. He was pleased to know that there had been an increase in coöperation between the general medical practitioner and the tuberculosis expert. It was no use getting the middle or the final cases; it was the early cases they wanted to get, and they could not get them unless a full-time tuberculosis officer was appointed. Mr. Chamberlain had also said very little about venereal disease. He referred to the diminution in the number of cases of ophthalmia neonatorum, but that was simply an example of the extra care which was being taken. The Minister did not mention how many of the 5000 cases were blind, but he (Dr. Davies) could safely say that with ordinary care and attention there should not be a single case of ophthalmia neonatorum. It was easily preventable, and he hoped the Minister would exercise all the moral and administrative pressure he could in regard to this particular disease. The Minister of Health could look back on a very successful four and a half years' administration. The work of the Ministry of Health during that time had advanced by leaps and bounds. The health of the country had improved, and the social services had advanced. Not the least remarkable result was the great admiration and respect shown to Mr. Chamberlain and to his colleague, Sir Kingsley Wood (the Parliamentary Secretary), by members of the medical profession. Although the Minister was not a medical man he had an uncanny knack of spotting a case, and he had no doubt that if Mr. Chamberlain had been fortunate enough to be a member of the medical profession, he would have risen to great heights. Turning to the vote itself, Dr. Davies said he noticed that under the heading, "Medical Staff (including Government Lymph Establishment)," there were 40 medical officers, two of whom were in receipt of pensions of £400 and £160 respectively per annum from Indian funds; one of a pension from Nigeria and Gold Coast funds to bring his emoluments up to a total of £1305; and two of Army retired pay of £365 and £510 per annum respectively. Were there no medical men in this country fit for these offices without taking retired officers from the Indian Medical Service? It was very essential, particularly in the National Health Insurance service, that a man who had a chance of working up from a general practitioner to a higher administrative office should not be pushed on one side and the job given to another man from another service. There was probably good reason for these appointments, but whatever it was he would be glad to know it.

Care of the Blind.

Captain FRASER said there was not enough general information in regard to the blind community in this country. There were about 48,000 blind persons in this country, of whom about 11,000 were under the age of 40. About 10,000 blind persons were employed, and about 33,000 were described as unemployable. The amount of blindness had decreased, but there was an increase in the number of those who were registered. That was partly due to the fact that the Ministry and the local authorities sought out hitherto unknown cases of blindness and put them on the register in order that they might be cared for. It was also partly due, curiously enough, to the Act of Parliament passed in 1926 for giving blind persons free wireless licences. That had led to an extraordinary increase in the number on the register, and in London alone 900 blind persons had been discovered as an indirect result of the Act. In 1924 the amount spent on the blind from public funds was about £477,000, and in the last year under the same heading £801,000 had been spent, or an increase of about 68 per cent. Considerable progress had been made, and this country could not fairly be charged with being behindhand in the care of the blind, but he hoped that the Minister would think that the time had come to go a little further. In recent years an inquiry had been made by the Ministers' Advisory Committee to find out the number of unemployable blind persons in the country. That inquiry must be nearing regard to the financial limitations of the country, and they would have to proceed slowly, bearing in mind that they could even now do a great deal to mitigate the lot of these unfortunate people, and to render them less dangerous to society and to themselves. He believed that under the Local Government Act, by which a large number of institutions were placed in the hands of the county and county borough authorities, it would be possible to devote some of those institutions to the reception of certain types both of mental deficients and of insane persons, and seeing that the cost of a bed in a mental hospital was about twice that in a mental deficiency colony, perhaps local authorities would make the best bargain for themselves if they allotted some of these institutions to the treatment of insanity.

Miss WILKINSON asked whether the Minister proposed to do anything to make further provision for the treatment of border-line cases which were not yet certified.

Mr. CHAMBERLAIN said that as far as the present administration was concerned that was the case. It was part of the general policy pursued by the Board of Control all over the country at the present time.

The Four State-aided Services.

The four State-aided health services which came under the Ministry of Health were tuberculosis, venereal disease, the welfare of the blind, and maternity and child welfare. Last year, 1928, there was the lowest death-rate on record both for pulmonary and non-pulmonary tuberculosis. He would call particular attention to the non-pulmonary cases, because 80 per cent. of the decline had occurred among children, and whereas the death-rate among these cases in the ten years from 1901 to 1910 was 500 per 1,000,000, last year it came down to 173. That was due to the greater care taken and the greater knowledge which now existed as to the best method of treating these cripples, as they generally were in the case of children. They had also to bear in mind that the condition of those who survived was very much better than it used to be. Many a child was to-day going about with straight limbs who formerly would have been a permanent cripple. Blind persons, too, were better looked after to-day than they ever were before. Most of them had come under the attention of the local authorities, and there were more and better means of making their sad lot tolerable. He would draw attention in particular to the cases of ophthalmia neonatorum, which in the past had given rise to so many cases of permanent blindness. In 1922 there were 8000 patients of this most distressing disease. In 1927, the latest year for which he had figures, the number had fallen to 5000.

Child Welfare.

The maternity and child welfare work had produced the most striking results of all their health services in the last generation. Last year the infant mortality-rate came down from 70 per 1000, as it was in the year before, to 65. In the five years since he had been at the Ministry of Health the figure had declined 10 points from 75 to 65 per 1000. In other words, in 1928, 6560 babies survived who would have died if they had been born under the conditions existing in 1924. They must, however, not only look at the lives saved; they were, so to speak, a barometer of the general rise in the standard of health among young children, and they might be quite certain that for everyone whose life had been saved there were half a dozen others who were stronger and healthier than they would have been. This wonderful fall in the death-rate in a single year was the product of a number of causes, all combining to work in the same direction, but the expenditure in grants showed that there was a steadily expanding service, and they might claim for that service at least a major share in the very satisfactory results. In 1924–25 the total amount spent by way of Exchequer grants on maternity and child welfare services was £814,000. In 1928–29 the sum was £1,072,000, and in the present Estimates the amount set aside for this purpose was £1,163,000.

Maternal Mortality.

Last year when presenting these Estimates he had referred to the fact that the figures of maternal mortality—deaths of mothers in childbirth—had practically not moved for the last 20 years. He said then that he felt the time had come when it was necessary to make some new and vigorous attempt to deal with this very distressing problem. He set up two committees, one to inquire into the whole conditions affecting the practice and profession of midwifery. That committee had nearly completed its labours, and he hoped that in a few weeks he would have its report. The other committee was one which was directed to trying to throw more light upon the causes of these deaths. Even now they were to a large extent ignorant of the causes of this persistent maternal mortality. He set on foot an investigation with the help of the general practitioners of the British Medical Association and the local authorities, with a view to getting a report on every case of maternal death right through the country. That work had been going on. The committee began to function in the latter part of last year, and 311 deaths formed the subject of reports. This year already they had had reports of 448 more cases. It was too soon to be able to say what conclusions they would be able to draw from this evidence, but already the focusing of the evidence upon these cases and the concentration of attention upon the whole subject had begun to show indications from which they believed they could see some of the flaws and weaknesses in their system which would enable them presently to direct their efforts to the weak spots. The general arousing of public interest, the fixing of attention upon this particular set of circumstances, upon the lamentable results to the health and life of the nation which came from this persistent mortality, in itself had meant that greater care had been given to these matters before and after birth, and although he did not prophesy as a rule he said with some confidence that from the mere fact of this attention being given without any special steps having been taken, they would see a large reduction in this figure which had persisted for so many years.

Small-pox.

There had been a good deal of discussion on the question of small-pox within the last few weeks, and some very embarrassing restrictions had been placed upon the entry of British nationals into another country. That had arisen partly owing to the presence of certain cases of virulent small-pox which had come to this country on a ship. He did not think that this state of affairs would have arisen at all had it not been that the attention of other countries had been drawn to the mounting figures of cases of small-pox of a mild character which had been so remarkable a feature of the last few years. In 1927 there were upwards of 14,000 such cases. Last year there were not quite so many. Although the very fact of these cases being mild had tended to prevent anxiety, he felt that so long as a large part of the population were unvaccinated the country was running a risk which might seem to be small to-day, but which, if there was any spread of a really virulent type of the disease, might cause something like a panic.

Cancer and Radium.

The other matter to which he wished to refer was cancer. Unfortunately the number of cases of that disease was still on the increase in this country, nor had they been able so far, in spite of much research, to say that they had got down to the real cause of cancer or of the agencies which encouraged its development in the human body. What they could say was that after many experiments and some mistakes they had obtained a fairly practical working knowledge of the method of treatment which had been singularly successful, and had, in fact, quite superseded the older methods of surgery—he meant treatment by radium in one form or another. So established was the practice now of the treatment of cancer in many cases by radium that the demands for that substance had become pressing and urgent. It was a substance only found in workable quantities in very few spots in the world, and owing to its powerful character it required most careful handling in its preparation. It was, therefore, a very costly substance, but a subcommittee appointed by the Committee of Civil Research examined into this matter, and informed the Government that 20 grammes of radium were all that could be properly and efficiently used at this moment. Twenty grammes could be obtained at a cost of £200,000, and in the opinion of the subcommittee it was desirable that the Government should offer pound for pound for any sums raised for this purpose by the public. The Government felt that they must at once accept that recommendation, and they undertook to find their share of the necessary money. It was very satisfactory that as a result of appeals which had been made in the Press a very large share of the sum required was already forthcoming. Many generous donors had come forward, and he believed that this was an appeal which was likely to have the sympathy of many people, for who knew which of them might not presently require the very treatment made available by this substance, and which of them, if that were so, would not be prepared to find any sum within his means to escape the anguish, the torture, and possibly death which might follow? It was a great satisfaction to him at the end of this period of his office to find that something had been done to bring relief to many sufferers in the future from this most terrible and terrifying of diseases. He was confident that in a few days they would find that the necessary money had been secured, and that they would be able to proceed to the use of this most beneficent discovery.

Criticisms of Ministerial Policy.

Mr. A. GREENWOOD moved the reduction of the vote by £100. He said that with most of what Mr. Chamberlain had said the Committee would be in general sympathy, but the opposition contended that the country was still faced with a serious housing problem, and the Government had hindered

ROCKEFELLER MEDICAL FELLOWSHIPS.—The Rockefeller Medical Fellowships for 1929–30 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1st. These Fellowships are provided from a fund with which the Medical Research Council have been entrusted by the Rockefeller Foundation. They are awarded by the Council, in accordance with the desire of the Foundation, to graduates who have had some training in research work in the primary sciences of medicine or in clinical medicine or surgery and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. In special circumstances the Fellowships may be tenable at centres of research not in America. A Fellowship held in America will have the value of not less than £350 a year for a single Fellow, with extra allowance for a married Fellow, payable monthly in advance. Travelling expenses and some other allowances will be paid in addition. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen-street, Westminster, S.W. 1.

THE death is announced on April 30th, at Christchurch, New Zealand, of Dr. Courtney Llewellyn Nedwill, visiting surgeon to Christchurch Hospital. Dr. Nedwill, who received his medical education at Cambridge and St. Bartholomew's Hospital, qualifying in 1902, was at one time Medical Inspector of Railways to the [illegible] Government at Atbara.

UNIVERSITY OF LEEDS.—The degree of doctor of medicine has been conferred on Dr. G. R. Baxter.

BIOCHEMICAL SOCIETY.—This society will meet at the University Museum, Oxford, at 3 P.M. on Saturday, May 11th.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS.—At a general meeting of the Society to be held on Thursday, May 30th, at 8 P.M., in the Essex Hall, Strand, Dr. Mather Thomson will lecture on Sterilisation of the Unfit.

Colonel R. J. Blackham, M.D., who is a member of the City of London Corporation and Clerk to the Worshipful Company of Glaziers, has recently been invested as Grand Sword Bearer of the Grand Lodge of Freemasons of England for the year 1929–30.

MEDICAL PRAYER UNION.—The annual medical missionary breakfast of this Union will be held at 8 A.M. on Wednesday, May 15th, at the Refectory, University College, Gower-street, London, W.C., under the presidency of Dame Mary Scharlieb. An address will be given by Dr. L. E. Sharp, of Ruanda, Uganda. Those wishing to be present should write to the hon. secretary, Dr. Tom Jays, Livingstone College, Leyton, E.10.

GLASGOW UNIVERSITY CLUB, LONDON.—The annual summer dinner of this club is to be at the Trocadero Restaurant, Piccadilly-circus, on Friday, May 31st, at 7.30 P.M. Emeritus Prof. F. O. Bower, President-elect of the British Association, is to preside. Any Glasgow University men who, though not members of the club, desire to attend, are requested to communicate with the Hon. Secretaries, at 62, Harley-house, N.W.1.

LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD: MEDICAL SCHOLARSHIPS.—This Board announces that an examination for six medical scholarships and exhibitions, and one dental scholarship, of an aggregate total value of £538, will begin on June 25th. They are tenable at University College and University College Hospital Medical School, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital Medical College. Full particulars and entry forms may be had from the secretary of the Board, Mr. S. C. Ranner, the Medical School, King's College Hospital, Denmark Hill, S.E. 5.

INTERNATIONAL SOCIETY FOR SEXUAL HYGIENE.—The second meeting of the *Internationale Gesellschaft für Sexualforschung* will be held in the House of the British Medical Association, Tavistock-square, London, from August 3rd–9th, 1930. It may be assumed that, as was the case in Berlin, the papers presented for discussion will fall into the following groups: biology; physiology, pathology, and therapeutics; psychology, pedagogy, ethics, æsthetics, religion; demography, statistics, social and racial hygiene: sociology, ethnology, and folk-lore. All the arrangements are in the hands of Prof. F. A. E. Crew, the University, West Mains road, Edinburgh, to whom those interested are asked to write.

DONATIONS AND BEQUESTS.—Among other bequests the late Mr. Obed Charles Hawkes, J.P., of Edgbaston and Birmingham, left £10,000 each to the Birmingham General Hospital, Queen's Hospital, Birmingham, the Birmingham and Midland Hospital for Women, and Birmingham University: £5000 to the Children's Hospital, Birmingham: and £500 each to the Birmingham Maternity Hospital, the Birmingham Cripples' Union and Royal Orthopædic and Spinal Hospital, the Birmingham and Midland Skin and Urinary Hospital, the Birmingham and Midland Eye Hospital, the Birmingham and Midland Ear and Throat Hospital, the Birmingham and Midland Homœopathic Hospital, the Birmingham General Dispensary, the Birmingham Royal Institution for the Blind, and the Institution for the Deaf and Dumb. Subject to other large bequests, the residue of his property will be divided between the Birmingham General Hospital, Queen's Hospital, Birmingham, the Birmingham and Midland Hospital for Women, and the Birmingham University, and the Children's Hospital, Birmingham.—Mr. Illtyd Williams, of Wilderton, Branksome Park, Bournemouth, left £20,000 to the Imperial Cancer Research Fund, but in the event of an established cure for cancer being found, any balance of this fund then remaining is to be applied by the Royal College of Surgeons and the Royal College of Physicians for such further investigation into the diseases of man as they may from time to time determine.

RADIUM AT THE CANCER HOSPITAL.—At the annual meeting last week it was stated that it had become imperatively necessary at once to rebuild the electrical and radio-therapeutic department. There is said to be a pressing need for more radium, of which the hospital holds about 1·25 g. Arrangements have been made for the admission of patients who are able to pay a small fee.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—The annual report of this hospital shows that the attendances of out-patients have almost doubled since 1918, and are nearly ten times as many as in 1907. Last year the number of beds was increased from 309 to 368, and a few weeks hence there will be 444. There is a debt of £60,000.

WEST SUSSEX HOSPITAL.—To meet the demand for accommodation for paying patients a portion of the new nurses' home, which is approaching completion, has been temporarily allocated for this purpose. A small maternity ward has also been provided. The West Sussex Associated Hospitals Contributory Fund now covers 26,000 persons.

TRAFFIC ACCIDENTS.—The annual report of the Leicester Royal Infirmary contains some significant figures of the traffic accidents treated during 1928. Injured persons treated numbered 1299, of whom 233 were admitted to the wards. Almost exactly one-half of these cases were the result of accidents to motor vehicles. The total number of persons injured in accidents of various kinds was 10,965, an increase of more than 900 over the preceding year, and the cost of treating them slightly exceeded £10,000.

RAT OFFICER FOR MANCHESTER.—The Manchester Port Sanitary Authority has decided to appoint a rat officer. This will link the practice at Manchester with an international movement against the rat. The International Convention of 1926 decided that the best way to combat the danger of the spread of plague by ship rats was to get some kind of uniformity of practice throughout the world. Under the scheme every ship should either be fumigated or hold an exemption certificate. *The rat officer will have to examine* carefully every ship applying for exemption, and afterwards make a report. Rat-catchers will still see to the catching of the rats, but the rat officer will supervise all the arrangements.

WORK OF MATERNITY HOSPITALS.—The annual report of Queen Charlotte's Hospital shows that 2375 patients were treated last year, "and many hundreds had to be turned away owing to lack of accommodation." The results, as between "booked" and "emergency" cases, were remarkable. Among the 2161 booked cases there were four deaths, a rate of 1·8 per 1000, whereas of the 211 emergency cases 15 died, a rate of 71·0 per 1000. The booked patients are those who receive care and treatment in the antenatal department for many weeks before their confinement. When the new hospital is built at Hammersmith a maternity home will be continued in Marylebone. The new building will have 200 beds, one half of them for paying patients.—The General Lying-in Hospital, in York-road, Lambeth, last year received 1043 in-patients and 1336 out-patients; the patients paid £1583. Under the lease the hospital must be rebuilt by the end of next year; the cost will be £40,000, of which only £18,000 is as yet available.—A new municipal maternity hospital and child welfare centre for the City of Portsmouth was opened a fortnight ago.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, May 14th.—5 P.M., THERAPEUTICS. Annual General Meeting: Election of Officers and Council. Discussion on The Action and Use of Ephedrine. The following have been invited to take part in the Discussion: Mr. Frank Coke, Prof. H. H. Dale, Prof. Francis R. Fraser, Dr. John Freeman, Prof. J. A. Gunn, Dr. J. H. Hannan, Dr. J. H. Thompson, Dr. J. W. Trevan. 8.30 P.M., PSYCHIATRY. Annual General Meeting. Election of Officers and Council. Short Papers: Dr. F. L. Golla: Some Recent Work on the Pathology of Schizophrenia. Dr. W. M. Ford Robertson: Gastro-intestinal Focal Infection in Relation to Oral Sepsis, with Special Reference to Anaerobes occurring in Six Cases of Mental Disorder. (Illustrated.)

WEDNESDAY.—8.15 P.M., TROPICAL DISEASES. Annual General Meeting; Election of Officers and Council. Paper by Prof. Besredka (Paris) on Vaccine Therapy.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Annual General Meeting: Election of Officers and Council. The Annual Dinner will be held the same evening.

FRIDAY.—8 P.M., OBSTETRICS AND GYNÆCOLOGY. Annual General Meeting: Election of Officers and Council. Short Communication. Dr. Herbert R. Spencer: A Straight Rod Pelvimeter. Short Paper. Mr. Gilbert I. Strachan (Cardiff): Some Contra-indications to Radiotherapy in Carcinoma of the Uterus. Paper: Mr. Victor Bonney: Results of the Surgical Treatment of Carcinoma of the Uterus.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, May 13th.—8 P.M., Annual General Meeting. 9 P.M., Prof. G. Grey Turner: Cancer of the Colon (Annual Oration). To be followed by a Conversazione.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, May 16th.—8.15 P.M., Meeting preceded by a Demonstration at 7.45 P.M. Dr. Vincent Hodson will read a Paper on Pulmonary Tuberculosis in the Tropics. The Discussion will be opened by Colonel S. Lyle Cummins.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 13th, to SATURDAY, May 18th.—MEDICAL SOCIETY Lecture Room, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Course of Instruction. Lectures on Tuesdays and Fridays at 8.30 P.M. Tues., Dr. A. Knyvett Gordon: The Clinical Significance of the Blood Film. Fri., Dr. Bernard Myers: Purpura.—CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, Victoria Park, E. Clinical Demonstration by Dr. J. R. B. Hern, Wed., at 4.30 P.M. Free.—WESTERN OPHTHALMIC HOSPITAL, Adelphi Rooms, 264, Edgware-road, W. Clinical Demonstration by Mr. Cole Marshall (O.P.) on Fri., at 2.30 P.M. Free.—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. Course of Four Lecture-demonstrations on Antenatal Treatment on four successive Fridays at 5 P.M.—CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C. Course of Clinical Instruction in Laryngology, &c., occupying all day. Last week.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Clinical Instruction every afternoon, lectures twice weekly. Second week.—MAUDSLEY HOSPITAL, Denmark Hill, S.E. Course in Psychological Medicine. Third week.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, May 13th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

MONDAY, May 13th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Pain and Paræsthesiæ.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Senile Paraplegia.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Intracranial Aneurysms.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Methods (in Exercise Room).

LONDON HOSPITAL MEDICAL COLLEGE, Mile End, E.

THURSDAY, May 16th.—5.30 P.M., Prof. J. J. R. Macleod: Physiology of Glycogen. (Lecture I.)

FRIDAY.—5.30 P.M., Lecture II.

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

THURSDAY, May 16th.—5 P.M., Prof. S. J. Cowell: Dietetics. (Third of six lectures).

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

WEDNESDAY, May 15th.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. H. E. Symes-Thompson: Spontaneous Pneumothorax.

ROYAL DENTAL HOSPITAL POST-GRADUATE LECTURES.

WEDNESDAY, May 15th.—6 P.M., Mr. F. St. J. Steadman: Fractures with Special Reference to Treatment.

UNIVERSITY COLLEGE, Gower-street, London.

Thursday, May 16th.—5 p.m., Mr. R. J. Lythgoe: Special Sense Physiology. (Third of six lectures.)

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C

Monday, May 13th.—5 p.m., Dr. J. E. M. Wigley: Napkin Area Eruptions in Infants.

Tuesday.—Dr. H. MacCormac: Treatment of Syphilis.

Thursday.—Dr. H. G. Burford: Pathology Demonstration.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, May 14th.—4.15 p.m., Dr. T. H. Oliver: Uræmia.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

Tuesday, May 14th.—3.30 p.m. (at the Jessop Hospital), Mr. King: Gynæcological Cases.

Friday.—3.30 p.m., Mr. Mouat: Treatment of Septic Conditions of the Hand.

Appointments.

McCowan, P. K., M.D. Edin., M.R.C.P. Lond., D.P.M., has been appointed Medical Superintendent, Cardiff City Mental Hospital, and Lecturer in Mental Diseases, University of Wales.

Rennie, J. K., M.D., Ch.B. Glasg., Honorary Physician to the Royal Infirmary, Bradford.

Turner, Beatrice, F.R.C.S. Edin., M.B., B.S. Lond., Junior Assistant Obstetrician, Elizabeth Garrett Anderson Hospital.

Vacancies.

For further information refer to the advertisement columns.

Accrington, Victoria Hospital.—H.S. £150.
Birmingham, General Hospital.—Two Res. Surg. Regs. Each £100 to £140.
Birmingham, City Babies Hospital.—Res. M.O. At rate of £150.
Blackburn and E. Lancashire Royal Infirmary.—Fourth H.S. At rate of £130.
Blackpool, Victoria Hospital.—H.S. £120.
Bolton Infirmary and Dispensary.—Res. Surg. O. £240. H.S. £150 also Asst. H.S. £100.
Bradford Royal Infirmary.—H.S. £150.
Brighton, New Sussex Hospital for Women, Windlesham-road.—H.S. Also H. P. Each £50.
Brighton, Sussex Maternity and Women's Hospital.—Res. H.S. £130.
Bristol Royal Infirmary.—H.S. At rate of £80.
Burnley, Victoria Hospital.—H.S. At rate of £125.
Bury St. Edmunds, West Suffolk General Hospital.—H.S. £150.
Cambridge, Papworth Village Settlement.—H.P. £100–£200.
Cambridge University.—E. G. Fearnside's Scholarship.
City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—Physician to Out-patients.
City of London Maternity Hospital, City-road, E.C.—Asst. Res. M.O. At rate of £80.
Colchester, Essex County Hospital.—Asst. H.S. £120.
Derby Guardians Institution and Infirmary.—Second Res. M.O. £250.
Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.—H.P., Obstetric Asst. and Three H.S.'s. Each at rate of £50.
Farringdon General Dispensary, Holborn Circus, E.C.—P. to Dis. of Skin Dept. Also S. to Dental Dept.
Gordon Hospital for Rectal Diseases, Vauxhall Bridge-road, S.W.—H.S. £75. Also Hon. Asst. Surgeon.
Gravesend and North Kent Hospital.—Jun. H. S. At rate of £80.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.
Hull Royal Infirmary.—Hon. Phys.
Kensington, Fulham and Chelsea General Hospital, 194, Finborough-road, S.W.—Hon. Radiologist.
Leamington Spa, Warneford General Hospital.—Res. H. P. Also Res. H.S. Each £165.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
Lenham Sanatorium.—Asst. M.O. £400.
Liverpool County Borough.—Jun. Asst. M.O. £600.
Liverpool Eye and Ear Infirmary, Myrtle-street.—H.S. to Ear, Nose and Throat Dept. £100.
Liverpool, Royal Southern Hospital.—Hon. Asst. Physician.
Liverpool, Walton Institution, Rice-lane.—Res. Asst. M.O. £200.
L.C.C. Mental Hospitals Service.—Eighth Asst. M.O. £300.
Manchester, County Mental Hospital, Prestwich.—Locum Tenens. £7 7s. weekly.
Manchester, Monsall Hospital for Infectious Diseases.—Jun. M.O. £350.
Manchester Royal Eye Hospital.—Two Jun. H.S.'s. Each £120.
Margate Royal Sea-Bathing Hospital.—H.S. At rate of £100. Also Asst. Med. Supt. £500.
Middlesex County Council.—Asst. M.O. £600.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Hon. Anæsthetist.
Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer. At rate of £150.
Newcastle-upon-Tyne, University of Durham College of Medicine.—Whole-time Assistant. £400.
Norwich, City of.—Asst. M.O., &c. £450.
Nottingham Children's Hospital.—Res. H.S. At rate of £130.
Nottingham General Hospital.—Res. Cas. O. At rate of £200.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. Physician to Dermatological Department.
Portsmouth Royal Hospital.—Sen. H.S. Also H.S. At rate of £175 and £130 respectively.
Queen's Hospital for Children, Hackney-road, E.—Cas. O. Also H.P. Each at rate of £100.
Rhondda Urban District Council.—Asst. M.O. £600.
Royal College of Surgeons of England.—Election of Professors and Lecturers.
Royal London Ophthalmic Hospital, City-road, E.C.—Pathologist and Curator. £200.
St. Albans, Napsbury Mental Hospital.—Jun. Asst. M.O. £485.
St. Bartholomew's Hospital, E.C.—Physician to Children's Dept.
St. George's-in-the-East Hospital, Raine-street, Old Gravel-lane, E. Res. Asst. M.O. £50.
St. John's Hospital, Lewisham, S.E.—Sen. Res. M.O. £250.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C. Clinical Pathologist. £250.
Salford City Infectious Diseases Hospital.—Jun. Asst. Res. M.O. £200.
Sheffield, Winter-street Hospital.—Asst. Tuber. O. £450.
Southport General Infirmary.—Jun. H.S. £100.
Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. for Ophthalmic and Aural Departments. £150. Also Asst. H.P. £125.
Stroud General Hospital.—H.S. At rate of £120.
Swansea Hospital.—H.S. £150.
Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.
University of London.—University Chair of Anatomy. £1000.
University of London, S. Kensington, S.W.—Studentship in Physiology. £100.
Ventnor, Isle of Wight, Royal National Hospital for Consumption, &c.—Asst. Res. M.O. At rate of £300.
Walsall General Hospital.—H.S. Also Jun. H.S. At rate of £125 and £100 respectively.
Weir Hospital, Grove-road, Balham, S.W.—Hon. Consultant to Ear, Nose and Throat Department.
West London Hospital, Hammersmith-road, W.—H.P., H.S., and Aural and Ophth. H.S. Each at rate of £100.
Whipps Cross Hospital, Whipps Cross-road, Leytonstone, E.—Res. Asst. M.O.'s. Each £300.
Will Edmonds Clinical Research Fund.—Fellowship. £500.
Willesden General Hospital, N.W.—Registrars.
Wolverhampton, Royal Hospital.—Cas. O. and Res. Anæsthetist. At rate of £215.
Workmen's Compensation Act.—Two Medical Practitioners, on Medical Board for Silicosis.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Witham (Essex) and Hertford (Herts).

Births, Marriages, and Deaths.

BIRTHS.

Gorsky.—On April 30th, at Overstrand-mansions, Battersea-Park, S.W., the wife of Dr. J. A. Gorsky, of a daughter.

Kessel.—On May 5th, at 11, Antrim Mansions, Hampstead, N.W.3, the wife of Herbert H. Kessel, M.R.C.S., L.R.C.P., of a son.

Salisbury.—On April 29th, at Woodlands, Billing-road, Northampton, the wife of Walter Salisbury, M.D., M.S., F.R.C.S., of a daughter.

Tasker.—On April 28th, the wife of D. G. C. Tasker, M.S., F.R.C.S., of Christchurch-road, Clifton, Bristol, of a son.

DEATHS.

Brodribb.—On April 29th, at Hove, Arthur Hubert Brodribb, M.R.C.S., L.R.C.P., late Hon. Consulting Medical Officer, formerly Hon. Surgeon, Royal Surrey County Hospital, Guildford, aged 57.

Jones.—On May 1st, at Emscote, Welwyn Heath, Herbert Jones, L.R.C.S., D.P.H., late M.O.H., Herefordshire Combined Districts, aged 71.

Sare.—On May 2nd, Robert Edward Sare, of "Cottsmoor," 24, The Avenue, Coulsdon, Surrey, Manager of The Lancet, in his 51st year.

Wanklyn.—On April 30th, suddenly, in his office at the County Hall, London, Dr. William McConnel Wanklyn, Medical Consultant, aged 62.

Weston.—On May 2nd, suddenly, at Lion House, Exmouth, Lieut.-Colonel George Edward Weston, R.A.M.C.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

BACTERIOLOGY OF RHEUMATISM.

Dr. F. E. Graham-Bonnalie read a paper on Some Aspects of Rheumatism at a meeting of the Brighton and Sussex Medico-Chirurgical Society on May 2nd. He pointed out that the successful treatment of most diseases depended upon a just appreciation of the ætiological factors. The greater part of research work tended to show that rheumatism was of bacterial origin, but the biochemical side of the picture should not be ignored. If, for the sake of argument, it was admitted that rheumatism was due to an infecting organism, could one go further and divide it into streptococcal and non-streptococcal? And if such definiteness was possible, why was there not more assurance of success in treatment?

Several possible reasons might be adduced to account for this. Perhaps, for instance, the right organism or the right strain of that organism had not been isolated. Dr. Graham-Bonnalie thought it possible that the streptococcus might alter its serological properties according to its particular domicile for the time being, and therefore he did not believe in using a vaccine prepared from too pure a culture, preferring to combine it with a stock vaccine. A further reason might be that a primary focus had not been eradicated, which focus was more liekly to be connected with the teeth or tonsils than anywhere else. Apparently the bowel was not uncommonly a primary focus, but (like the gall-bladder) was probably more often secondary. Such secondary foci were among the causes of failure, and a factor which had to be taken into account was the sensitiveness of the patient to vaccines, owing to the presence of these foci, or because too large doses were given at the outset, or because a reaction was not always recognised as such. It was not necessary to give large doses to produce improvement. On the contrary, the smaller the dose which produced good results the more efficacious the treatment was likely to be. Sometimes where the patient was sensitive and no localised focal sepsis could be found, improvement continued even if repeated small doses of the same strength had to be employed. An underdose was never wrong; an overdose, especially at the outset, might be disastrous in a case which was at all acute.

In a series of 60 consecutive cases Dr. Graham-Bonnalie had tried to find some relationship between signs and symptoms on the one hand, and the pathological findings on the other, but with no great success. There seemed to be little doubt, he said, that of all the organisms isolated from rheumatic patients, whether from teeth, tonsil, or bowel, the commonest was the *Streptococcus viridans*. In his opinion the problem of dental infection was not so difficult as it seemed, provided all the factors were taken into consideration. He also thought that pyorrhœa probably played little part in the primary production of rheumatism, though it was probably a potent cause of secondary infection of the tonsil, bowel, &c. He had had several cases in which the same organism was isolated from the teeth, tonsil, and bowel, and which had responded to vaccines prepared from the bowel.

COMMITTEE OF MATERNAL HEALTH.

FIVE years ago a Committee of Maternal Health was appointed in the United States to serve "as a clearing-house and centre of information on certain medical aspects of human fertility." It was formed because it was felt by a number of American medical men that the subject of human fertility was of immense social and personal importance and that, for various reasons, it had received insufficient attention from the medical profession. Certain aspects of the subject—eugenical sterilisation of the defective and feeble-minded, for instance—have been expansively treated by lay writers. But for a number of reasons, of which professional timidity is quoted as one, the medical profession has avoided these subjects. The Committee of Maternal Health exists to remedy this omission, and the biennial report for 1927 and 1928 of the Committee is now obtainable.[1] "Timidity" on the part of the medical profession in America is easily comprehensible in view of the existing state of the law. Since 1873 it has been a crime in the eyes of the law to import or transport any publication, article, or information "calculated to lead another to use or apply it for preventing conception or producing abortion, or for any indecent or immoral purpose." In 11 States physicians are expressly forbidden to give advice on contraception. The law is explicit and sweeping, and there are no exceptions either by statute or interpretation. The States are Massachusetts, Pennsylvania, the District of Columbia, Missouri, Nebraska, Kansas, Mississippi, Montana, Arizona, Idaho and Washington. In others the law is less uncompromising and merely contains implications that physicians may not give such advice. In spite of all this legislation, however, birth control is practised throughout the United States as a matter of course by intelligent persons, with or without medical advice, and there are now more birth control clinics there than in this country. The subjects which are specifically studied by the Committee of Maternal Health are control of conception, sterilisation, therapeutic and eugenic, involuntary sterility, and the sex life of socially normal men and women. And the Committee is also trying to secure through the intervention of medical societies an amendment of the Federal laws relating to the physician's attitude to birth control.

THE SEPARATE RAILWAY COMPARTMENT.

A CORRESPONDENT writes: Do the conditions of travel in railway carriages of the non-corridor type give adequate protection to passengers? While there is no need to alarm the nervous, it is reasonable to ask that persons who are shut up with haphazard companions in closed compartments for journeys of considerable length should have the utmost security obtainable. The Minister of Transport, it seems, is not prepared to insist upon the discontinuance of non-corridor carriages. He appears to rely upon the use of the communication cord and upon the provision of compartments reserved for ladies only. Correspondents in the daily press have suggested the provision of some kind of window in the partition between two compartments whereby any molestation of a passenger might be brought to the notice of other passengers next door. Some contrivance of this sort was adopted many years ago after a sensational train outrage, but it lacked popularity, and was perhaps an indifferent aid to safety. Are we to wait for some similar occurrence before making a fresh attempt to solve the problem? The most recent statistics indicate that, out of 893 criminal lunatics who were under detention a year ago, no fewer than 398 had been charged with murder. There may be heavy odds against having a homicidal maniac for a fellow-passenger, but there are other companions hardly more welcome, especially where girls and young women are the travellers concerned. According to the latest figures sexual offences are increasing. Indecent assaults on females were more numerous in 1926 than in 1925, and still more numerous in 1927 than in 1926. More than 2000 persons were proceeded against in 1927 for indecent exposure, a total in excess of the quinquennial average. It is not suggested that any high proportion of these offences was committed in railway carriages, but it is not unreasonable to suppose that the offenders occasionally travelled by train; certainly the existence of closed compartments increases the offender's opportunity. It is not unlikely that the statistics of such offences fall far short of those which actually occur. Many parents and teachers become aware of complaints which are never made the subject of police proceedings. Complaints are made reluctantly and often after so long a delay that identification of the offender is impossible. In any case there is a natural hesitation to increase the discomfort of the victims of these occurrences by subjecting them to the ordeal of the witness-box. The past history of our railway companies hardly suggests that they will move in such a matter in advance of strong public pressure. These are not times when the railways can be expected to make any costly changes: nevertheless, if the railways wish to retain and increase their passenger traffic they must pay attention to a problem which causes not a little misgiving in the public mind.

THE DANGEROUS DRUGS ACTS MEMORANDUM.

X. Y. Z.—There has, we understand, been no general distribution of the Home Office memorandum to medical practitioners, but certain arrangements have been made for its distribution, as occasion offers, through the medical officers of the Ministry of Health, and copies have been circulated to all insurance practitioners by the Department of Health for Scotland. The Home Office will supply a copy to any practitioner who desires it.

M.A., M.B.—Such a door-plate would be an innovation in the Metropolis, but, inasmuch as in many places notice of practice along other special lines is thus indicated our correspondent would not seem to err in any ethical manner if he stated publicly his own line of work as he suggests.

A BRIGHTON CASUALTY DEPARTMENT.—Prince Arthur of Connaught opened the "Bernhard Baron Casualty Department" of the Royal Sussex Hospital last week. In 30 years the number of casualties treated in the hospital has grown from 3000 to 10,000 a year.

An Address

ON

CANCER OF THE COLON.

Being the Annual Oration of the Medical Society of London, delivered on May 13th, 1929,

BY G. GREY TURNER, F.R.C.S. ENG.,

SURGEON TO THE ROYAL INFIRMARY, NEWCASTLE-UPON-TYNE; PROFESSOR OF SURGERY IN THE UNIVERSITY OF DURHAM.

"Let us cherish a sober mind, and take for granted that in our best performances there are latent many errors which in their own time will come to light. . . ."—W. E. GLADSTONE, 1887.

("Locksley Hall" and the Jubilee. Nineteenth Century. No. CXIX.)

MR. PRESIDENT AND FELLOWS,—While deeply conscious of the honour which you have paid me in electing me your orator, I must confess that I am appalled at the task which I have undertaken, and especially do I feel the responsibility when I look down the list of distinguished orators of the past. I can only assume that the invitation is kindly meant as a compliment to the provinces, or I had rather say to the periphery of the provinces, to which I belong. But this does not relieve my anxiety, for I the more feel the responsibility and my utter inability to attain to that high standard which your provincial orators have set.

When John Coakley Lettsom was 45 years of age he wrote as follows of his early training in London: "Having no more money than to carry me through the hospitals I could not attend many lectures, and upon this depended my improvement; for instead of hearing and learning of lectures, I was compelled to learn at the bed of sickness. Here I saw nature and learnt my art without the leading-strings of professors."

Perhaps Lettsom was not unfamiliar with the dictum of the brightest light in the medical firmament of those days, for William Hunter was fond of saying: "Were I to make a man truly great in his profession, I would place him in a large hospital where he might attend the sick and dissect the dead."

In the choice of subject I have followed the example of your distinguished founder and have decided upon a clinical one, in the hope that a personal record of practical work may be of some interest. I like to think that the district from which I hail bears some parental relationship to the development of intestinal surgery, for it is recorded—though I am unable to trace the reference—that in the days of the border raids some skilful leech successfully sutured a case of lacerated bowel, the patient surviving to fight the Scots another day! As I have been working up my material for this occasion, I have often been afflicted by that chilly feeling which comes over one on realising that everything which I have to tell you now has been spoken of before, and that the ground has been tilled and retilled to a high state of cultivation. To me it has been fascinating to see the progress of this branch of surgery during the last 30 years, and to have witnessed the great improvements that have so changed the outlook in my time. It is further interesting to look back only a few years and to find that, in the light of to-day, so much that is comparatively recent has already to be readjusted.

On this occasion I address myself for the most part *to my younger surgical friends, and to the practitioners* who are members of your society. I am reminded of a great politician who said that it had been his life's ambition to do something for the "cottage man." Equally, if I may say so without appearing to patronise, I feel that those of us who have the unique opportunity of working in large hospitals can best help forward the progress of surgery by doing something to encourage and help the younger surgeon, and his trusty henchman, the general *practitioner*.

At this present time, when the action of radium on malignant growths is proving so startling and wonderful, and when its use is being tentatively extended to the internal organs, it seems more than ever important to review the results of our work, so as to be able to state just *what operative surgery has to offer* in the treatment of malignant disease. Further, in view of the other methods of treatment for cancer which are being earnestly tried by so many workers, and the results of which were debated with such heat in this very room, it appears to me more and more important that we should know the natural history of cancer, not only as to its causes and early stages, but as to its end-results. A surgical giant, reared in a school of giants, and himself a teacher of surgeons the world over, made the following pronouncement not quite ten years ago:—

> "Growths in the colon are low in the scale of malignancy; they do not spread widely or rapidly in, or away from, the bowel; their vascular and lymph vascular territories so closely correspond that a free removal of glands can safely be made, wide resection is easy, and subsequent anastomoses are made without difficulty. The primary growth, its extensions in the intestinal wall, and all primary and many secondary glands, can therefore in most cases be removed in one block. These are all facts which entitle us to say that few places in the body affected by carcinoma *are so accessible and safe to curative operations.*"—(*Moynihan.*)

THE RESULTS OF OPERATION.

As an ordinary surgeon, I invite you to review with me the results of my own efforts. The members of my audience are sufficiently familiar with this subject to know that the ideal at which we must aim is the removal of the growth with a sufficiently wide area of healthy tissue, including the path of probable malignant invasion and followed by restoration of the continuity of the canal, or, if that is impossible, the removal must be carried out at the price of a permanent colotomy.

I have now interfered surgically in 241 cases of cancer of the colon. I regret that I am not able to state how many cases I have seen in all, and in how many I have decided to do some operation of one sort or another, but not many cases have been wholly rejected, which is to say, the operability rate has been high. In any event, such a computation as I have mentioned would not be entirely accurate, as only cases in which something surgical was thought feasible would be sent to a surgeon. However, it is interesting to note that, out of the total number of cases, it was possible to carry out a radical operation in 142, —that is, 58·92 per cent.—only a palliative anastomosis or some type of colostomy in 85, or 35·28 per cent., and a mere exploration in 14, or 5·80 per cent., *of the total. Among the 142 cases in which the growth* was removed in the hope, though not always with the expectation, that it would prove a radical cure, there were 27 deaths, a mortality of 19 per cent.

On Dec. 6th, 1920, there was an interesting and important discussion on this subject held in these rooms, when Lord Moynihan made the pronouncement referred to. At that meeting I reviewed my cases up to the end of 1919. In that series there were 58 resections with 15 deaths, a mortality of 25·86 per cent. Since that time I have carried out resection in a further 84, with 12 deaths, a mortality of 14·28 per cent. This happier result is probably due to the lessons learnt at that discussion, and I would indeed be gratified if I felt that anything that I can say would still further improve the figures.

It is a necessary and salutary duty to review the cause of the deaths, and these are set out in the following table.

Among the group of 15 cases due to peritonitis there are several in which this was undoubtedly diffused by operating in the presence of sepsis, such as abscesses in connexion with the growths, or imperfectly drained bowel, or bowel harbouring stercoral ulcers, which in two cases gave way. In some cases there was failure of union of the anastomosis, and in one case it followed the closure of a colotomy, the last step in a three-stage operation. In some others the sepsis may have been introduced.

Causes of Death in 142 Resections.

Peritonitis or other sepsis	15	Heart failure	1
Intestinal obstruction ..	3	Exhaustion	1
Pneumonia	3	Not known	1
Hæmorrhage	1		
Shock	1		27
Diarrhœa	1		

These and the other conditions tabulated are of the kind that account for death after other major surgical undertakings in the abdominal cavity, and I have no desire to attempt to explain them away or to whitewash my failures. A surgeon who looks back must have many regrets, and indeed he is fortunate if he can always avoid that remorse which Robert Burns confessed was so heavy a burden. I am conscious of many errors of judgment—call them mistakes if you will—and this knowledge encourages me to believe that there are good reasons to hope that, without diminution in surgical enterprise, this mortality may be considerably reduced. Unhappily, in their daily work, surgeons are constantly reminded that "ideals are not for attainment but for pursuit," and in this chase I like to think that we might arrive at a mortality of about 5 per cent., which I believe would represent the result of the acme of judgment and perfection of technical skill. But progress is evasive and "knowledge comes while wisdom lingers," or I would not have regretfully to confess that the last two cases of my series have both died, one as the result of a leaking anastomosis, and the other from heart failure because I carried out at one sitting what ought to have been a two-stage operation in a weakly and frightened subject.

This matter of the mortality cannot be viewed alone, for it has a very definite relationship to the question of operability. For my own part I suspect a surgeon of being too timorous who has a low mortality with only a low operability-rate. On the other hand, a surgeon with a high operability-rate and a heightened mortality is certainly endeavouring to do more for his patients, though he may engage in some desperate adventures.

Parts of the Bowel Involved.

—	Cases.	Deaths.	Percentage.	Stages of operation.
Cæcum	22	4	18·18	All in one.
Ascending colon	6	2	33·3	3 in one. 3 in two.
Hepatic flexure	7	0	—	3 in one. 4 in two.
Transverse colon	14	4	28·57	9 in one. 5 in two.
Splenic flexure	15	2	13·3	3 in one. 12 in two.
Descending colon ..	9	3	33·3	4 in one. 5 in two.
Sigmoid	69	12	17·39	26 in one. 43 in two.
Totals	142	27	19	70 in one. 72 in two.

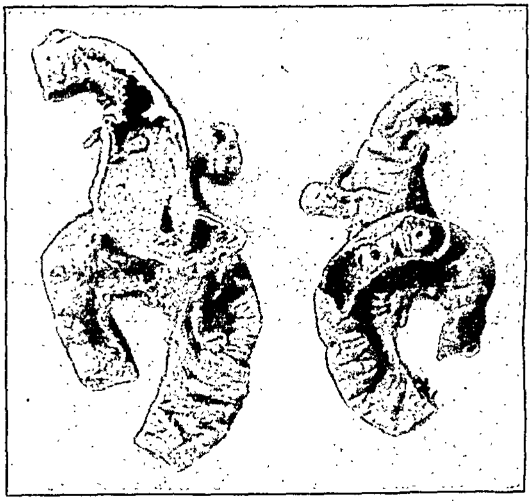
SITE OF GROWTHS.

It is interesting to note that in nearly half the cases the growths were in the sigmoid, and if we add those in the descending colon to the latter, then this region shows a marked preponderance—78 cases to 64 in the remaining parts of the great bowel taken together.

It is often stated that there are very marked differences between growths in the right half as contrasted with the left half of the colon, and that these differences have much bearing on the symptoms, the problems of diagnosis and treatment, the operative mortality, and the after-results. I can only say that I have not found it so marked, though, of course, my series is trivial as compared with the very large numbers dealt with in, for instance, the Mayo Clinic. There is this very clear difference—that the more urgent cases of obstruction, in which bowel drainage is clearly indicated, are far more frequent when the growth is situated from the splenic flexure onwards. In this gross difference a fallacy is concealed, for surgeons are often tempted to underestimate the significance of the lesser degrees of obstruction which do constantly occur with growths situated between the ileo-cæcal valve and the splenic flexure.

The consideration of these points leads to a study of the relationship of obstruction to the mortality of the operation of excision. My cases show that where patients have been subjected to preliminary drainage, the mortality of the subsequent excision has been almost halved.

FIG. 1.



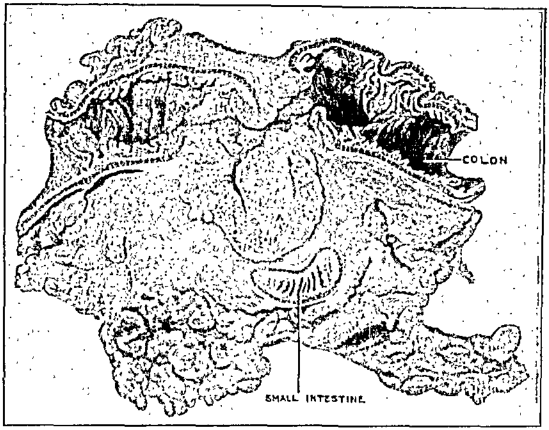
Carcinoma of the colon involving the small intestine and with three natural anastomoses. The uterine appendages were also involved. The patient was 65 years of age and had suffered from recurring colic for four years and bleeding for 12 months. This patient died after removal of the growth and at the post mortem no evidence of dissemination could be found. (Case 4 in table of multiple resections.)

CONDUCT OF THE OPERATION.

Seventy of the cases were operated on in one stage with 18 deaths (25·71 per cent.); whilst 72 were done in two or more stages with 9 deaths (12·5 per cent.). In 62 cases there was a preliminary cæcostomy or colotomy, and in 10 there were preliminary anastomoses. The mortality of the one-stage operations is the more to be regretted because they probably include most of the cases where the local conditions were the more favourable for removal.

Surgeons often deplore the fact that they do not get an opportunity of carrying out operation in cases of cancer of the colon until obstruction has developed, but these figures show that it is probably a matter for congratulation rather than complete regret, and that it is more correct to speak of obstruction as a fortunate accident rather than an unfavourable complication. There are two varieties of obstruction in connexion with big bowel growths; there is the sudden and acute obstruction which may be the first and only symptom that anything is wrong in that particular case. In my opinion this is a most fortunate happening, and reminds me of Kocher's dictum that the patient with the malignant growth at the outlet of the stomach was to be congratulated in that the mechanical obstacle drew so much earlier attention to the presence of the neoplasm and demanded earlier surgical interference. The other, and slower, obstruction, which culminates in an acute attack is rather different, and in this particular class of case the final acute obstruction is more unfavourable, because the bowel has become chronically distended, infected and sodden, *and there may be stercoral* ulcers, and it does not so quickly or readily recover as when the process has developed acutely. Though the patients' symptoms are not so obviously insistent there is more damage from toxæmia and more time is necessary for this to be overcome.

FIG. 2B.



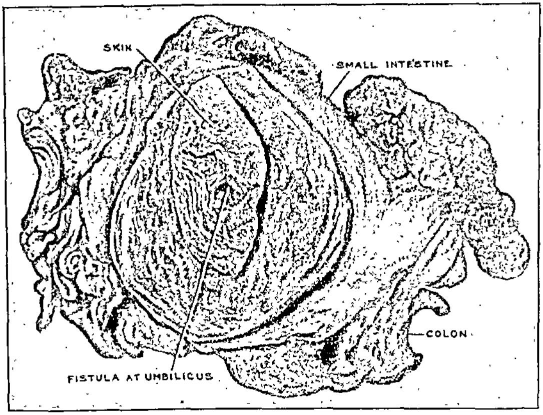
Shows the reverse of previous figure. The colon growth is seen in section. The portion of small intestine was as long as the piece of colon but is buried in the mass removed.

OPERABILITY.

This seems the proper place to deal with the question of operability. One principle has always guided *me in dealing* with intra-abdominal malignant disease—viz., *unless there is some unequivocal evidence of distant dissemination the patient deserves the chance which operation alone offers.* Whatever the future may have in store, in my opinion the time has not yet arrived when the progressive surgeon dare allow himself to be guided by any other rule. Undoubted secondary deposits in the liver, or diffused nodules in the peritoneum, or involvement of the glands in the left posterior triangle, or other distant metastases, are absolute contra-indications to radical operations. Free fluid in the abdomen is always of evil omen and, if associated with the presence of nodules felt in the recto-vesical pouch or elsewhere, means diffusion of the growth, but smaller amounts of fluid, and without evidence of nodules, may result from a slight persistent obstruction and need not debar us from successful interference.

The mere size of a growth, or its fixity, or the involvement of neighbouring structures need not mean that it is necessarily irremovable. In fact, I have long held that the larger growths, if of slow development, are often the more favourable. The size of the growth and the reaction of the surrounding tissues, as shown by the development of adhesions, suggest to me that, in that particular case, the body is capable of a good resistence to the malignant invasion and are really signs of good prognostic omen.

FIG. 2A.



Malignant growth of transverse colon invading an area of the abdominal wall around the umbilicus and with a fistula at the site of the latter. A loop of small intestine was also involved and had to be removed. The continuity of both parts of the bowel was *restored* and the patient was alive and *free from recurrence 9 years* and 4 months afterwards. (Case 8 in list of multiple resections.)

Not many years ago I was accustomed to see most capable surgeons declare growths to be irremovable simply because they were locally fixed and could not *be lifted out of an abdominal* incision. Of course, there is a fixation that is due to direct invasion of the surrounding parts by the growth, and that is undoubtedly more serious, but I can truthfully say that, in the absence of dissemination, the local conditions have seldom proved a bar to successful removal. Whether or not such removal has always been justified by the after-result is a difficult question to answer.

Generally speaking, extension of the growth into the mesentery is much more unfavourable than extension in the opposite direction, and few cases ultimately do well in which such mesenteric extension has occurred.

In dealing with malignant disease in general, the importance of assessing the degree of malignancy of any particular growth while it is yet in situ is one of the greatest desiderata. To the naked eye, regardless of its training, and later to *ordinary* microscopic examination, there are no means of telling which growths will soon recur, and which may be expected to pursue a less rapid course. I make bold to assume that the behaviour of malignant growths may depend as much on the soil—that is to say, on the individual affected—as on the particular growth. But this I can say, that when I have felt that a radical operation could not be done because of the presence of dissemination, or the local extension of the growth, or the presence of glands, and have carried out a short-circuiting or other palliative measure, my patients have speedily gone downhill towards an inevitable fatal issue. It has not been my experience to have patients survive for many years after any of these palliative measures.

Multiple Resections.

No.	Extent.	Stages.	Result.	Remarks.
1	Transverse colon, loop small bowel with abscess.	One	D.	Peritonitis 5th day.
2	Sigmoid with uterus, tubes and pelvic pertoneum.	Two	C.	Permanent colotomy. Died recurrence 3½ yrs. later.
3	Cæcum and ascending colon with 9 feet small intestine and abdominal wall.	One	C.	Died at 12 mths. Apoplexy.
4	Sigmoid with small intestine and left appendages.	One	D.	Peritonitis—anastomosis gave way (Fig. 1).
5	Sigmoid with uterus, ovary and pelvic peritoneum.	One	C.	Permanent colotomy. Died 5 yrs. and 8 mths. later without recurrence.
6	Ascending colon and large mass small intestine.	One	D.	Peritonitis.
7	Sigmoid with left appendages.	Two	C.	Permanent colotomy. Died 14 yrs. and 4 mths. later. No recurrence.
8	Transverse colon, small intestine, abdominal wall.	Two	C.	Alive without recurrence, 9 yrs. and 4 mths. later (Fig. 2).
9	Cæcum, ascending colon and piece of duodenum.	One	C.	Died of recurrence in 3 mths.
10	Sigmoid and piece of bladder.	Two	C.	Permanent colotomy. Alive and well at 8 yrs.
11	Splenic flexure with strip of fundus of stomach and tail of pancreas.	Two	C.	Alive and well 7 yrs. and 10 mths. later.
12	Sigmoid with uterus and appendages.	Two	C.	Died of recurrence at 1 yr. and 7 mths.
13	Sigmoid and loop small intestine.	Two	C.	Alive and well at 4 yrs. and 7 mths. (Fig. 3)
14	Sigmoid with large area abdominal wall.	One	C.	Alive and well at 4 yrs. and 8 mths. (Fig. 6).
15	Sigmoid with left appendages.	Two	C.	Died of recurrence at 1 yr. and 3 mths.
16	Splenic flexure, small intestine, cuff of stomach.	Two	C.	Alive and well at 2 yrs. and 4 mths. (Fig. 4).
17	Sigmoid, small intestine and uterus.	One	C.	Secondary anastomosis. Alive and well at 2 yrs.
18	Splenic flexure and small intestine.	One	C.	Died in a few months; secondaries in liver.
19	Sigmoid with left appendages.	Two	C.	Died of recurrence at 1 yr. and 10 mths.
20	Sigmoid with uterus and appendages.	Two	C.	Secondary anastomosis; early recurrence.
21	Sigmoid with uterus.	Two	D.	Paralytic ileus.
22	Transverse colon with pylorus.	Two	C.	Recent.

Total, 22 cases with 4 deaths = 18·18 per cent.

Much has been said about the low grade of malignancy of bowel growths, but that general statement requires some qualification. While a large proportion of these tumours display this comparative benignity, another large group certainly do not. Among the latter are many where dissemination occurs early and where natural termination occurs in as many months as the other type may take years.

Quite possibly surgeons get a distorted view of this matter, for they are only likely to see the cases which have *remained local for long*, and are not consulted about those where early local or general dissemination has left them under the care of those who recognise that the need for surgical interference never arises.

I have seen many of this type. Some figure among those of my series where exploratory laparotomy only was carried out, and many among the cases subjected to the makeshift operations. Many of those which follow an acute course probably masquerade under the care of the physician because they early develop peritoneal deposits with ascites, or secondary deposits in the liver, either of which overshadow the symptoms of the primary growth. Thus, those which may have been slow in arriving at such a condition in which surgical intervention may be required, *often seem less virulent in their progress*, though it may be that the measures necessary for their removal, or for other surgical treatment by palliative operations, may sometimes be the means of hastening their progress. When the case appears to be of the more indolent type the surgeon may take heart of grace, for it is wonderful for how long they may remain local (Fig. 1).

Deep conviction leads many in our profession to believe that cancer is never a local disease, and that it can never be eradicated by local interference. This attitude may certainly apply "the spur to investigation, and the rein to hope," but it is indeed an unhappy frame of mind for the surgeon. I am accustomed to tell students that in dealing with cancer the surgeon should have faith in its local nature, *such faith as is suggested by Millet's famous* picture, "The Angelus." Without such faith the half-hearted efforts of the timorous rob them and their patients of their just rewards. The best commentary I can make on this question of operability is to refer you to the table of multiple resections.

THE FUNCTIONAL RESTORATION OF THE PATIENT.

Patients have no real knowledge of, and less sympathy with, technical difficulties, and only value the work of the surgeon and the worth of his operations by the perfection of the functional results. We therefore aim at restoring the continuity of the intestinal canal, and often at considerable risk. In this series of 142 bowel excisions, this happy result was brought about in 124, and only in 18 was it necessary to leave a permanent colotomy after successful removal of the growth. In eight cases Paul's method was employed, and I would like to say how much the work of that surgeon has helped in the progress of the surgery of the large bowel. It will always remain as a milestone that will not be forgotten.

So much for the immediate results and the technical success of the measures employed. The following list epitomises the after-history of those cases which survived:—

After-history of 115 Patients who Survived the Operation.

- 32 are either alive or are known to have died without recurrence more than five years after operation.
  - 26 are alive and well more than five years after operation.
  - 6 are dead, but without recurrence more than five years after operation.
- 30 are known to be alive and well without recurrence less than five years after operation.
- 2 died within a year without recurrence.
- 41 are known to have died of recurrence.
- 3 are alive, but with recurrence.
- 7 have not been traced.

It would ill become me to endeavour to bias you in favour of the results which I am able to present, but in order that they may be the more encouraging, and in common fairness, I would point out that there has been no exclusive selection of cases, for I have always believed that in the gastro-intestinal canal, excision of a malignant growth is the best method of palliation. Many unfavourable cases have been tackled with this in view, but they have not been differentiated in making the analysis of the results. Had I only included the cases in which there seemed to be a good prospect of ultimate success, the record would have been a better one, though the numbers must have been considerably smaller.

Details of 26 Patients Alive and Well More than Five Years after Operation.

2	after	15 yrs.	2	after	9 yrs.
1	,,	14 yrs. 4 mths.	2	,,	8 yrs. 8 mths.
3	,,	14 yrs.	1	,,	8 yrs.
2	between	11 and 12 yrs.	3	between	7 and 8 yrs.
1	after	10 yrs.	5	,,	6 and 7 yrs.
1	,,	9 yrs. 8 mths.	3	,,	5 and 6 yrs.

Six patients died without recurrence more than five years after operation. Thus:—

Details of Six Patients who Died More than Five Years after Operation Without Recurrence.

1 died at 14 years and 10 months from old age.
1 ,, 14 ,, ,, 4 ,, from apoplexy.
1 ,, 10 ,, from apoplexy.
1 ,, 7 ,, and 3 months from influenza.
1 ,, 7 ,, from cirrhosis of the liver.
1 ,, 5 ,, and 8 months from nephritis.

As there was no post-mortem examination, some may express a doubt about the case returned as dead from cirrhosis of the liver. This man was a life-long alcoholic and was known to have continued in his evil ways after the operation, and his medical attendant was himself sure that cirrhosis and not cancer was the cause of death.

There is no period at which a patient may be said to be free from the possibility of recurrence, but the likelihood diminishes rapidly after five years, and I always feel anxiety with regard to recurrence until that period has passed.

Details of 30 Patients who are Alive and Well Less than Five Years after Operation.

5	between	4 and 5 yrs.	8	between	2 and 3 yrs.
5	,,	3 and 4 yrs.	12	less than	2 yrs.

These results are brought out in percentages as follows:—

Five-year Period.—Out of 82 cases operated upon, and who survived the operation, 32, or 39 per cent., are either alive without recurrence, or are known to have died without recurrence.

Three-year Period.—Out of 97 cases 42, or 43·3 per cent., are alive and well without recurrence.

The remarks already made about the absence of selection for the operation of excision bear equally, but in the opposite sense, on the results as set out below:—

Details of 41 Patients known to have Died with Recurrence.

1	over	7 yrs.	5	between	3 and 4 yrs.
1	between	6 and 7 yrs.	3	,,	2 and 3 yrs.
1	,,	5 and 6 yrs.	15	,,	1 and 2 yrs.
1	,,	4 and 5 yrs.	14	less than	12 mths.

The intermediate health of the patients who survived for a year or more was usually remarkably good, and for the most part the symptoms of recurrence only appeared a few months before death. Those who died within the year were probably examples of continued disease, rather than the victims of recurrence.

MAKESHIFT OPERATIONS.

As has been already pointed out, my effort has always been directed to the carrying out of an excision, for though it sometimes appears to have little chance of leading to a long period of relief, it often turns out better than is expected, and usually gives the patient more complete and longer relief than an operation that leaves the growth, and aims at palliation by other methods. This preliminary statement is by way of explaining my title of *makeshift operations*, and is to prepare you for the sorry tale which I must now unfold.

It has not been my lot to meet with those long and unexpected periods of relief after palliative operations which others have often recorded. Indeed, were it so, I would suspect that I had been too reticent in my interference, too timorous and unenterprising. As bearing on this I have to record that in both cases that have survived after colotomy for four years and four months, and for three years, no portion was removed for microscopic examination, and there remains the element of doubt as to their pathology, though I had no sort of doubt at the time of the original exploration. In both cases the colotomy was carried out tentatively, and it was hoped that if they improved sufficiently, or did better than might be expected, a further operation would be carried out. One of the patients is reasonably well and content with the colotomy, and in the other extraneous circumstances have intervened to make it economically sounder for his family that he should not face the very considerable risk that a further operation would involve.

Results of the Makeshift Operations.

Short Circuiting.

45 cases with 9 deaths, or 20 per cent.
7 have not been traced.
29 are dead, the average duration of life being just under eight months. The longest survival was 2 years and 5 months.

Some Type of Colostomy.

40 cases with 15 deaths, or 37·5 per cent.
5 have not been traced.
4 are alive { 1 at 4 years and 4 months.
1 at 3 years.
2 are recent.
16 are dead, the average duration of life being just over eight months. The longest survival was two years.

Explorations only.

14 cases with 6 deaths, or 42·85 per cent.

Even in the presence of obvious dissemination interference may be called for to relieve symptoms due to obstruction, &c., and none need be denied the benefits of a timely palliative operation if by its means pain and discomfort can be relieved, so that they may be able to say with Don Quixote:—

> "Come Death with gently stealing pace
> And take me unperceived away,
> Nor let me see thy wished for face,
> Lest joy my fleeting life should stay."
> (*Translation from the Spanish by Charles Jarvis.*)

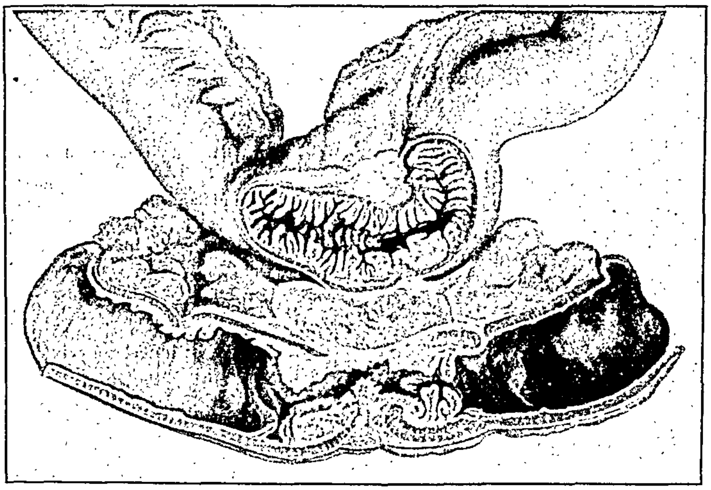
In the light of these results I would suggest: that excision holds out a good prospect of long relief; that it can frequently be carried out and with a lower mortality than palliative operations; that excision, even if followed by early recurrence, is the best palliative in most cases; that the operation of excision is much safer if carried out in stages; and that obstruction has usually proved a beneficent complication.

DIAGNOSIS.

When we come to deal with actual patients, this is the first problem we have to face. As surgeons, we constantly complain that cases of colon growth reach us too late, and on the other hand I am afraid we as constantly assume that they might have come much earlier. In my series no less than 62 of the cases have first come under my care with some degree of obstruction. So far as the patients themselves have been concerned, the first symptoms, or the symptoms which have culminated in an attack leading to the necessity for an abdominal operation, have been obstructive in character. In this particular group there have not always been the preliminary symptoms which one assumes must have been present. In other words, an attack of obstruction may be the first sign of the presence of a colon growth. Other patients have undoubtedly suffered for long periods from symptoms which, in the light of subsequent developments, can only be regarded as of a preliminary nature. These, again, fall into two very different groups: those who have *attacks* of obstruction, pain or hæmorrhage, which pass off and leave them in complete freedom for a varying time, during which they naturally congratulate themselves on their complete restoration to health; the other group who suffer from continuous disturbances, slight though they may be, of abdominal disorder of one sort and another. The more often I am confronted with the problem of making a diagnosis where the symptoms are not definite, the more am I impressed with the difficulties which present themselves, and the more and more do I sympathise with the position in which the medical man frequently finds himself.

The symptoms which suggest the presence of a bowel growth are well known, but the classical descriptions given in many books are only of the later stages, when the disease is already well established. The most important early symptoms are pain, in the form of attacks of mild colic, irregularity of the bowels in those previously regular (this usually means quite unexpected constipation); indigestion with bowel irregularity; considerable loss of blood and with any of these symptoms recurrence, in spite of intelligent treatment, and progressive loss of weight and vigour. I have not personally encountered many of the cases in which obvious anæmia has been a prominent early feature.

FIG. 3.



A growth of the summit of the sigmoid with a loop of involved small intestine. The operation was carried out in two stages and the continuity of the bowel restored. The patient is alive and well 4 years and 7 months afterwards. (Case 13 in list of multiple resections.)

What, then, are the routine steps to be taken when the symptoms indicate that suspicion of a bowel growth is well founded? The first and foremost is ordinary clinical examination. Of the abdomen in the first place for the presence of a lump, to estimate the significance of slight distension or fullness, and to carefully look for the presence of exalted peristalsis. Further, it must be a routine to search for evidence of that tell-tale dissemination which may be unexpectedly present, such as other lumps in the abdomen, deposits in the pouch of Douglas, peritoneal fluid, or a gland in the left posterior triangle of the neck. Rectal examination is always essential, for it may disclose a low-lying growth and, what is commonly forgotten, it reminds us of the necessity for bimanual examination, which may occasionally yield valuable information, even when carried out without anæsthesia. Secondly, inspection by the sigmoidoscope; thirdly, the result of an opaque enema or of a bismuth meal in this order; and, fourthly, inspection of the evacuations for mucus and blood.

I know how you would all welcome the announcement of some new test or the elaboration of some method for the more certain diagnosis of these cases, but I feel that I have often to plead unpopular causes, and I have now only to urge that when, in spite of the negative result of all these methods of examination, the symptoms continue, then the most valuable method *is repeated ordinary examination under varying conditions.* Over and over again a lump which is not to be felt at one time is only too obvious at another. Or on some occasion, and especially during an attack of pain, a localised contraction of the cæcum, or some other part of the large bowel, is perfectly obvious; whilst on other occasions, in the same patient, there may be nothing whatever to be made out. It is just because a repeated examination under different conditions is so important that one has to recognise that in this matter the general practitioner may be so helpful. It is often wiser to have these doubtful cases under observation in hospitals, whether private or public, and I cannot let this opportunity pass without saying how greatly we are hampered in our work in this country by the inadequate bed accommodation in surgical hospitals, so that we are robbed of the opportunity of that leisurely observation which is often so essential.

The most difficult and dangerous thing is to make a negative diagnosis and to say that because of the absence of signs under the various heads which have been mentioned, no growth is present. This causes a sense of artificial security, the patient may be content to be doctored or to doctor himself for many valuable months until some blatant development confirms the suspicion which has existed for long, but which makes the outlook for the patient considerably worse. This especially applies with regard to the negative result of radiographic examination, which I have no hesitation in saying is as yet, and in the hands of most people, the least valuable of the methods of diagnosis. As recently as eight years ago a prominent surgeon and teacher wrote as follows in connexion with this question:—

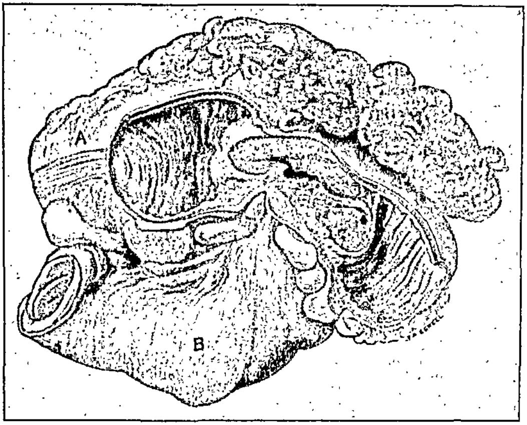
> "Although the disease runs a chronic course, and the sign-posts which point to its presence are generally obvious enough, it is surprising, as well as somewhat deplorable, to find so many cases do not reach the surgeon until the symptoms have culminated in complete obstruction. The symptoms ought to be sufficiently appreciated by the medical attendant to rouse his suspicion at any rate, and all he has to do is to call in the aid of a good radiographer who can not only settle the diagnosis but, what is equally important from the surgeon's point of view, can also demonstrate the position of the tumour."

I feel sure that no radiographer or clinician could entirely agree with the latter part of this statement to-day, but the impression has unfortunately not yet been eradicated from the minds of the public.

Before leaving this question I want to utter a warning about the use of the sigmoidoscope. It is frequently urged that this instrument should be in the hands of every practitioner, and should be used as freely as the laryngoscope, or even the tongue depressor! Its use is certainly not without danger, especially when it is passed blindly, as is sometimes recommended even at the present day. Many years ago I unfortunately perforated the sigmoid in two places with this instrument, and in spite of immediate laparotomy the patient died of peritonitis. Recently I had the curiosity to write to six of my surgical friends in various parts of the country, and as a result of their kind response, I have heard of four other cases in which the accident has occurred. This experience ought to be a sufficient warning.

When reasonable doubt exists and the methods of diagnosis prove inconclusive, an exploratory operation is certainly not only justifiable but indicated. Such an exploration must be very thorough. I have to confess that I have actually opened the abdomen, and have failed to discover a string carcinoma of the splenic flexure, which was found at a post-mortem examination some few days afterwards. The only bright spot in the dull picture is the fact that at the time of operation the patient was actually suffering from pylephlebitis, so that my oversight had really nothing to do with the unfortunate sequel.

FIG. 4A.



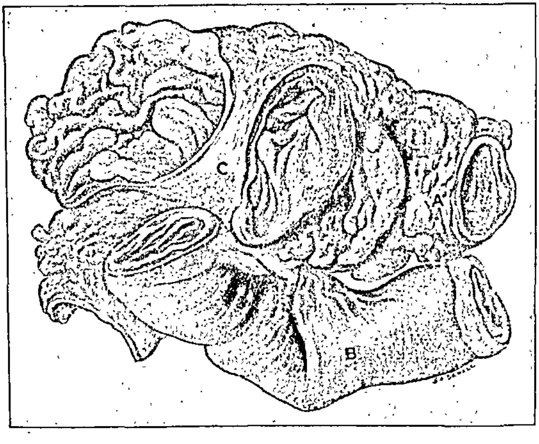
Carcinoma of the splenic flexure. A, involving a loop of jejunum: B, and also the stomach. Fig. 4B shows the portion of stomach C. The operation was done in two stages and the patient is alive and well 2 years and 4 months afterwards. (Case 16 in list of multiple resections.)

INVOLVEMENT OF THE GLANDS.

This seems a convenient place merely to mention one or two pathological matters that have a bearing on the management of these cases and on the after-results. Surgeons the world over are greatly indebted to those who have done so much to elucidate the vascular and lymphatic arrangements of the large bowel. The work of Jamieson and Dobson is universally recognised as a sure guide, and it is a great and well-deserved compliment that time and the experience and practice of all surgeons confirm their observations. The careful papers of Clogg are also most helpful.

From the point of view of living pathology I would just say that it is often impossible to express a naked-eye opinion of any value with regard to the lymphatic glands, as seen in situ. Obvious infiltration, as when colloid substance shines through their capsules, or when they are so crammed with growth that they are uniformly white and hard, is unmistakable. It is the significance of their mere enlargement which is so difficult to assess. At the outset of my operative career I became impressed by this in some cases of gastric cancer, for I learnt that suspicious-looking glands were as often as not merely septic or hyperplastic in nature. Later, I have come to believe that glands may probably overcome even an appreciable cancerous invasion.

FIG. 4B.



Same case as Fig. 4A. Shows the portion of stomach C.

The practical lesson I want to convey is the importance of not being deterred by the presence of these suspicious glands, and if an excision can be made without actually cutting through glands, then I do so, rather than not give the patient the chance of being relieved of an otherwise removable growth. In the case of one of my first excisions of the cæcum the glands and lymphatic vessels as high up as the point of ligature appeared to be invaded with growth, and yet that patient is to-day, 15 years afterwards, alive and free from recurrence.

In this series one of the growths was a sarcoma, the remainder being columnar-celled carcinoma. Only a small proportion were definitely of the colloid type.

In the concluding part of his Oration, which will appear in our next issue, Mr. Grey Turner deals with the Actual Management of Cases.

Oliver-Sharpey Lectures

ON THE

PHYSIOLOGICAL ANALYSIS OF SOME CLINICALLY OBSERVED DISORDERS OF MOVEMENT.

Delivered before the Royal College of Physicians of London

BY F. M. R. WALSHE, M.D., D.Sc. LOND.,
FELLOW OF THE COLLEGE; PHYSICIAN-IN-CHARGE OF THE NEUROLOGICAL DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL, AND PHYSICIAN TO OUT-PATIENTS, THE NATIONAL HOSPITAL, QUEEN-SQUARE.

LECTURE II.*—THE TREMOR-RIGIDITY SYMPTOM-COMPLEX.

(*Delivered on May 2nd, 1929.*)

THE tremor-rigidity symptom-complex is seen in characteristic form in Parkinson's disease and as a sequel of epidemic encephalitis. In the latter condition frequently, and in the former occasionally, rigidity may be observed without visible tremor. On the other hand, tremor may dominate the clinical picture in either condition, but is never found without some rigidity in the muscles which produce the tremor. It is probable that the apparent separation of rigidity from tremor is not absolute, since the "cog-wheel phenomenon," so common in these circumstances, is almost certainly an expression of the disorder of innervation which, when present in greater degree, produces visible tremor.

In pure cases of the symptom-complex signs of disturbance of function in the pyramidal system are lacking, and we may assume that this component of the motor mechanism is intact. Considered, therefore, from Jackson's point of view we are dealing with an example of *local dissolution* of function in some one or more components of the neuromuscular mechanism subordinate to the pyramidal system. From what has been said earlier it will be apparent that the resulting disorder of function must be of the nature of a general reaction, in the sense that this has been defined.

In a preliminary classification of the disorders of motor function seen in a typical case of paralysis agitans, we may place under the heading of *defect symptoms* the following items: a certain slight but definite falling off in the force of voluntary movements, a slowing of the rate and a limitation of the range of voluntary movements, a damping down—amounting sometimes almost to extinction—of the normal movements of facial expression and of the limb gestures that may accompany them, and also of those accessory movements of the head, trunk, and limbs which accompany free voluntary movements of the individual as a whole, such as the swing of the arms and trunk in walking.

CHARACTER OF THE DISTURBANCES OF MOVEMENT.

It has been maintained by some authorities that there is a specific impairment or loss of these so-called automatic and expressional movements, as contrasted with what are called voluntary movements, and a special representation of the former groups in the basal ganglia has been postulated. Any distinction, other than one of degree, between voluntary and automatic movements is artificial. We may, perhaps, in Jackson's terminology, speak of some skilled acquired movement of the hand as "most voluntary and least automatic," or of some such simple movement as clenching the fist as "least voluntary and most automatic," but which of these qualifying terms is to be applied to a given movement must depend on the circumstances of its performance. Further, the view that a group of automatic movements has a special striatal localisation involves us in the hypothesis that a given movement comes to have two separate cerebral representations, cortical and striatal, or that at some undefined stage in the motor education of the individual such a movement changes its cerebral localisation from cortex to basal ganglia. Therefore, *followed to its logical conclusions*, the distinction between voluntary and automatic movements is seen to be wholly unphysiological.

Moreover, the clinical evidence affords no confirmation of the selective loss of movements defined as automatic. *All* movement is affected, and this according to a much simpler formula than the one above discussed. It is, in fact, the force with which a movement is normally carried out that seems to determine the degree to which it is damped down. The movements of facial expression afford a ready illustration of this generalisation. The normal play of expression over the face, when powerful emotions are not involved, is compounded of fleeting muscular contractions of minimal force, involving fractional activity of the muscles concerned and little expenditure of energy. That there is no true loss of these movements is revealed by their appearance in ample range if an adequate emotional stimulus be forthcoming. In such circumstances, a broad smile may be seen to dawn slowly on the previously immobile parkinsonian face, slowly to reach its maximum, and after an unduly prolonged stay as slowly to pass off. In less striking degree the movements of the trunk and arms accessory to normal walking may in a measure be brought out, and it is a common experience that under pressure of emergency or under stress of feeling the subject of paralysis agitans will abandon transiently his short-stepped, festinant, and monotonous gait for a free and rapid action in which the arms partake. There is, therefore, no loss of any movement, but there is a damping down of the range and speed of all movements and an apparent extinction of those which are normally of feeble intensity. Hence it is that in walking the accessory movements tend to disappear, leaving in action—themselves by no means unimpaired—only those primary components of the total movement-complex which are essential to the achievement of the subject's purpose.

If we now consider these primary and essential components—as we may call them—of a given purposive movement we find them to be abnormally slow in starting and in performance. They tend to decelerate progressively in many cases and may be brought prematurely to a stop in mid-course. For example, if the subject of a moderately severe grade of paralysis agitans be asked to remove his coat, we may see him become immobile with the garment only half doffed. A fresh effort is then needed to re-start and complete the interrupted movement. That this disability is not a measure of a loss of voluntary power in the muscles concerned may readily be demonstrated by requiring the patient to maintain some active posture of a limb against resistance. We find that he can, for example, maintain flexion at the elbow against powerful traction on the forearm.

Further, in the performance of such alternating movements as flexion-extension of the fingers, or pronation-supination of the forearm, we observe a progressive deceleration and decrease of range in each successive component movement until nothing but a tremulous oscillation round a fixed point remains. It seems almost impossible for the patient indefinitely to carry on any rhythmic movement of greater amplitude than that of the ordinary parkinsonian tremor.

Whereas in a normal subject carrying out some free unresisted movement the force exerted is maximal at the initiation of movement and thereafter wanes, it appears that throughout the whole course of a movement in the subject of paralysis agitans a maintained, or even a waxing effort is required to achieve completion.

Related to these difficulties in active movement must be the striking immobility of attitude which many individuals thus afflicted show, even under considerable cutaneous stimulation, such as contact with hot objects or the tickling caused by a fly crawling over the skin.

---

* Lecture I. appeared in THE LANCET of May 11th.

If we attempt a generalisation of these peculiarities, we may say that while active postures can be maintained with approximately normal force, those muscular activities which necessitate free active changes in the length of the muscles—that is, lengthening and shortening of the constituent muscle-fibres—are seriously impaired. They are abnormally slow in initiation and performance, they are restricted in range, and may be brought to a stop before completion. In short, it seems that *in voluntary movement there is some impediment to changes in length of the muscle-fibres, but relatively little impairment of the power of the muscle-fibre to maintain tension at fixed lengths.*

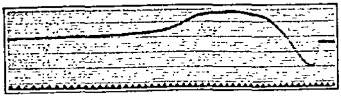
It seems necessary to qualify this generalisation by the introduction of the word "voluntary," since in the tendon-jerks and in the abdominal reflexes free muscular contraction of full range appears to take place at approximately normal speed. That is, the activation of the muscle-fibres by purely spinal reflex mechanisms seems able to produce contraction of the normal order.

Under the heading of *release symptoms,* tremor and rigidity must clearly come in our provisional classification, but there are one or two other characteristic symptoms which cannot yet be so easily placed in their proper category. Such are the festinant gait, the propulsion and retropulsion seen in so many subjects with paralysis agitans. The discussion of these may be deferred until we have considered the rigidity and its influence upon movement.

PARKINSONIAN RIGIDITY.

The salient features of this form of rigidity may be summarised as follows: (*a*) It is diffuse in distribution and lacks the selective incidence of spasticity and of decerebrate rigidity. (*b*) It remains of unvarying intensity through the fullest possible range of shortening and lengthening. There is no "clasp-knife" phenomenon—that is, no trace of lengthening reaction. (*c*) While it responds to sudden stretch by a tendon-jerk, sustained stretch does not produce clonus, and the graphic record of the knee-jerk lacks the "hump" characteristic of the spastic and decerebrate knee-jerks. (*d*) It is apparently wholly uninfluenced by afferent impulses arising in the labyrinths or in proprioceptors in muscles elsewhere. Therefore there is no trace of the tonic reflexes of Magnus and de Kleijn. (*e*) The rigidity is not subject to inhibition by intercurrent exteroceptive or cutaneous reflexes, but persists at a remarkably constant level unaffected by environmental stimuli of all kinds. (*f*) It is not accompanied by release of the spinal flexion or crossed extension reflexes, and the plantar responses remain of normal type. (*g*) Finally, it appears to be proprioceptive in origin, since de-afferenting the muscle by novocaine injections abolishes rigidity.

FIG. 1.



Graphic record of knee-jerk from a subject with parkinsonian rigidity. If the record be compared with those figured in Lecture I., it will be found to present a characteristic ascent curve, plateau, and curve of relaxation, all differing from these components of the normal and spastic knee-jerks. This record was made by Dr. E. A. Pritchard. Read from right to left. *Time-marker strokes correspond to 0·01 second.*

From this résumé it is clear that we are dealing with a form of tonic muscular activity profoundly different from that considered in my previous lecture.

The integrity of the afferent nerve-supply to the muscle appears essential to the development of any form of tonic muscular contraction. In observations recorded elsewhere [10] I found that the intramuscular injection of novocaine in a 1 per cent. solution into the belly of a muscle showing parkinsonian rigidity abolished this rigidity, while leaving the voluntary power of the muscle intact. The effect of this procedure, as Liljestrand and Magnus [7] have shown, is to paralyse the afferent nerves of the muscle while leaving the motor nerves intact. Thus a physiological de-afferentation is produced. Pyramidal spasticity is also abolished in this way, and we may therefore regard both forms of tonic contraction as proprioceptive in origin.

Prominent among the features in which parkinsonian rigidity differs from the forms of hypertonus considered in the last lecture are the lack of a reciprocal relationship between extensors and extensors, and an apparent immunity to many of the sources of inhibition that modify decerebrate rigidity and normal tonus.

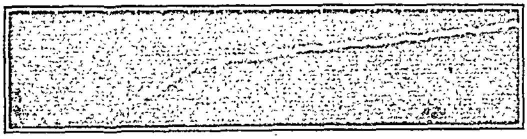
The occurrence of brisk tendon-jerks shows that the stretch reflex mechanism is active, while the form and time relations of the graphically recorded knee-jerk indicate that the inhibition which normally ensues upon sudden stretch excitation of the muscle is in operation. Yet the maintenance of this stretch does not produce clonus, a condition in which excitation and inhibition alternate. Similarly, the complete absence of the "clasp-knife" phenomenon—that is, the lengthening reaction—also points to some derangement of normal inhibition. Further, the facility with which decerebrate rigidity is transiently overset by cutaneous stimuli of various kinds is not found in parkinsonian rigidity.

Denny-Brown[8] believes that the inhibitory end-organ in the muscle is the muscle spindle, a structure so situated as to respond to passive changes in tension produced by muscular contraction. In this connexion the observations of Byrnes [8] may have some significance. Byrnes examined histologically pieces of the small hand muscles from rigid subjects of paralysis agitans, and records widespread and intense degenerative changes in the muscle spindles. He suggests, therefore, that the spindle must be a tone inhibiting organ, the destruction of which allows the development of hypertonus. At first sight the hypothesis is attractive, but on close analysis is found to contain insuperable difficulties in the way of its complete acceptance. Thus, in a single case of post-encephalitic parkinsonism with rigidity, the muscles examined by Byrnes revealed no lesion whatever of these afferent end-organs. If typical parkinsonian rigidity can develop in the presence of normal spindle innervation, the degeneration of the spindles in paralysis agitans cannot stand in any causal relationship to the rigidity. Further, a degree of spindle degeneration capable of resulting in rigidity must profoundly modify the curve of relaxation of the knee-jerk, since this relaxation is in part an inhibitory phenomenon. In fact, the observations of Pritchard, already referred to, show no such modification.

Finally, the mode of onset and the progress of paralysis agitans do not suggest that the underlying lesion is a degeneration of peripheral nerve-endings. Occasionally, a Babinski response is seen as a neighbourhood symptom in cases of post-encephalitic parkinsonism, and when not present may sometimes be produced as a transient phenomenon by the hypodermic injection of scopolamine.[11] Its occurrence in these circumstances is regarded as indicating a spread of the relevant pathological process in the region of the basal ganglia into the internal capsule. It is not possible to understand how this sign could appear were we dealing with a muscle spindle lesion. Even Byrnes himself is forced to invoke changes in the basal ganglia to explain the rigidity following encephalitis. Therefore, it is difficult to see how his observations can be correlated with the rigidity of paralysis agitans.

Striking as are the differences in behaviour of the rigidity of paralysis agitans, when compared with at rapid rates is from two to five per second, or more rarely as high as ten per second. The electromyogram reveals that this clonus is associated with an "abrupt tetanus of asynchronous volleys (of impulses) at the rate of 160 to 180 per second" consisting in all of some three to five volleys for each beat. It is possible, then, that the wave rhythm of voluntary innervation is of cortical origin. To this question we must later return.

FIG. 6.

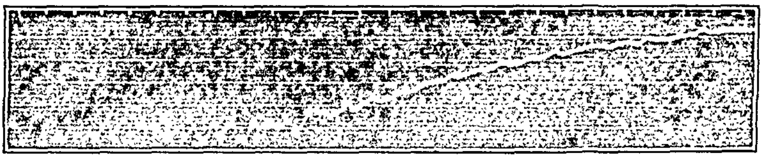


Curve of voluntary index flexor contraction from same subject as Fig. 4, but from opposite arm. No visible tremor. Rhythm 8·5 per second (arm less rigid than opposite arm) but accelerating and increasing in amplitude at turning point.

Is there any relationship between this normal rhythm and the cog-wheel phenomenon and tremor of paralysis agitans?

In the subjects of post-encephalitic parkinsonism without visible tremor a similar slow movement curve is obtainable. Fig. 5 is such a curve recorded on a smoked drum, while Fig. 6 is an optical record obtained from the same patient. Here the form of the curve is the same as the normal one, differing in that the waves are somewhat slower (7–8 per second) and of greater amplitude. There is no qualitative difference of any kind.

FIG. 7.



Curve of voluntary index flexor contraction from a case of paralysis agitans with rigidity and tremor. Rhythm 7 per second. Waves accelerate slightly and increase in amplitude as digit steadies at turning point. At this point a visible tremor appeared. In this subject resting tremor-rate 5 per second.

If we pass now to paralysis agitans with both tremor and rigidity we obtain such a curve as Fig. 7. Here the waves are still more ample, easily visible at the end of movement, and of an even slower rhythm (6–7·5 per second), which is that of the spontaneous tremor of the subject during movement. In this case the resting tremor was of a rate of five per second. Similar curves taken from a series of subjects with varying degrees of rigidity and tremor, and some without visible tremor, show every gradation between the normal amplitude and rate of wave and those illustrated in Fig. 7.

From these observations it seems a justifiable hypothesis that the cog-wheel phenomenon and the tremor of paralysis agitans and of post-encephalitic parkinsonism are not more than the exaggeration of a normal phenomenon. The slighter degrees of exaggeration are shown by the cog-wheel phenomenon alone, greater degrees by the appearance of tremor during the maintenance of postures, and the maximal degree in a free and ample tremor which is virtually constant. The slowing of the rate of beat is probably a result of muscular rigidity, to the degree of which it seems proportional.

The fact that this exaggerated beat tends in more rapid movements to be smoothed out even in the subject of visible tremor, as is seen in Fig. 8 obtained from the same patient as Fig. 7, tends to corroborate this view of the origin and nature of tremor. Further confirmation of the view is the fact that in many instances rapid movement of a tremulous member tends to obliterate tremor temporarily, while abrogation of cortical innervation as in hemiplegia also stops it.

As has been mentioned earlier, it is probable that the waves seen in the curves of voluntary contraction are of cortical origin, and that they stand in some relationship with the rate of discharge of the cortex. The electromyographic studies of Adrian and Bronk[1] indicate that with increased force of muscular contraction, either voluntary or reflex, there is a greater frequency of central efferent discharge to the muscle associated with a greater frequency of contractions in the individual muscle-fibres.

It may be that the waves seen in the curves of slow voluntary contraction express a slow rate of cortical discharge, while the disappearance of these waves in rapid movement is due to a more rapid rate of discharge from the cortex. In parkinsonian rigidity without visible tremor this wave fusion occurs less readily, while in paralysis agitans with tremor it does not occur at all, or only when extensive and rapid muscular contraction occurs.

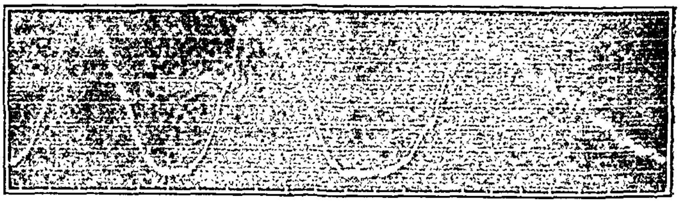
It may also be, assuming the rates of cortical discharge to be relatively little variable, that it is a function of some lower level nervous mechanism to "smother" the cortical rhythm, the impairment of this mechanism in paralysis agitans allowing this rhythm to come through. Possibly, again, both factors are at work in the production of tremor.

We may, therefore, reach this provisional conclusion that tremor is not a new phenomenon representing a mode of innervation peculiar to paralysis agitans, but is the emergence of a normal cortical rhythm through defect of lower level mechanisms.

If this view be well founded, we must conclude that there are factors underlying the development of tremor that play no part in that of muscular rigidity.

The observation referred to earlier, showing that tremor persists undiminished in the de-afferented muscle, whereas rigidity is abolished corroborates such a conclusion.

FIG. 8.



Curve of voluntary flexor extensor contraction at increasing speed. As in Fig. 3, from a normal subject *the waves wane in amplitude and tend to disappear as speed increases*, but they are not so readily "smothered" as in the normal subject. The curve at left represents the maximum possible speed for the subject.

One further point remains for brief consideration. Is tremor related to the ordinary proprioceptive clonus seen in spasticity and in decerebrate rigidity? Its persistence after de-afferentation of the tremulous muscle, and the absence of proprioceptive clonus in paralysis agitans both negative such a suggestion.

A further conclusion now seems justified—namely, that cortical activity is an essential condition of the appearance of tremor, but has nothing to do with that of rigidity, and, on the other hand, an intact proprioceptive system is essential to the development of rigidity, but not to that of tremor.

It is interesting to consider whether there may not be some common factor, a loss of function in some lower level mechanism, that, allowing tremor to appear on cortical activation, responds to proprioceptive influences by permitting the development of rigidity. The relationship cannot be such a simple one since it would involve the appearance of both phenomena in direct proportions, whereas we know that the relationship between the two tends to be an inverse one. We are probably not in a position to determine the nature of the factor or factors common to both, in the present state of knowledge.

CONCLUSION.

This completes the survey attempted on physiological lines of the two symptom-complexes we have been considering. It is clearly an incomplete one. To many of the questions raised, for example, that of the causation of parkinsonian rigidity, it has not been possible to provide a solution.

Probably others, pursuing the same method, will bring these problems nearer a satisfactory solution, but it will be by this means that they must ultimately be solved and not by those methods that were the subject of criticism in my last lecture. It may be urged that too great a part of these lectures has been devoted to these criticisms, largely destructive as they are. Yet the ground must be cleared of the luxuriant growth of speculation before we can hope to see the nature of the problems that confront us, and we must be delivered from the bondage of abstract conceptions that are out of touch with reality before our hands are free to deal with them.

It can only be by the careful correlation of clinico-pathological observations with the experimental physiology of the nervous system that now, as in the past, we can achieve a rational interpretation of the symptoms of disordered function produced by disease of the nervous system.

TIME OF DAY IN RELATION TO CONVULSIONS IN EPILEPSY.

BY MARY LANGDON-DOWN, M.B., B.S. LOND.,

AND

W. RUSSELL BRAIN, D.M. OXF., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL AND TO THE HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

(From the Medical Unit, the London Hospital, and The Colony, Lingfield, Surrey.)

THE following paper contains the results of an investigation into the influence of time of day in causing epileptic convulsions. That epileptic patients are more liable to be convulsed at certain hours than at others, and that individuals vary in this respect, has of course been familiar for many years. Gowers[1] investigated this point in his large series of cases, and we shall have occasion to allude to his findings later. His method was to note certain broad facts concerning the time incidence of fits in his patients,—for example, whether they occurred by day only or by night only. Our approach to the question has been somewhat different and, in a sense, complementary to that of Gowers. We have subjected to detailed analysis the time incidence of the major fits in a group of 66 epileptics, living under similar conditions in the same institution, the hour of every major fit of each individual, 2524 fits in all, being recorded over a period of six months. A smaller group of patients in another institution have been similarly investigated over a period of two years, and the results used for purposes of comparison. Except where otherwise stated, the figures quoted are derived from the larger group.

All but five of the 66 patients were examples of so-called idiopathic epilepsy—that is to say, they presented no clinical evidence of organic disease of the nervous system. The remaining five patients comprised four cases of hemiplegia and one patient in whom epilepsy supervened upon a fracture of the skull. We shall briefly discuss these cases separately later, but as in respect of the subject of our investigation they showed no peculiarities to differentiate them from the rest of the group, their figures are included with the others.

General Classification.

We have already alluded to the distinction between patients whose attacks occur only or predominantly by day, and those whose convulsions are mainly, if not exclusively, nocturnal. We find also a third group in which the attacks occur both by day and by night. For brevity we shall refer to these groups as "diurnal," "nocturnal," and "diffused." The number of our patients is very small compared with Gowers's series, but it is interesting to find that the relative frequency of the three types among our patients is almost identical with that obtaining among his patients. These figures are given in Table I.

TABLE I.

Type.	Percentage of total (Gowers).	Percentage of total (present series).
Diurnal	45	42·5
Nocturnal	22	21·2
Diffused	33	33·3

A factor of subordinate importance which appears to influence the type of time distribution of fits is the duration of the disease. Table II. shows the incidence of the three types in patients grouped according to the duration of the disease.

TABLE II.

Type.	Duration under 10 years. Percentage.	Duration 10–20 years. Percentage.	Duration over 20 years. Percentage.
Diurnal ..	47	40	36·0
Nocturnal ..	28	20	21·5
Diffused ..	25	40	42·5

It will be seen that the longer the duration of the disease the greater the proportion of "diffused" as compared with "diurnal" and "nocturnal" types. There is thus a tendency for time to convert both the diurnal and the nocturnal types into the diffused type. Many patients, however, show no evidence of this tendency, for even after 20 years' duration of the illness 57·5 per cent. of the patients remain of the clear-cut diurnal or nocturnal type.

The close correspondence between Gowers' and our own series in respect of the incidence of the different types, and the persistence of the original type throughout the illness in a large proportion of cases, suggest that beneath these differences there exists a deeply-rooted distinction between the individuals composing the different groups. This is a point to which we shall return.

---

[1] Gowers, W. R.: Epilepsy and other Chronic Convulsive Diseases. London, 1901.

Relative Severity of the Disorder in the Different Types.

The relative severity of the disorder in individuals of different types may be estimated as follows. If we calculate the average number of fits in the period investigated per individual for each group, we find that in the "diurnal" group there were 28 patients, having an average of 23 fits per patient in six months. In the "nocturnal" group there were 16 patients with an average of 48 fits per patient, and in the "diffused" group, 22 patients with an average of 51 fits per patient. Estimated thus, the severity of the disorder in those whose fits are solely or mainly diurnal is less than half that in the other two groups. Since the nocturnal occurrence of fits is common to both of the latter it may be said that the regular occurrence of nocturnal fits is a sign of bad prognosis. Corresponding probably to these differences in the severity of the disease, differences in the intelligence of the patients in the three groups were found. Patients in the diurnal group were somewhat more intelligent than the others, having an average intelligence quotient, actual or assessed, of 0·7, compared with 0·6 in the patients of the other two groups. Moreover, in the diurnal group 28·5 per cent. of the patients were neither mentally unstable nor deteriorating, while in the other two groups combined only 13·5 per cent. could be so described.

FIG. 1.

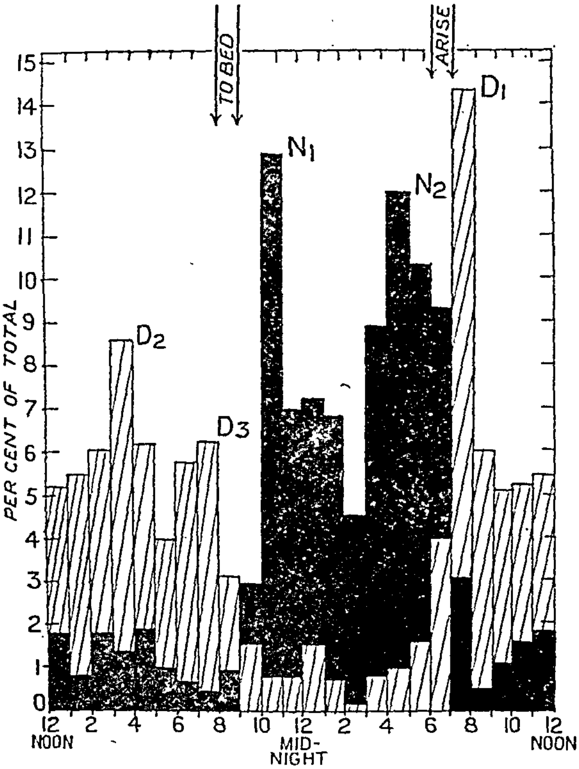

Chart showing the time distribution of the pooled fits of the patients in the diurnal and nocturnal groups. The ordinates are percentages of the total number of fits in each group over a period of six months. The abscissæ are hours of the day. The fits of the nocturnal group are represented in black, those of the diurnal group in cross-hatching. The patients arise between 6 and 7 A.M., the majority retire to bed between 8 and 9 P.M.

Time Peaks.

We now reach the most interesting result of the investigation—namely, the occurrence of "time peaks." By this term we mean that if either the attacks of individual epileptics or the pooled attacks of a group are recorded graphically, the resulting graph exhibits peaks occurring at certain hours of the day or night. To demonstrate this it is necessary to consider the diurnal and nocturnal groups separately (Fig. 1). The diffused group will be dealt with later.

Nocturnal Peaks.—The time incidence of fits in the nocturnal group is represented by the black areas in Fig. 1. This is seen to maintain a low level during the day, only about 15 per cent. of the total of fits in this group occurring between 8 A.M. and 8 P.M. Between 9 and 10 P.M. the number of fits is treble that in the preceding hour, and between 10 and 11 P.M. this rise is continued and intensified, to reach the first nocturnal peak, N 1. During the next hour the number falls to about half, and is maintained at this level until the hour 2 to 3 A.M., when there is a further fall. The second nocturnal peak, N 2, reaches its maximum between the hours 4 and 5 A.M., the number rising fairly sharply during the preceding hour. The fall is more gradual until 7 A.M., when the decline becomes precipitate, and in the subsequent hour, 8 to 9 A.M., the number reaches its lowest point in the 24 hours.

Individual patients may exhibit either or both of the two nocturnal peaks, N 1 and N 2. Most frequently N 2 alone is present, and this was the case in 13 out of 23 patients with well-defined peaks. Six patients showed both peaks, and four showed N 1 only.

Diurnal Peaks.—The time incidence of fits in the diurnal group is represented by the areas of cross-hatching in Fig. 1. Three diurnal peaks can be detected. The incidence of fits is lowest for the diurnal group of patients between 2 and 3 A.M. Thereafter there is a very gradual rise until 6 A.M., when it becomes much sharper, and between 7 and 8 A.M. occurs the first diurnal peak D 1, which was shown by 16 patients. During this hour occur about 14½ per cent. of the total fits of the patients in this group. The fall is almost as abrupt as the rise, and after 8 A.M. the incidence of fits is steady until 4 to 5 P.M., when the second diurnal peak, D 2, occurs. This peak is followed by a fall to somewhat below the usual level for the day, with a subsequent rise, D 3, at 7 to 8 P.M., before the fall to the low nocturnal level.

Peaks in the Diffused Group.—Examination of the charts of individuals of the diffused group reveals that they fall into two classes. A few patients in this group exhibit some of the peaks already described, usually one or both of the nocturnal peaks, with the addition of a considerable number of fits during the day. The majority, however, show no special time incidence in their attacks which appear to occur indiscriminately at any hour of the day or night.

Individual charts illustrating the various classes of epileptic are reproduced in Figs. 2 to 5.

Interpretation of the Peaks.

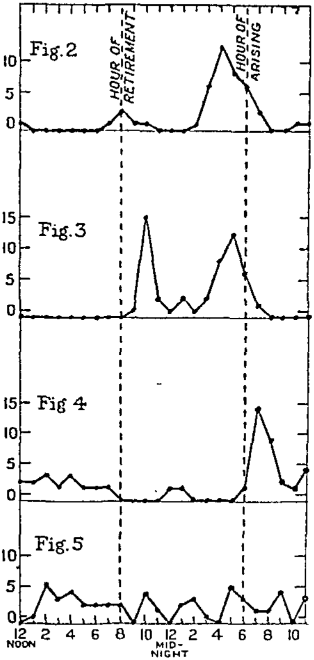
The special liability of epileptics to be convulsed at certain hours of the day and night is a problem of great interest and importance which we are at present not in a position to elucidate by any means fully. We shall first consider the interpretation as far as is possible of the individual peaks, and we shall then briefly indicate the direction in which it appears to us that further elucidation must be sought.

Peak N 1.—The patients who form the subject of this communication live in four separate houses and do not all retire to bed at the same time. Their bedtime ranges from 6 to 9.30 P.M. The majority of those exhibiting the N 1 peak go to bed between 8 and 9 P.M. This peak attains its maximum between 10 and 11 P.M., which is for most of the patients the second hour after retiring to bed. There is no direct evidence available in our cases as to the relation to sleep of fits occurring at this time; but it seems probable that the peak N 1 is the response of certain patients, either to the act of falling asleep or to the early stages of sleep itself.

Peak N 2.—This peak, which begins to rise at 3 A.M., attains its maximum between 4 and 5 o'clock. Any explanation of this increased tendency to fits in the latter part of the night must at present be purely speculative, but certain negative inferences can be drawn from the mode of decline of the peak. It is seen to fall slowly from 5 to 7 A.M., and thereafter much more rapidly. The patients in question arise between 6.30 and 7 A.M., so that the sharp fall in this peak corresponds to the period of awakening and getting up. It is unlikely therefore that the rise of peak N 2 is due to a tendency of the patients to awaken spontaneously during the latter part of the night and to be convulsed on awakening. If this were the case the peak would continue to rise until after the time of getting up. Actually we find that in this group the incidence of fits is falling during the two hours preceding getting up and falls still more sharply during the subsequent hour.

Peak D 1.—This peak is a very abrupt one, reaching its maximum between 7 and 8 A.M., a period which begins half an hour after the patients arise. The conclusion seems *inevitable that in this group* awakening and arising act as strong precipitants of convulsions. At present it seems impossible to analyse these precipitating factors further. It is well known that some patients may be convulsed at the moment of awakening. This may contribute to the rise of the earlier part of this peak, but its maximum is attained during the subsequent hour. There seems no reason, however, why this should not be a deferred effect of awakening. Gowers discusses how far the assumption of the erect posture on getting out of bed may be a precipitating factor in patients who have fits soon after arising, and concludes that it is unimportant because such patients are often convulsed at the usual hour even though they remain in bed.

FIGS. 2–5.



Representative charts showing the time distribution of the fits in individual patients over a period of six months. Ordinates, number of fits: abscissæ, hours of the day. Dotted lines indicate hours of retirement to bed and of arising.

FIG. 2.—A patient of the nocturnal group, exhibiting the peak N 2 only.

FIG. 3.—A patient of the nocturnal group, exhibiting the peaks N 1 and N 2.

FIG. 4.—A patient of the diurnal group, exhibiting the peak D 1.

FIG. 5.—A patient of the diffused group.

Peaks D 2 and D 3.—These peaks are comparatively small and occur in only a small proportion of patients. They are found at approximately the same interval, three to four hours, after the second and third meals of the day, but there is no evidence as to their cause.

Epilepsy associated with Gross Organic Lesions.

As we have already stated, five patients in our series were examples of the association of epilepsy with gross organic lesions, four being examples of infantile hemiplegia and one having developed epilepsy after sustaining a fracture of the skull during the war. The four cases of infantile hemiplegia belonged to the nocturnal group, two showing the peak N 1 and two the peak N 2. The patient with traumatic epilepsy belonged to the diurnal group and exhibited the D 1 peak. There was no feature of the time incidence of their fits peculiar to these patients with a gross organic lesion, and we have therefore included them with the rest. No conclusion can be drawn from so few cases, but this evidence supports the view that in cases of traumatic epilepsy there is a constitutional disturbance which is common to these cases and to the cases of so-called idiopathic epilepsy, for we can distinguish in both groups similar variations in the time incidence of the convulsions.

Influence of Sedative Drugs on the Time Distribution of Convulsions.

It is natural to inquire what influence, if any, the administration of sedative drugs exerts upon the time distribution of the convulsions, and on investigating this point we find as far as can be ascertained their influence is negligible. This, of course, does not mean that the total number of fits is uninfluenced by drugs, but that the characteristic time peaks occur in spite of the exhibition of sedatives at such times as have been judged most suitable for their prevention. The method of administration of sedatives to the patients to whom our records refer has been to give bromides, and in a small number of cases luminal in the morning, at night, or at both times. The average daily dose per patient was grs. 18 of potassium bromide and gr. ½ of luminal. The general plan has been to give the larger and in some cases the sole dose at bedtime, when the patients' fits were mainly nocturnal, and in the early morning when the convulsions occurred principally by day. As may be seen from Fig. 1 and from individual time-charts, this mode of administration has not prevented the occurrence of well-marked time peaks. The possibility was considered that the administration of a large dose of bromide or luminal at bedtime might be responsible for deferring the rise of peak N 1 for some hours and so causing peak N 2. This, however, seems unlikely when we consider that both peaks not infrequently occur together in the same patient, and that three patients who exhibited the N 2 peak were receiving no sedative in the latter part of the day. No one will gainsay that bromides and luminal diminish the total number of fits in the majority of patients, yet we find the *time distribution of the fits little if at all affected.* It would appear therefore that these drugs, administered by the method described, suppress a proportion of the fits completely but do not defer any to a later hour. Thus they do not smooth out the inequalities of time distribution which constitute the time peaks.

General Conclusions.

We have seen that approximately two-thirds of a group of 66 epileptics manifested a marked difference in the diurnal and the nocturnal incidence of their convulsions, and approximately three-fifths exhibited one or more "time peaks,"—that is, a concentration of their attacks at or around certain hours. Five such peaks have been recognised, two nocturnal and three diurnal. The second nocturnal peak (maximum 3–4 A.M.) is the most frequent and was found in 35 per cent. of patients; the first nocturnal peak (maximum 9–10 P.M.) occurred in 18 per cent. These two peaks were found together in 13·6 per cent.; the first nocturnal peak occurred alone in 4·5 per cent., and the second alone in 21·2 per cent. The principal diurnal peak, D 1 (maximum 7–8 A.M.), occurred in 24·2 per cent. of patients.

Reference to Fig. 1 reveals certain marked contrasts between the patients of the nocturnal and the diurnal group. Not only is their response to day and night in general diametrically opposite, but this antithesis extends to points of detail as is well shown by the behaviour of the two curves between the hours 4 and 7 A.M. This is the period of awakening and arising from bed. During this period the incidence of fits in patients of the nocturnal group falls from the highest but one level of the 24 hours to the lowest. In the diurnal group it rises from almost the lowest to the highest. It is natural to inquire what is the factor to which the two groups are responding in opposite ways. An answer to this question is rendered difficult by the coincidence in time of at least three important functional changes: (1) the change from sleep to waking, (2) the change from the supine to the upright posture, and (3) the change from inactivity to the motor activities of dressing, &c.

The contrast between the two groups is demonstrated in an equally striking fashion by comparing the response of the nocturnal group to bedtime and sleep with that of the diurnal group to awakening and arising. The former is expressed by the black areas in Fig. 1 between the hours of 8 A.M. and 2 P.M., the latter by the areas of cross-hatching in the same figure between the hours of 5 A.M. and 11 A.M. The marked resemblance between the two curves indicates that a similar pathophysiological effect is produced in the one group by retirement to bed and the onset of sleep, and in the other by awakening and getting up.

It is tempting to consider these facts in relation to what is known of the physiology of sleep, but any such correlation must be purely speculative. Pavlov's conception of sleep as widespread cortical inhibition is now well known. The rôle of inhibition in the physiology of convulsive states has aroused interest for many years, but is one of the most difficult problems in neurophysiology. It may be that the difference between patients in the diurnal and nocturnal groups is a difference in the effect of the inhibitory factor of sleep upon their convulsive tendency. This, at least, is one direction in which we look for more light upon these phenomena. Biochemistry affords another avenue of approach to the problem. There are indications that both sleep and inhibition possess a biochemical basis. It would be difficult otherwise to explain the action of sedative drugs. The bromides not only induce sleep but also, as Pavlov has shown, strengthen cortical inhibitory processes, thereby affording strong indirect support for his identification of sleep and inhibition. Little is known at present concerning the biochemistry of normal sleep, but further knowledge of both general and cerebral metabolism in the sleeping state may help to explain the striking but obscure relationships between sleep and epilepsy.

Summary.

1. The influence of time of day in precipitating major or epileptic convulsions has been investigated in 66 epileptic patients.

2. It is found that they fall into three groups—namely, those in which the attacks are mainly diurnal, mainly nocturnal, or occur indifferently by day and night.

3. Attacks are more frequent in the last two groups than in the first.

4. The term "time peak" is used to describe the increased tendency to convulsions at certain hours.

5. Five such time peaks can be recognised, three diurnal and two nocturnal. Their interpretation is discussed.

6. Patients of the "diurnal" and "nocturnal" groups are found to respond in an opposite manner to the onset and cessation of sleep.

7. Five patients suffered from organic lesions of the nervous system. No distinction in respect of the time incidence of fits can be drawn between these and the 61 cases of "idiopathic" epilepsy.

We desire to express our thanks to Dr. J. Tylor Fox and Dr. R. Langdon-Down for kindly allowing us to use the records of their patients for this investigation, the expenses of which were in part defrayed by a grant from the Medical Research Council.

THE
EXCITABILITY OF THE RESPIRATORY CENTRE OF PSYCHOTIC PATIENTS.

BY R. G. B. MARSH, M.R.C.S. ENG., D.P.M.,
ASSISTANT MEDICAL OFFICER, CLAYBURY MENTAL HOSPITAL.

THIS paper contains an investigation of the excitability of the respiratory centre in certified cases of insanity. Observations made on various cases of psychosis at the Central Laboratory at the Maudsley Hospital have furnished evidence that a state of disturbance of the acid-base equilibrium is characteristic of a large number of psychotics. Studies of the blood-sugar curves,[1] the vasomotor responses,[2 3] of the pH of the urine after sleep and after ingestion of food,[4] the responses to insulin and other drugs have all tended to show that a failure of the acid-base equilibrium exists and that this condition closely resembles that obtaining during sleep in the normal individual.[5 6 7]

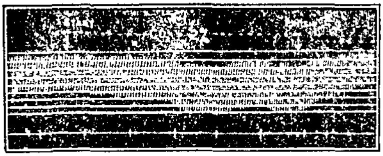
Using an electrically controlled plethysmograph devised by Golla it was shown in a recent paper [8] that the determining factor in this condition of disturbed acid-base equilibrium is a lowered excitability of the respiratory centre to the stimulus of carbon dioxide. The present paper records a further investigation of the occurrence of this depression of the respiratory centres which I have made in a large number of cases of certified insanity in Claybury Mental Hospital.

Method.

The method used was the same as that adopted in the previous investigation. It was found convenient to substitute rubber spear-head valves of the type used in the army gas-protection outfit for the Chauveau valves in Golla's automatic plethysmograph, and with this improvement, since the valves no longer had to be fixed in an immovable position, it was no longer necessary to have a long tube with a consequent dead space leading from the nose to the valves. As has been pointed out in the previous investigations. the great merit of the automatic plethysmograph with the nasal leads is that it favours the continuance of normal respiration and is in fact so little felt by the subject that various patients have been known to go to sleep during an experiment.

An examination was attempted at Claybury on all new male admissions and on every case in two chronic male wards irrespective of the mental condition of the patients. As was to be expected it was found impossible to obtain reliable records from a large number of the patients examined owing to resistiveness, negativism, and in some cases mania. Again, in some few cases reliable results were not obtained owing to the patient obviously having his respiratory mechanism upset by the fact of having an experiment performed, the error usually introduced being one of overbreathing. The normal controls were obtained from the medical and male nursing staff at the Maudsley Hospital and Claybury Mental Hospital.

The subjects were introduced to the apparatus and allowed to examine it; they were then made to lie on a couch with the apparatus slightly behind them and the gasometer out of the range of vision. The nose-piece was introduced and the subject given a few minutes to accustom himself to it. The apparatus was then connected up and no attempt at recording the result was made until the respirations were regular. The first reading taken was regarded as a trial and was discarded and the second and subsequent readings were used for the process of calculation. In many cases the readings used were taken on days subsequent to the subject's introduction to the apparatus.



Record of normal response to 2 per cent. CO_2. Parallel horizontal lines represent calibrations in terms of 100 c.cm. Time in minutes.

Results.

The results were calculated by measuring the total excursion of the recording stylus on the record for one minute previous to the administration of the CO_2 and for the fifth minute after the CO_2 had commenced. This was reduced to terms of the total ventilation per minute by means of calibration and the result is expressed as the percentage increase of volume of respiration over the normal.

It was found that subjects who increased their ventilation to CO_2 responded in a varying manner; some increased the rate of respiration, some increased the volume of each separate respiration, and a third group responded by a mixture of both methods. The figure shows a typical response of a normal subject to 2 per cent. CO_2.

The Normal Response.—Twenty-five normal male subjects were examined and gave the results shown in Table I.:—

TABLE I.

Increased % ventilation to 2 % CO_2 ..	0–5 %	5·5–10 %	10·5–15 %	15·5–20 %	20·5–25 %
Number of subjects..	1	2	9	7	6

Thus 88 per cent. of the normals respond to 2 per cent. CO_2 by an increase of over 10 per cent. of the total ventilation, 8 per cent. by an increase of over 5 per cent., and 4 per cent. (a single case) increased by less than 5 per cent. This case, an apparently normal individual, increased his ventilation 2·1 per cent.

Of a total of 140 psychotic patients examined reliable results in which the patient could be induced to coöperate intelligently were obtained in 73 cases. The diagnoses in the following tables were those officially recorded on the hospital records. It will, of course, be obvious to anyone with a knowledge of clinical psychiatry that such diagnosis in the case of newly admitted patients must be regarded as to a great extent provisional and in the present state of psychiatrical classification subject to the individual bias of the observer.

Two groups of cases are considered separately: those suffering from congenital mental deficiency and those suffering from epilepsy.

Six cases of congenital mental deficiency were examined, one of them being also the subject of epilepsy. Of these six one case fell in column 1 of Table II., one in column 2, three in column 3, and one in column 4. The number examined is, of course, too small to permit of any conclusion being drawn.

TABLE II.

Increased % ventilation to 2 % CO_2 ..	0–5 %	5·5–10 %	10·5–15 %	15·5–20 %	20·5–25 %
Dementia præcox ..	17	6	2	—	1
Melancholia.. ..	13	4	—	—	—
Mania	1	—	—	1	—
Manic depressive ..	2	—	—	—	—
Senile dementia ..	1	—	—	—	—
Alcoholic psychosis .	—	—	1	—	—
Dementia præcox with epilepsy ..	—	—	1	—	—
Total	34	10	4	1	1
Percentage round figures	68 %	20 %	8 %	2 %	2 %

Sixteen cases of epileptic insanity were also examined. The following table shows their response to CO_2.

TABLE III.

Increased % ventilation to 2 % CO_2 ..	0–5 %	5·5–10 %	10·5–15 %	15·5–20 %	20·5–25 %
Number of cases ..	6	1	1	3	5

The number of cases is, of course, small, but the increase at each end of the table gives some indication of the possible existence of two groups of patients among the insane suffering from epilepsy, one group showing a tendency to a normal, and another with a psychotic form of reaction. Further investigations on this subject are being pursued.

It has been previously stated that an increased total ventilation in normal subjects may be accomplished either by an increased frequency or an increased depth of respiration, or by both factors acting simultaneously. An examination of the curves obtained from the psychotic patients failed to reveal any preponderance of one or other factor in any particular form of psychosis. No correlation between the conduct of the psychotic during examination and the response to 2 per cent. CO_2 could be detected—some of the cases were excited, others depressed or katatonic, and others outwardly normal. The diminished excitability of the respiratory centre cannot therefore be interpreted as a mere bodily sign of a psychical condition, but must be regarded as a particular symptom of a bodily syndrome of which the psychosis is the salient feature.

Since writing this article I have seen a paper by Loevenhart, Lorenz, and Waters[9] who state that by stimulating stuporous cases of dementia præcox with from 10–15 per cent. CO_2 in 85–90 per cent. oxygen they have succeeded in temporarily improving their mental state.

In conclusion, I should like to express my gratitude to Dr. F. Golla for his great help in the writing of this paper and under whose direction the work was carried out. In addition I wish to thank Dr. G. F. Barham, superintendent of Claybury Mental Hospital for the facilities given and the interest shown in this investigation.

Clinical and Laboratory Notes.

A NEW INDEX OF INTESTINAL PUTREFACTION.

BY N. MUTCH, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO GUY'S HOSPITAL.

THE definition of intestinal toxæmia as a clinical entity is beset with difficulty. To many the symptomatology seems cumbersome and vague. Chemical tests have proved unsatisfactory, because they have failed to discriminate between minor degrees of toxæmia and those which are significant. Ethereal sulphates are merely a measure of the total aromatic flotsam and jetsam which reaches the ileocæcal region. The tests for indican and urorosein are too sensitive, not only chemically, but also in the clinical sense. They depend upon the occurrence in the urine of products derived from tryptophane. It is only during the latest phases of digestion that trytophane is liberated from the protein complex. If there should be a little weakness in the digestive ferments, a little rise in the bacterial level in the gut, or if the food should pass too quickly through the ileum, unabsorbed tryptophane will come into contact with bacteria of the coli group, and indican or urorosein appear in the urine.

The test about to be described discriminates between the trivial and the serious. A positive result is not obtained unless putrefaction is of some moment. It also furnishes evidence of the absorption of intermediate products of bacterial action, and it is amongst these more elaborate compounds that the most poisonous substances are to be sought. The end-products, phenol, indoxyl, and so forth are relatively inert.

In contrast to tryptophane, which is one of the last crystalloids to be split from the protein molecule, tyrosin is liberated at a very early stage in digestion. If intermediate products of tyrosin putrefaction appear in the urine, it can be assumed that a great part of protein digestion is proceeding in a contaminated medium instead of under the normal aseptic conditions of health. The two first stages in the disintegration of tyrosin yield tyramine and the corresponding hydroxyacid. Both substances appear in the urine in the same form because tyramine is converted by the liver into the acid before excretion. This substance, *p*-hydroxyphenyl-acetic acid was first isolated from the urine by the author some years ago [1] and furnishes the chemical basis for the test.

Test.—To 50 c.cm. of urine add 5 c.cm. of 25 per cent. sulphuric acid and extract by shaking with 15 c.cm. of ether. Pour off 2 c.cm. of the ether into a dry tube and evaporate by dipping into hot water. Take up the residue in 2 c.cm. of water. Add Millon's reagent drop by drop and boil. A positive reaction is indicated by red coloration. (The quantities mentioned are approximate and need not be measured carefully.)

Quantitative significance.—Some idea of the amount of absorption of tyrosin intermediate products which is actually taking place can be gained by comparing the depth of the colour reaction with that obtained from the urine of a normal subject after the ingestion of tyramine. A daily excretion corresponding to half a gramme of tyramine is by no means rare.

Pitfalls and fallacies.—Simple phenolic end-products are commonly found in urine and give a positive reaction when the Millon test is applied to untreated urine. They are insoluble in ether and therefore do not interfere with the reaction when carried out as described. Many cheeses contain preformed tyramine. A positive reaction cannot therefore be regarded as evidence of tyrosin putrefaction in the bowel if cheese has been taken during the preceding 24 hours. Aspirin and salicylates give a similar reaction and should be excluded. Their presence is easily revealed by making a duplicate ethereal extract and noting the purple colour produced with ferric chloride solution.

Prevalence.—A series of urines from 308 unselected patients in the medical wards at Guy's Hospital was examined with the following results: positive reactions, 42 per cent.; negative or doubtful, 58 per cent.

Relationship to indican reaction.—Faults in digestion of one degree or another are very common amongst patients of all classes and lead to indicanuria. In the present series positive reactions for indican or urorosein were given in 81 per cent. of cases, but in only one half of these patients did the process of putrefaction extend to the tyrosin molecule. Indicanuria without tyrosin-acid excretion was frequently noted, but a positive tyrosin-acid reaction was rarely obtained in the absence of indican or urorosein. It was only noted in two cases—that is, in less than 1 per cent. of the series.

It would thus appear justifiable to look upon this reaction as an index of bacterial activity more extensive in degree and scope than that associated with simple indicanuria.

Its relationships to some of the common causes of putrefaction in the bowel were investigated in a smaller series of cases. For this purpose cases were selected which showed definite tyrosin-acid reactions, and an approximate estimation was made of the total daily excretion on average diet in terms of tyramine.

Ileal stasis.—This condition facilitates the invasion of the small intestine by bacteria from the cæcum. Taking one case with another, tyrosin decomposition is greatest when stagnation in the ileum is greatest.

Cases.	Ileal stasis (emptying time of ileum).	Proportion of cases showing the following daily excretions of tyrosin acid.		
		0·4 g.	0·2 g.	Less than 0·05 g.
10	Greater than 10 hours.	20 %	60 %	20 %
5	8 to 10 hours.	0 %	20 %	80 %

Infection of the ileum by organisms of the Coli group.—Samples of chyme were obtained from the ileum at operation and the density of the flora measured by cultivation. The cases in which infection was severe and a loopful of chyme yielded 500 or more colonies of coliform organism gave an average reaction equivalent to 0·22 g. tyramine. Where the infection was mild and a loopful of chyme yielded 5 colonies or less the excretion was equivalent to 0·13 g. tyramine.

Acidity of the gastric juice.—In the absence of hydrochloric acid digestion is slower and more unabsorbed food reaches the ileocæcal region. Hypochlorhydria indirectly furnishes the colon with a rich culture medium and encourages putrefaction.

Ewald test-meals were carried out on 21 patients who were known to excrete tyrosin acid, and the following observations recorded.

Cases.	Active HCl.	Average daily excretion (in terms of tyramine).
	Per cent.	
5	0·2 to 0·3	0·17 g.
9	0·1 ,, 0·2	0·13 g.
7	Nil ,, 0·1	0·23 g.

Lack of acid in the gastric juice was associated with a pronounced increase in the excretion of tyrosin intermediate products.

In brief, the excretion of tyrosin acid is definitely encouraged by ileal stasis, *B. coli* infection of the ileum, and by hypochlorhydria. It is doubtless encouraged by many other factors which promote saprophytic activity in the gut, but these three examples will suffice to indicate the direct clinical association between the reaction described and putrefactive processes in the bowel. Only qualified inferences can be made from a negative finding. Much abnormal decomposition may occur even when this particular urine reaction is negative because only a limited number of bacterial strains have the power of destroying tyrosin. A positive finding, however, is always significant. The suggestion is that a positive finding should be regarded as evidence of serious absorption of bacterial products from the colon or small intestine.

INTRANASAL IMMUNISATION AGAINST SCARLET FEVER.

By B. A. Peters, M.D., D.P.H. Camb.,
MEDICAL OFFICER IN CHARGE, HAM GREEN HOSPITAL AND SANATORIUM, BRISTOL; LECTURER IN FEVERS, UNIVERSITY OF BRISTOL;
AND
S. F. Allison, M.B. Edin., D.P.H. Camb.,
LATE FIRST ASSISTANT MEDICAL OFFICER, HAM GREEN HOSPITAL.

As many people have a rooted objection to hypodermic inoculations and as the reactions produced by scarlet fever toxin are decidedly unpleasant, we have investigated the possibility of producing immunity to scarlet fever by the application of scarlet fever toxin to the nasal mucous membrane. For many months we have tested all cases of diphtheria with the Dick test on admission, as knowledge of their susceptibility or otherwise to scarlet fever is of great value in controlling any outbreak of that disease in a convalescent diphtheria ward—an ever-present anxiety in fever hospital practice. We have used for this investigation patients with a strong initial positive.

The method employed is to spray the nose every other day by means of an atomiser with the scarlet fever toxin, "B" strength, supplied by Messrs. Burroughs Wellcome and Co. (5000 skin test doses per 1·0 c.cm.). The nose is first sprayed with a solution of 1 per cent. sodium taurocholate with the aim of aiding absorption. During one period of the investigation this preliminary was omitted and decidedly inferior results followed. As the average time in hospital of diphtheria cases is five weeks we re-tested at the end of that time those who had been sprayed. Nine of those who still gave positive results were re-tested a fortnight later, as they were still in hospital. Out of the first 52 cases half were used as controls, taking alternate cases. Ten new members of our staff with positive tests were also used; half of them became negative on re-test and are not included in the table of results given below.

Results on Dick Test.

—	Number.	Negative.	Much reduced.	No change.
Spray cases ..	61	22	24	15
Controls	26	1	2	23

Five of those marked "much reduced" were re-tested a fortnight later, when three of them gave completely negative tests and two showed no further change. Four of those recorded as "no change" were also re-tested a fortnight later, when one of them gave a reduced test and three still remained strongly positive. As we have pointed out on a former occasion that three skin-tests may convert a positive into a negative,[1] we do not feel inclined to stress the result of these repeated re-tests.

An interesting difference in the anatomical site of the reaction was noted in those marked "much reduced"; this was only observed in two control re-test cases and never in the initial tests, and was certainly not due to a technical error in the test. An initial positive Dick-test in a child with a thin skin shows itself as a brilliant homogeneous patch of erythema from 2 to 5 cm. in diameter with a well-defined edge, situated in the extreme superficial layers of the skin. In the "much reduced" cases the area was much smaller, less definite, less brilliant in colour, and with the appearance of being much deeper seated, as though viewed through the superficial layers of the skin. We are disposed to think from the second re-tests that this type of reaction indicates the *beginning of immunity* and that, if we had had an opportunity to continue the spraying for a longer period the proportion of complete negatives would have been doubled and would have approximated to the numbers rendered Dick-negative by the end of the fifth week of an attack of scarlet fever. This, as we showed previously, is only 70 per cent.

During the investigation two small outbreaks of scarlet fever occurred in a convalescent diphtheria ward of 40 patients. None of those rendered negative contracted the disease, but five controls and three who had been sprayed and were still positive after five weeks contracted it. These last three cases show that the spraying does not produce local tissue immunity, as is claimed for the ingestion of dead cultures of *Bacillus typhosus*, but that a general antitoxic immunity must develop before the patient is immune. However, one of these attacks was so extremely mild that, had it not occurred during this outbreak, we might have thought it to be an allergic reaction due to the toxin itself and not true scarlet fever.

We are continuing this investigation, using a more concentrated toxin and only spraying twice a week. So far the results seem to be the same as those obtained by spraying every other day.

We have no means at our disposal to prove the duration of the immunity, as our patients are only under our care for a brief period, but someone in charge of a resident institution may, we hope, give the method a trial—spraying, say, twice a week for eight weeks—as this method of immunisation is free from the objections of inoculation, and produces no *observable effects whatever on the patient except* the development of immunity in a considerable proportion of cases.

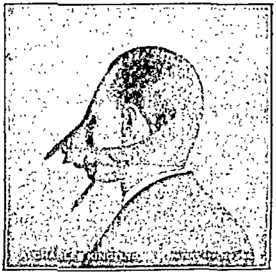
New Inventions.

A RETENTION APPARATUS FOR ANÆSTHETIC MASKS.

When giving gas-oxygen anæsthesia the need is often felt for a means of retaining the mask in place. Not only may this be tiring to the anæsthetist in long operations, but he may need his hands free for changing cylinders, moving the patient, or giving spinal or other injections. The simple fitting here illustrated is adapted for use with any ordinary mask; it can be easily washed or boiled, and will maintain a firm, even pressure of the mask in most cases, with little tendency to slip or to cause respiratory obstruction. It consists of a Y-shaped rubber strap moulded to fit the head. The perforated ends fasten on to hooks on a wire ring, which fits loosely over the mount of the mask. Alternatively, the hooks may be permanently incorporated in the mask, if desired.



The makers are Messrs A. Charles King, Ltd., 34, Devonshire-street, London, W.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

A meeting of this Section took place on May 14th with Prof. J. A. Gunn, the President, in the chair. The meeting was devoted to a discussion on the

Action and Use of Ephedrine.

The President said that ephedrine was an alkaloid derived from a plant which had been known to the Chinese 5000 years, having been used by them from ancient times as a circulatory stimulant and as a diaphoretic. The alkaloid was isolated from the plant in 1887, but for a long time little attention was paid to it. Five or six years ago it was found to be very close in chemical structure to adrenalin, the chief difference being the absence in ephedrine of the OH groups. There were six possible varieties of ephedrine, but only three possibles of adrenalin. As isolated from the plant the alkaloid contained 80 per cent. ephedrine and 20 per cent. pseudo-ephedrine. The possible variants probably largely accounted for the varied behaviour reported concerning the drug. In Germany ephedrine had been synthesised and with a mixture of dextrose placed upon the market as ephetonine. Ephedrine was less readily oxidised than adrenalin; it was also less active than the latter, the difference being as much as 1 to 120. Perhaps the fact that ephedrine changed much more slowly in the body than adrenalin accounted for its value being retained when given by mouth. Ephedrine was not readily destroyed by boiling, hence it could be sterilised by this means. In asthmatic patients tolerance to ephedrine was produced more quickly than to adrenalin; the doses of the former must be, for chronic cases, gradually increased; sometimes the effects disappeared altogether. In America ephedrine had been widely used for counteracting the effects of shock, and especially to neutralise the results of operation under spinal anæsthesia. Apparently its records in these respects were quite good. It had also been employed to dilate the pupil of the eye and, in place of cocaine, to contract the blood-vessels in mucous membranes. In connexion with the use of ephedrine headache had been described, also insomnia. Sweating also followed, but apparently only after large doses; indeed this symptom indicated that the dose had been too large. There was need for care with the dosage of ephedrine. Though he was not aware of any deaths from its use there had been cases of serious collapse. Ephedrine was useful for stopping the morphine habit.

Mr. J. H. Thompson said he had been investigating the action of ephedrine on the normal human subject, by means of the sphygmanograph, which permitted of a continuous record of blood pressure. He used the ephedrine hydrochloride as supplied by Burroughs Wellcome and Co., and though his results, so far, were incomplete, the inquiry had disclosed some interesting facts. He had found that a considerable number of people failed to respond to ephedrine, and this failure could not be attributed to inactivity of any of the samples used, nor to the channel of administration. The only abnormality he could detect about those persons was a failure of full development of secondary male characteristics. Before the rise of blood pressure normally occurring after its use he had observed a definite latent period; used subcutaneously or intramuscularly this latent period was two and a half to three minutes, and it was extended to 7 to 10 minutes when the administration was oral. During the latent period there was an initial fall in blood pressure, quite irrespective of the method of administration, and the amount of such fall might be as much as 20 mm. of mercury. A rapid recovery followed, however. The effect of the drug was not so lasting when injected as when given by the mouth, and in the latter case the effect was greatest when taken into an empty stomach. After injection of ephedrine there was at first a well-marked rise in the blood pressure, persisting for seven or eight minutes. There was then a return to the normal blood pressure, this being succeeded by a second rise. Five or six such rises might occur, extending for 60 to 75 minutes after giving ephedrine by the mouth. When ephedrine was given by the intramuscular or the subcutaneous method rises were higher and more frequent. Then, after the series of rises had occurred the blood pressure fell below the normal. In one subject whose normal blood pressure was 125 mm. a dose of 1 c.cm. produced a rise to 155 in two and a half minutes; it lasted for seven minutes and then became normal. A second rise of the same order followed, then a third, not quite so high, and after this the pressure reached the subnormal figure of 109, where it remained for 40 minutes; and as it was only 117 an hour later the recovery to normal was very slow. In this stage some complained of renal pain. These phenomena indicated the need for caution in the administration. Sometimes the rise exhibited a dip or step, such as resulted from stimulation of the splanchnic nerve under anæsthesia. In the human subject, when a dose was repeated, the after-fall was much greater, and sometimes was precipitous.

Mr. Frank Coke spoke of the clinical observations he had made on the effects of this drug, which had been very widely discussed during the last few years in relation to asthma. It now passed under a trade name and was readily procurable over the counter by the public. Whether that was to the good he would not say. The treatment of asthma consisted more in the discovery and neutralisation of what was its cause in the particular individual than in the giving of any special drug; but when appealed to by an asthmatic sufferer in the height of his visitation one was glad to have at hand a drug which would do good. The type of patient for whom he had used ephedrine was the person who had attacks of severe asthma separated by long intervals. These had mostly been a good deal benefited, and the patient had been tided over critical periods. Administration might be thought dangerous, but he had not been in the habit of regarding the asthmatic as necessarily neurotic and likely to acquire the drug habit. One great advantage in using ephedrine was that it did not need to be injected, it could be given by the mouth, and it conferred immunity from asthma for two to three hours, even longer. It relieved contraction of the bronchial muscle, and it seemed to have an extraordinary effect on nasal mucous membrane, reducing its turgescence. Following the use of large doses of ephedrine the symptoms were tremor, palpitation, and (though he had not noted this) insomnia. In the reported case of a patient who took grs. 15 of the drug in 20 days acute cardiac decompensation developed accompanied by marked sweating, tremors, weakness, and palpitation. He had noted that patients who had taken a large dose not only could not micturate, but had no desire to do so; indeed they felt as if the mechanism for the act were absent This seemed to indicate a power of paralysing the bladder as well as the mucous membranes of the bronchioles and the nose. He suggested that the drug be supplied in tablets of gr. ¼.

Dr. John Freeman said he began to use ephedrine for asthmatic cases three years ago, but after a time he gave it up. It seemed to do good at first, but in a definitely less degree if persisted in. He took it up again recently, on hearing good effects attributed to it, but the results in his hands were the same. He tried alternating ephedrine with normal saline, unknown to the patient, a woman, and she was unable to tell the difference.

Dr. J. H. Hannan spoke of his use of ephedrine in gynæcological and obstetric practice. In the obstetric shock usually seen there was always some loss of blood, and as a means of carrying the patient temporarily over this condition he had found the drug of considerable assistance. He gave gr. 1 of it in 8 c.cm. of normal saline. Shock in the newly-born was a condition which, in the past, had been overtreated; artificial respiration did much to extinguish the small spark of life which the infant possessed. When definite shock was to be anticipated after operation he had given ephedrine gr. 1 an hour before the operation. Women at the menopause were strangely sensitive to adrenalin, but they were tolerant of ephedrine. Intramuscular injections of gr. 1 produced no effect on the blood pressure. One patient who took an overdose complained of slight irritation of the bladder, two others spoke of nothing beyond abnormal perspiration. One result of injections of the drug was to induce a feeling of general well-being, a euphoria; he had experienced it himself.

Dr. **Philip Hamill** said he had used adrenalin with success in Stokes-Adams syndrome. He had been watching for a case in which transient attacks occurred, passing from the normal rhythm to complete heart-block, with transient unconsciousness, so that he could try on such a patient the effect of ephedrine. He had found it improved some old people whose constant complaint was of tiredness and who had continual low blood pressure.

Dr. **George Graham** said he found that if people required a great deal of adrenalin ephedrine had no effect on them. In two medical colleagues he saw good effects from ephedrine in hay-fever, the dose taken being gr. 1 twice a day. Dr. Graham considered that ephedrine had a future for hay-fever.

Dr. **E. P. Poulton** related the case of an Austrian doctor who had a bad attack of asthma as soon as he arrived in this country which prostrated him, and who said ephedrine was the only treatment which brought him benefit.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY.

At a meeting of this Section on April 19th, when Dr. **T. T. O'Farrell**, the President, was in the chair, a patient with

Spirochætal Empyema

was shown by Dr. **John McGrath**.

He was a farmer, robust in appearance, and was admitted to St. Vincent's Hospital on Feb. 8th. He said he had never been sick in his life until he felt ill on Dec. 23rd, 1928, when his local medical attendant sent him to bed for several days, telling him that he was suffering from influenza. When he was out and about again after Christmas he began to feel progressively weaker.

On admission to hospital the temperature was 101° F., the pulse 80, and the respirations 20 per minute. For the succeeding few days his temperature was normal, but at the end of a week it was 99·5° F. in the evening for four days. On admission there were no physical signs indicative of chest or other trouble; the urine had a slight trace of albumin, but the sediment contained no pus, blood, or casts. On Feb. 16th, however, slight dullness was detected at the base of the left lung. This was needled and a small amount of pus, of a brownish-red colour, was withdrawn.

This pus contained numerous pus cells and moderately numerous spirochætes. No other organisms were seen in the smear preparations, and on culture no growth appeared, either aerobically or anaerobically. The spirochætes found were then non-motile; they stained easily, being Gram-negative; they were 4–10μ long, rather thick, and with two to eight undulations. They resembled *Spirochæta refringens*, but several of them seemed too short and too regularly curved to be of this species. A blood count on Feb. 17th showed: red cells 4,120,000 per c.mm., hæmoglobin 65 per cent., colour-index 0·7, white cells 15,080 per c.mm. The red cells displayed very slight anisocytosis, and of the white cells 70 per cent. were polymorphonuclear leucocytes and 1 per cent. were eosinophiles. Tubercle bacilli could not be found in the sputum, nor could spirochætes, and the Wassermann reaction was negative.

On Feb. 17th two ribs were resected, and several pints of fluid like tomato-soup were evacuated. This fluid gave similar results to the small specimen first examined. A drain was left in. On April 12th the fluid showed on spirochætes, and culturally gave a growth of pneumococcic and a coliform organism. The patient was given injections of novarsenobenzol, and a vaccine was prepared from the last cultures of the fluid. The urine, on April 17th, contained a considerable amount of albumin and several hyaline and some granular casts; but the patient's condition appeared to be good.

Few cases of spirochætal empyema appeared to be recorded, said Dr. McGrath, and especially rare was a case, such as the one described, in which the condition was not associated with gangrene of the lung or the presence of other organisms. A case with coexistent spirochætal empyema and gangrene of the lung had been reported by French observers in May, 1928, but in Dr. McGrath's case he was assured that there was no suggestion of gangrene of the lung. The patient's teeth were in good condition, but showed one small and one moderately large cavity. Since it had been stated that in tropical broncho-pulmonary spirochætosis, *S. castellanii* could nearly always be isolated from bad teeth, smear preparations of scrapings from the patient's teeth cavities were examined. Micro-organisms were present in very large numbers, but spirochætes could not be found.

Reports and Analytical Records.

PILSNER URQUELL BEER.

(Imported and Bottled by Pilsner Urquell and Co., Ltd.
77, St. Thomas's-street, S.E. 1. Brewed by the
Bürgerliches Brauhaus (Citizens Brewery),
Pilsen, Czecho-Slovakia.)

When analysed this beer gave the following results:—

Original gravity (before fermentation) ..	1049·39
Present gravity	1014·02
Alcohol	4·15 per cent.
Acidity (acetic acid)	0·08 „
Colour	5°
Preservatives	Nil

This beer possesses the delicate flavour typical of a matured high-class lager. It is very pale in colour, more lightly hopped than English beers of similar gravity, and is fully fermented.

Extension of the Elizabeth Garrett Anderson Hospital.—Last week the Queen opened the new "Queen Mary's Wing" of this hospital in the Euston-road. The institution dates from 1866, and the foundation-stone of the present building was laid by Queen Alexandra in 1889. The hospital now contains 106 beds with 28 beds at the Rosa Morison House of Recovery. In the new wing there are two surgical and medical wards of 18 beds each, a maternity department, a children's ward, two operating theatres, a new X ray department, and an enlarged out-patients' department with its own operating theatres. Further contemplated extensions are a new nurses' home, a pathological block, an isolation block, and wards for paying patients.

Royal Sussex County Hospital.—The appeal launched in 1920 for funds for the extension of this large hospital at Brighton has been disappointing in its results and the governors are therefore proceeding with their centenary scheme in stages rather than commit the hospital to a burden of debt. Last year the extension of the nurses' home and the lecture room and separate provision for the domestic staff were completed. This year it was decided to provide a new casualty department, but the new development was only made possible by a gift of £10,000 from Mr. Bernhard Baron. The department, which was opened on April 30th by Prince Arthur of Connaught, consists of a surgery, waiting-room, a minor operating theatre, and the accommodation needed for dealing with casualty patients, of whom there were 11,000 last year.

Reviews and Notices of Books.

CONTRIBUTIONS TO PSYCHIATRY, NEUROLOGY, AND SOCIOLOGY.

Dedicated to the late Sir FREDERICK MOTT, K.B.E., Hon. LL.D., M.D., F.R.C.P., F.R.S., by his colleagues, friends, and former pupils. Edited on behalf of the Mott Memorial Committee by J. R. LORD, C.B.E., M.D., F.R.C.P.E. With an appreciation by W. D. HALLIBURTON, M.D., F.R.C.P., F.R.S. London: H. K. Lewis and Co., Ltd. 1929. Pp. 401. 21*s.*

THE purchase of a handsome memorial volume is an act of piety not always rewarded by the acquisition of a solid addition to a library. An enthusiastic response to an invitation may cool in the interval between promise and performance, and contributions keenly anticipated too often take a perfunctory form when delivered. The high level of the original matter supplied by those who have been chosen to pay tribute to the memory of Sir Frederick Mott is thus noteworthy. The Mott Memorial Committee, under whose direction the book was prepared, consists of Sir Hubert Bond, Dr. F. L. Golla, Dr. Douglas Macrae, Dr. Thomas Beaton, and Colonel J. R. Lord, the last-named acting as editor. Reminiscences of some of Mott's many activities and details of his career are set out by Prof. C. von Monakow, of Zurich, and Dr. W. A. Aikin, while Prof. W. D. Halliburton supplies informal notes, giving a charming picture of a man whose happy wit, musical talent, and culinary accomplishments were a continuous source of pleasure to his friends. The articles range from highly technical pronouncements on the histology of the central nervous system in health and disease, and on biochemical changes found in psychotic subjects, to accounts of the development in Great Britain of those facilities for early treatment of mental disorders which the pioneer work of Sir Frederick Mott helped to make available. Contributions have been enlisted from workers in America (F. Petersen and S. E. Jelliffe), Australia (W. S. Dawson), France (G. Roussy and G. Levy), Germany (F. Plaut), Holland (C. U .A. Kappers), Japan (T. Morowoka), Italy (G. Pighini), Sweden (G. H. Monrad-Krohn), and Switzerland (C. von Monakow), as well as from those in the British Isles; among the latter figure appropriately papers from the Central Pathological Laboratory of the London County Mental Hospitals, from the laboratories of the Joint Board of Research for Mental Diseases, Birmingham, and from University College Hospital. Physiology is represented by Sir E. Sharpey-Schafer, anatomy by Prof. G. Elliot Smith. The frontispiece shows a picture of Mott in middle-life, and excellent plates illustrate some of the articles. In a preface the editor writes of the origin of the volume, which is the outcome of a suggestion made by Dr. Golla at a meeting of the Royal Medico-Psychological Association held just after Mott's death. The members will rejoice that the project then outlined has been achieved with signal success, and that a memorial worthy of the teacher and colleague who inspired it has been produced.

A HANDBOOK OF MIDWIFERY.

For Midwives, Maternity Nurses, and Obstetric Dressers. Seventh edition. By COMYNS BERKELEY, M.A., M.C., M.D. Cantab., F.R.C.P. Lond., F.R.C.S. Eng., Obstetric and Gynæcological Surgeon to the Middlesex Hospital. London: Cassell and Co., Ltd. 1929. Pp. 575. 8*s.*

ON every page of this handbook is to be found evidence of the author's vast experience of teaching pupil midwives, not only those who are already trained nurses and therefore better able to understand the principles of midwifery, but also the older untrained women who often find the theoretical side of their work so difficult and exacting. Throughout, the teaching is dogmatic. The midwife is first told how and why some event takes place. She is then told exactly what she herself must do and when to send for medical aid. Lastly, the procedure of the doctor is explained. No doubt many medical men of limited experience have been grateful for the presence of this little book in the midwife's bag.

The extensive revision to which the seventh edition has been subjected has necessitated the omission of the chapters on physiology and the questions and answers founded on the rules of the C.M.B. These, with certain additions, now appear in separate form under the title of "Physiology for Pupil-Midwives."

CLINICAL PATHOLOGY.

The Principles of Clinical Pathology in Practice. By GEOFFREY BOURNE, M.D., M.R.C.P., Casualty Physician, St. Bartholomew's Hospital; and KENNETH STONE, M.D., M.R.C.P., late Senior Demonstrator of Pathology, St. Bartholomew's Hospital. London: Humphrey Milford, Oxford University Press. 1929. Pp. 392. 16*s.*

THE title of this book hardly represents its content. It is, in fact, concerned less with principles than with their application. The authors state that the work is an attempt to "collect what are the most constant clinical pathological findings in disease, to state when the result of a test, whether positive or negative, is of value, and to record when such a test is worth doing and when it is capable of giving help." Such guidance is certainly needed by the practitioner, but the difficulties besetting its provision are not light. With the possible exception of the Wassermann reaction for the diagnosis of syphilis there are no clear-cut "tests" in clinical pathology. The business of the clinical pathologist is to use his laboratory as a means of elucidating the nature of morbid processes. This can only be done by the careful collection of evidence at the bench and by comparison of such evidence with that obtained at the bedside.

Where the pathologist is invited to see the patient in consultation with a physician or surgeon the diagnosis is likely to rest on surer ground than when each does his part of the investigation separately, and the correlation of the results is left to an assessor. But where joint work is not possible a pathologist who has to supply a written report is likely to be guarded sometimes to the extent of describing fully the nature of the material sent him without giving any indication of the significance of any abnormalities noticed or of their relative importance. In order to use such a report the practitioner must know in what terms a report on normal material would be couched and what variations are within normal limits; he must also discriminate, for example, between those changes which are recognised indications of diseased structure, disordered function, or parasitic invasions, and those which are merely signs of unusual formation, idiosyncrasy, or symbiotic association. In this book, written jointly by a clinician and pathologist, a creditable attempt is made to familiarise the practitioner with the sort of reports he may expect to receive and with the range of the deductions to be drawn from them. Unfortunately, it is not arranged on a uniform plan. For example, the section on diseases of the respiratory system very properly begins with a chapter on the significance of various abnormalities in the sputum, and a chapter on the estimation of renal efficiency precedes the discussion of various diseases of the kidney. But in some subsequent chapters the outlook is changed and the description of the pathological findings starts with the assumption that the diagnosis has been made. Similarly, the section on Diseases of the Gastro-Intestinal System is divided into seven chapters, six of which deal with diseases of various parts of the tract and the pathological disturbances characteristic of them. Interpolated among them is an excellent account of the examination of the stools marred only by the omission of a discussion on occult blood, which has been dealt with in a chapter headed Diseases of the Stomach. The authors have not always remembered that the most urgent problem confronting the practitioner is to interpret reports on cases still undiagnosed, and, therefore, impossible to classify

On page 286 the statement that the "commonest discoverable causes" of pure chronic nephrosis "seem to be chronic sepsis, tuberculosis, and syphilis," is not helpful; the cause is not yet discovered, and on page 303 the statement that acute pyelonephritis is a "rare condition in which an acute pyelitis extends from the pelvis into the renal tissue" is hardly in accord with modern views.

For the most part, however, the interpretations offered will be acceptable alike to pathologist and clinician, and Dr. Bourne and Dr. Stone deserve credit for having produced one of the first books in which descriptions of technique are entirely subordinated to explanations of the extent to which pertinent answers to definite questions can be obtained from the laboratory.

TUBERCULOSIS.

Some Methods for the Prevention of Tuberculosis. By W. BOLTON TOMSON, M.D., Medical Superintendent of the "Sea-View" Sanatorium, St. Leonards-on-Sea. London: Baillière, Tindall and Cox. 1929. Pp. 143. 6*s.*

Part I. of Dr. Tomson's book gives an account of the campaign against tuberculosis in France, Belgium, Switzerland, Norway, Sweden, and America. It is so rare for the enthusiast in preventive measures to look beyond the borders of his own country for information that there is good reason for wishing to encourage an author with extra-territorial sympathies; but it must be confessed that the information he has provided us from abroad is very sketchy, and should be described rather as glimpses than as panoramic views. However, as far as France is concerned, his account of the *Œuvre Grancher* and *Placement Familial des Tout-Petits* is complete enough to be interesting. Part II., which represents approximately two-thirds of the whole book, deals with the campaign against tuberculosis in England, and includes an eloquent defence of tuberculosis village settlements, of which the author records his conviction "that no better agent has been devised in this or any other country for combating the disease." Here is a challenge indeed. For it is safe to assume that not one tithe of the vast sums of money which have hitherto been spent on tuberculosis throughout the world have gone into village settlements. The author's claim is bold, perhaps extravagant. But it deserves to be treated seriously for this, among other reasons, that he gives in much detail the arguments which have generated his faith in this measure. He is not even afraid to deal with the weak spots in village settlements—their finances. The book concludes with a most interesting account of antituberculosis work in Hastings, much of the efficiency of which is due to the author.

INDUSTRIAL PSYCHOLOGY.

By Several Authors. Edited by CHARLES S. MYERS, M.D., Sc.D., F.R.S., Director of the National Institute of Industrial Psychology. Home University Library. London: Thornton Butterworth and Co., Ltd. 1929. Pp. 243. 2*s.* 6*d.*

IT would appear that the new science of industrial psychology is carrying on a menage à trois, being indissolubly wedded both to economics and to physiology. The essays that constitute this volume are, with the exception of Prof. Drever's chapter on the human factor, the work of Dr. Myers (who gives an all too brief introduction) and of his colleagues of the National Institute. The aim of industrial psychology is, as the editor states, to discover the best possible conditions in occupational work, whether they relate to the choice of a vocation, the selection of the most suitable workers, the most effective way of avoiding fatigue and boredom, the study and provision of incentives, the causes and remedies for irritation, discontent, and unrest, and the best methods of lighting, ventilation, temperature, lay-out of material, and of organisation. Each of these topics receive detailed treatment at the hands of specialists, and the essays go far to illustrate the liaisons to which we have already referred. This is no reproach, but a testimony to the breadth of the foundations and the height of the aims of this new science of industrial psychology. Such a science is pragmatic in the extreme, and in the interest of human happiness and productiveness takes all knowledge to be its province. The volume lives up to the high reputation of the series.

Practice, Oscillation, and Fatigue. A Study of Work at High Pressure. By J. C. FLUGEL, B.A. Monograph XII., British Journal of Psychology. London: Cambridge University Press. 1928. Pp. 92. 8*s.* 6*d.*

THE object of this research was to set a task of a large amount of easy work to be done with the maximum speed, and from the results obtained to estimate the curves of practice and fatigue and oscillation in the individual and in the group. The curves are related to one another, and the effect of practice, fatigue, and oscillation are measured and compared.

The research is a model of its kind both in lay-out and in conscientiousness of detail and logic. The shortcomings involved in the giving of incentives—in the form of rewards for speed—is realised, and the complexity of the factors involved in oscillation is admitted.

It was found that subjects suffered less from fatigue with the growth of practice, and that those who were the most easily fatigued were the less improvable. With this increase in speed following practice is connected a decrease in subjective fluctuation, as was shown by the diminished oscillation during the latter days of the experiment. Similarly, increase in fatigue involved a greater tendency to fluctuations. It is noteworthy that, when parallel intelligence tests were carried out on the young subjects, the correlation of ability in the experiment with ability in the test proved to be very low.

The monograph calls for careful study by educationists and students of industrial psychology.

THE MEDICAL ANNUAL.

Forty-seventh year. Bristol: John Wright and Sons, Ltd. 1929. Pp. 612. 20*s.*

THE "Medical Annual" stands alone in British medical literature and surpasses most corresponding foreign issues in quantity and quality. It is attractively bound and printed, embellished this year with 71 plates and many other illustrations, and soundly compiled. To any of our readers who may be unfamiliar with the scope and purpose of this book, we may say that it consists of authoritative reviews of progress and literature in all the medical sciences, handily arranged in topical, alphabetical order and interspaced with blocks of bibliographical references. Dr. Carey F. Coombs and Mr. A. Rendle Short are associated as editors, and the panel of contributors includes Prof. John Fraser, Dr. Robert Hutchison, Prof. Hey Groves, Prof. Hugh MacLean, Sir Leonard Rogers, Sir John Thomson-Walker, and Prof. Beckwith Whitehouse, to mention only a few of those whose coöperation has been enlisted. The surveys are comprehensive and impartial and, though mostly concerned with British work, include numerous references to collateral European and American advances. Crisp comments by the contributors and reproductions of many photographs, charts, prescriptions, tables, and diagrams add greatly to the value of the synopses of original articles. It happens, this year, that the preponderance is slightly on the surgical side. The work of H. Lilienthal, A. A. Law, J. R. Coffey, J. L. Yates, and others is discussed with reference to surgery in the treatment of phthisis, empyema, cancer of the lung, and bronchiectasis. This section is well illustrated by photographs and drawings of the stages of thoracoplasty as done by Coffey. A similar composite review deals with the different methods of spinal fixation in tuberculous spondylitis, including the ingenious new technique of S. A Grantham; fractures and injuries of the spine; and Kümmell's disease. A brief discussion of pre- and post-operative measures against shock, embolism, and parotitis continues the series of articles on these topics in previous Annuals. Notes on technique in intestinal surgery are given by the surgical editor. Advances in surgery of vessels are recounted in several parts of the book, notably in the section on periarterial sympathectomy. The articles on stomach and kidney surgery are shorter than the corresponding articles in 1928 and supplementary to them. A general survey of surgery in the East is contributed by Prof. A. Dickson Wright, of Singapore. A useful section is that by Prof. G. Hadfield on the conduct of post-mortems in general practice. This includes detailed technical instructions, a table of post-mortem changes, discussions on special cases of traumatic and sudden death, and a subsection on the medico-legal aspects of pregnancy, abortion, and infanticide. As in previous issues, there are reports of judicial decisions, the workings of the Workmen's Compensation Act, and new facts in industrial medicine. A good account of pulmonary asbestosis is included.

As to general medicine, there is ample justification for the claim that "the volume is full of suggestions as to treatment of everyday diseases." In commenting on new drugs, such as parathormone and ethyl hydrocupreine, the contributors maintain a delicate balance between undue conservatism and a readiness to accept everything new in an uncritical spirit. The sections on bronchitis, anæmia, gonorrhœa, rickets, and pneumonia are especially informative. The fuller reviews concern angina pectoris, the thyroid gland, and encephalitis, among other subjects. Endocrine therapy is fully discussed, and complete notes are supplied of the three ovarian hormones. There is a highly technical article on syphilis and the Kahn test, many interesting sections on ophthalmological work, and a mention of lysozyme. The accounts of modern developments in radium, radiotherapy, and phototherapy appear to be trustworthy and detailed.

In short, the contents of this year's "Medical Annual" are up to standard, and practitioners who have not hitherto made a habit of buying the volume year by year would be well advised to begin now.

A MANUAL OF OTOLOGY.

Eighth edition. By GORHAM BACON, A.B., M.D., F.A.C.S., Consulting Surgeon of the New York Eye and Ear Infirmary; and TRUMAN LAURENCE SAUNDERS, A.B., M.D., F.A.C.S., Aural Surgeon, New York Eye and Ear Infirmary. Philadelphia: Lea and Febiger. 1928. Pp. 576.

THE affections of the ear are clearly described in this book and the discussions of methods of treatment are full, well balanced, and in accordance with generally accepted principles. Numerous illustrative cases are related in the sections on diagnosis and treatment; these are of value in awakening the interest of the student, but may irritate the busy general practitioner in need of a compact book of reference. Some obsolete methods of treatment are included only to be condemned—for example intratympanic operations for chronic catarrhal deafness, such as removal of the stapes and artificial perforation of the membrana tympani. A monometric test for lateral sinus thrombosis is given five pages, a greater space than a new and almost untried method is entitled to occupy. The method depends on the fact that compression of the jugular vein raises the cerebro-spinal pressure as shown by a manometer attached to a lumbar puncture cannula, and that, when the lateral sinus is blocked, this rise of pressure does not occur. The description of the tests of labyrinthine function has been included among the symptoms of suppurative labyrinthitis, whereas it would have been better placed in the chapter on examination of the ear.

The work can be confidently recommended as an excellent text-book.

BLOOD GROUPS.

L'Individualité du Sang. En Biologie, en Clinique et en Médecine Légale. Par LEONE LATTES, Professeur à la Faculté de Médecine de Modène. Paris: Masson et Cie. 1929. Pp. 150. Fr.50.

THIS book represents the first really serious attempt in any language to bring together all the facts known up to the present in regard to the blood groups. Prof. Lattes has ranged the whole of the literature on the subject; no work of importance appears to have escaped him and he has succeeded in bringing together an immense mass of information. This is not one of those works in which the reader is presented with a mass of facts and left to digest them as best he can. Prof. Lattes's own work on the subject renders him a sound and competent judge of values; he has succeeded in binding his material together into a reasoned and well-knit whole. This book is a landmark in its particular field. It has already appeared in German, French, and Italian, and we look forward to the issue of an English translation. Prof. Lattes supports the limitation of the agglutinogens of the blood to the original A and B of von Dungern and Hirschfeld, and his authority, backed by the evidence brought together in this book, should serve to lay the phantoms of the multiple agglutinogens which have hovered over the subject for the last five years. He believes that in postulating these multiple agglutinogens, their originators were led astray by failure to realise the possible variations in titre of both agglutinogen and agglutinin in different bloods of the same groups; to this may be added the impulse irresistible to many, to make simple things complex. Prof. Lattes gives an admirable survey of the hypothesis of Bernstein, and concludes on all the evidence that his view that inheritance of the groups is governed by the presence of the three allelomorphs A, B, and O must replace the hypothesis of von Dungern and Hirschfeld.

The section devoted to the medico-legal application of blood grouping is of particular interest; in this section Prof. Lattes cites much of his own work, including such surprising feats as the grouping of blood from the stain of a squashed flea on clothing and from drops of blood on straw and pebbles. In legal medicine the blood groups have hitherto been considered chiefly as a means of determining non-paternity, but the matter has other applications, and the author points out that in Bavaria, Würtemberg, and Russia it is already laid down by statute that in all cases of "crime sanglant" the blood group of the victim must be determined, at autopsy if necessary, with a view to comparison later with blood stains on the clothing of accused persons.

APPLIED BACTERIOLOGY FOR NURSES.

By JEAN MARTIN WHITE, R.N., Instructor in Sciences, School of Nursing of St. Mark's Hospital, New York City; formerly Visiting Instructor, Schools of Nursing, of Bellevue and Harlem Hospitals, New York City. New York: Macmillan Company. 1928. Pp. 200. 12*s*.

THIS little book is written clearly, attractively, and soundly, and the views expressed are commonsense ones not overloaded with technical details. There is an admirable insistence upon the practical matters of specimen collecting, and upon the liaison between the ward or theatre and the laboratory, which should be taken to heart. Some of the diagrams do not make for the simplicity they are intended to produce, but on the whole the selection of matter has been judiciously made and readably presented.

HE LANCET.

DON: SATURDAY, MAY 18, 1929.

MILITARY MEDICINE.

ifth International Congress of Military and Pharmacy, whose proceedings are in THE LANCET last week and this, came to ion on Saturday last. The Congress was in y a success, and hearty congratulations may l upon this fact to the Director-General of y Medical Services, Sir MATTHEW FELL, alike of the Congress and the main-spring of its . In his inaugural address Sir MATTHEW well the essential objects of the Congress, pointed out that medical services in the rmies, and air forces of a nation were united ommon bond of membership of the medical , and should take full advantage of inter-exchanges of ideas and experiences, directed the care and treatment of the sick and in war. For here each nation, in whatever of alliance or of enmity it may find itself, the identical desire to relieve the misery of batants. Only by organised meetings at e intervals can the results of such ideas and es be considered in their real bearing upon ent organisations set up to deal with the mass of human suffering which war must bring.

nd this it is important to recollect—while ervice, as arranged for national defence or unctions in accordance with the principles ations required by the commands of the ich are served, the congresses of the officers arge these responsibilities must be of great civil medicine and indeed to all the world, will assist in the application of advances in cience to peace conditions. The aim to-day l civilised nations of medical endeavour for urposes makes for the maintenance of the andards of hygiene and sanitation, and while during actual war must be directed almost y to producing the least possible delay in he sick and wounded within the immediate edical care, the general lessons of value to munities receive remarkable illustration So that from the military necessities of a d there springs the permanent development measures for all. The point was well made OYNIHAN when he introduced the name of NIGHTINGALE into his eloquent address at all banquet, for from what that great woman e Crimean War sprang the whole of the rvice as it exists to-day in this country, in ll as in military hospitals. And much of the and intensive research conducted in the es of the belligerent services during the late bearing fruit in civil hospitals and in public ministration; so that it is for the advance- he good of all that the lessons of this work regularly reviewed in the light of progressive nt.

ressions of those who attended the Congress, ientific sessions and its many social diver- went to prove that the labours of the conveners and of the officiate were well repaid in results. First there was a distinct development of international friendship in spite of the difficulty of language, and may not too much be made of this difficulty? Most of the representatives present at the Congress knew some English and some French; most of their hosts knew some French; and in dialogue, at any rate, the advantage could be reaped of a common education along special lines and having a high standard. This ensured that, however imperfect might be the command of each other's language, conversations, though started in a halting manner, would often develop into real intercourse as each found a way to understanding the other. But it must be admitted that the English were usually the slower to take the plunge, the less ready to guess at meanings, and the more self-conscious of their limitations. None the less a real interchange of view was often effected between members of the Congress upon such matters as the standardisation of certain essentials of war equipment, the work which is done here by the various committees of the Red Cross—for example in laying down forms for the recording of casualties—and the regulations in our own army concerning the details of first field dressings, the uniformity of stretcher-fittings, and many analogous matters. No doubt the great difference in our military organisation, as a voluntary and permanent one, including completely separate services for the Army, Navy, and Air Force must have given our foreign guests a great deal to think about, much, we trust, to admire, and something perhaps to criticise; but in one respect criticism was wholly withheld, for of the nursing in our Service hospitals our foreign guests spoke with unbounded admiration, contrasting it with the nursing made possible under a conscription system. That these things should have been discussed by men of experience face to face will produce valuable consequences, and it is to the fine coöperation of our civil medical bodies that the great occasions for such discussions were due last week. We feel that we are speaking in the name of the organisation of the Military Congress when we speak thus of the hospitality extended to the members.

◆

THERAPEUTIC SPLENECTOMY.

ALMOST the only thing a surgeon can do to the spleen is to remove it, and we may well feel a little surprise that this drastic form of intervention should have found an undisputed place in therapeutics For little is really known of the physiology of the organ and no more of the part it plays in pathology, and the operation was originally undertaken on the crude assumption that in certain diseases the spleen was enlarged, and therefore presumably a diseased structure which the body would be better without. Of late years, however, splenectomy has gradually been assigned a settled rôle in the treatment of one or two conditions whilst leaving considerable excuse for doubt in others. Since the total experience of one person can never be very large, owing to the rarity of splenic disorders, it is useful to pool the knowledge obtained from various sources, and hence a good deal of interest attaches to the recent debate on this subject at the Royal Society of Medicine, reported in our last issue. Dr. HUGH THURSFIELD cleared the ground by making a clear statement of the few undisputed facts of splenic physiology, pointing out that the spleen has been proved to be a reservoir of blood which can be tapped at need; that it certainly plays some part in infections, as it almost always enlarges in their presence; that its removal can be adequately compensated for; and that it is seldom if ever the only representative of splenic tissue in the abdomen, a fact which is of great importance to the surgeon. Beyond this, as he pointed out, little further is known for certain about the uses of the spleen. As for surgical interference with it, the conclusions reached by Mr. A. J. WALTON in the course of his masterly review seem to be those accepted by most physicians and surgeons. Apart from injuries and torsion and the very rare neoplasms for which splenectomy gives brilliant results, the indications for operation are few—not nearly so many, in fact, as we were disposed to think a few years ago. Even these indications are hedged round with conditions which must be observed if success is to be achieved. Cure may, indeed, be brought about in Banti's disease, but only at an early stage when damage to the liver is not far advanced; in purpura hæmorrhagica the bleeding may be stopped, but care must first be taken to make sure of the nature of the case, for if there is thrombocythæmia and not thrombocytopenia the addition (caused by the operation) of more platelets to the excessive number already in the blood may lead to widespread and fatal abdominal thrombosis. The functions of the blood-platelets, to which attention is drawn this week in another column, have here a surgical significance. In acholuric jaundice, again, particularly of the acquired type, very satisfactory results have followed splenectomy; but here the list of successes begins to tail off, for in all the other conditions in which the operation has been tried, reports are conflicting and not as a rule enthusiastic. Amelioration without cure is their general purport, and advocacy of this form of treatment is apt to be rather half-hearted. Certainly splenectomy seems inadvisable in pernicious anæmia, where much more effective medical treatment is available, and in the leukæmias, where enlargement of the spleen is only a part of a general leucocytic disease. In Gaucher's disease, too, the advantages of the operation are very doubtful on similar grounds. Certain cases of chronic sepsis admittedly furnish arguments for the operation, and also early cirrhosis of the liver, which has now become a rare disease, but more experience and further study is needed before a sound judgment on these points can be made. Here the subject must be left for the present. Where indications are precise and action is taken, it must always be remembered that the operation may prove very formidable. The organ lies deep, the supplying vessels are much enlarged and nearly always friable, whilst adhesions are often numerous. Nevertheless surgical handicraft has found fairly satisfactory ways of dealing with the difficulties which arise, whilst the possibility of preliminary or simultaneous transfusion of blood is an important factor making for safety. If splenectomy is required at all, we may say broadly that the earlier it is undertaken the better the chances of success.

THE LONDON RHEUMATISM CLINIC.

THE proposed Clinic for the treatment of rheumatic diseases in London has made good progress and is now likely to be open in the coming autumn. All the money has been collected and building is in full swing in Regent's Park Square East where the Clinic is to provide a working unit of sufficient size to treat a normal average of 400 cases a day. There is no need to set out here what the raw material of this Clinic is to consist of. Both the captains of industry as well as those who represent the interests of the workers are at last conscious of the extent to which rheumatic disease is proving a blight on industry and an intolerable burden on the benefit funds of approved societies. We have in this country given an international lead on the incidence of rheumatic disease and in the search for its origin and causation, but although we have admirable hospitals at our spas and watering-places which can deal with at least 5000 bed-patients annually, there is no clearing-house in the industrial areas to sort out those who need in-patient treatment, no proper clinic for out-patient treatment of those in the early stages of disease who can remain at home, and no place where those who have had the benefit of institutional treatment can receive the continued observation and after-care which will alone ensure results. The London Rheumatism Clinic will be the first example of this type of institution, the first link in the chain of a complete rheumatic service, which has for its further development the arthritis unit and the spa hospital. The physical treatment clinic is not only the first but the most important of the three, for here we have only to regard the position in Holland where there are no spas and where, none the less, multitudes of early cases of rheumatic disability are completely cured in the local clinic at Amsterdam. To the British Committee on Rheumatism is due the inception of this Red Cross Clinic, and the Committee is unanimous in believing that physical treatment, properly given in conjunction with other special methods, is the best prescription for early and chronic rheumatic disorder. Arrangements will be made in the Clinic for treatment by means of at least four groups of physical agents including (1) heat and movement in baths, and local application of water vapour and hot air: (2) manipulation massage and exercises, alone or in combination with heat, by the hand or by douches or whirling water; (3) radiation in the form of heat, light, and ultra-violet rays; (4) electricity in the form of constant, interrupted, and high-frequency current. It is expected that the majority of patients will require a course of four to six weeks comprising ten to fifteen attendances which will enable some 12,000 individuals to pass through the Clinic in the course of the year. Those who are able and willing to pay a reasonable fee for treatment will do so and there is every prospect that the industrial assurance societies, all of whom have coöperated, will contribute. In this way the Clinic itself should be self-supporting or something like it.

Last week the important step was taken of appointing a consulting staff of honorary physicians to attend the Clinic in an honorary capacity; various directors and experts in special forms of treatment are to be appointed later. The decision to staff the Clinic on the lines of a general hospital differs from continental practice in such matters, as may be seen from the appendix to the concluding article on Modern Physical Treatment in Relation to Rheumatism which we publish on another page of this issue. The Amsterdam Institute, for instance, is in charge of a director who is responsible for both the administrative and the clinical sides, and in general this may be said to be the practice of all such special clinics on the Continent or in America. Our own experience of the voluntary hospital system is a peculiarly happy one; its beneficent spirit is much to be desired at such a clinic, and we hope that a combination of this spirit with that of the continental clinic will be workable. The question of a director, in accordance with the Continental pattern, will be a matter for later consideration. Dr. Glover's

Report to the Ministry of Health (A Report on Chronic Arthritis. Ministry of Health Reports on Public Health and Medical Subjects, No. 52) admitted general agreement on the fact that physical treatment is more successful when a combination of methods is employed and that variation of treatment is often desirable. It would hardly be within the physical compass of a part-time consulting staff to effect such an intimate liaison that this combination of methods would be open to each individual patient without expert direction by a whole-time resident. It is not, as a recent correspondent imagined, as though balneology requires no skilled and qualified operators. Experience in the action and uses of baths is hard to come by, and at the present time at all events implies careful *study of continental methods. The position, it may be* hoped, will be otherwise in the future, for the London centre should serve as a training ground for those who wish to qualify for the charge of similar establishments which are certain to be set up in other large centres of population. As yet the practitioner under whose care the patient is at home has not sufficient knowledge at his disposal to prescribe the physical treatment which is needed, and it is to be borne in mind that no patient will be accepted at the Clinic save with the recommendation of a doctor. The organisation of the London Rheumatism Clinic is a turning point in the effective treatment of rheumatic affections in this country and no care could be too great in finding the best method for choosing and training the staff who are to control its destiny.

◆

PROGNOSIS IN SOLAR DERMATITIS.

In a recent leading article[1] we dealt with a group of cases in which the response to the sun's rays is far in excess of the normal, indicating what is at present known of their nature and causation. It only remains to add that any promise of betterment in solar dermatitis should be guarded. The prognosis is worse the longer the condition has persisted, and the congenital cases with hæmatoporphyrinuria, which presumably depend on some inherited dyscrasia of liver function, are most intractable. The milder cases which develop in early youth are relatively favourable, most of them clearing up after puberty. When the symptoms develop suddenly in girls in their teens the outlook is not too gloomy if the patient can afford a systematic investigation. The urine should be examined—chemically, microscopically, and with the spectroscope—and the physician should not be content with a simple statement that blood, sugar, albumin, and hæmatoporphyrin are absent. Notice should be taken of any abnormal blood pigment, such as methæmoglobin or bilirubin, &c., and of the presence of indican. Intestinal toxæmia may be revealed by high lavage and bacteriological investigation, although it should be borne in mind that pathological organisms found in the gut may have been excreted from a distant source, such as a diseased antrum or a dead tooth. When such obvious foci have been dealt with autogenous vaccine treatment may help. Measures directed to the improvement of intestinal toxæmia, if present, may be successful; if none can be found an attempt may be made to desensitise by empirical means, such as intravenous peptone injections or autohæmatotherapy. Local protection of the skin by lotions or ointments containing ichthyol or quinine, or the specially prepared ultra-zeozon cream, and powder are worthy of trial.

Annotations.

"Ne quid nimis."

SIR CLIFFORD ALLBUTT.

A BRONZE portrait of the late Sir Clifford Allbutt, *to be placed in the Library at the Medical School at* Cambridge, is being unveiled to-day (Saturday) in the presence of Lady Allbutt, the donor of the portrait, and a small number of personal friends. Sir Clifford Allbutt, Regius Professor of Physic in the University of Cambridge, died in 1925 at the ripe age of 88, the acknowledged leader of the medical profession in this country. To an extensive clinical experience he added a deep knowledge of the literature of medicine, and his academic teaching and powers of organisation alike gained for him his high position, while his personal character endeared him to all with whom he came into contact. A permanent memorial to his memory is fittingly placed in the medical school at Cambridge, where, when over 50 years of age, and without any experience as a professor or a college don, he took his place at once in the front of university life.

IMMUNISATION AGAINST DIPHTHERIA.

THE campaign against diphtheria in New York City, after flagging for a time, has been prosecuted with renewed vigour and considerable success during the last few months. This revival of effort is largely due to public health administrative changes and the formation of a Diphtheria Prevention Commission. Parents desiring immunisation for their children are *in many instances now referred to their family* doctor whose coöperation in the scheme is thereby enlisted. The need for a renewal of effort is shown by the rise in prevalence of diphtheria in 1927 after successive years of decline. In 1926 there were 7530 cases and 477 deaths in New York City; in 1927 13,500 cases and 717 deaths, and in 1928 10,770 cases and 642 deaths. The rise in incidence is probably mainly attributable to the existence of nearly a million unprotected children, mostly under the age of five. In order to reach these children of pre-school age the coöperation of the private physician is essential, and every practitioner has been asked to circulate among his patients a joint letter from the Health Department and the County Medical Societies urging the importance of diphtheria prevention. Hitherto there has been some feeling among family doctors that preventive measures instigated by the health authorities tend to trespass on their preserves. On the other hand, the health authorities complain that the family doctor has not hitherto taken his due share in attempts to prevent disease, though his special position affords ample opportunity for such work. The Diphtheria Prevention Commission have therefore arranged for the free supply of toxin-antitoxin to practitioners, and it is estimated that during the first ten weeks of the year nearly 6000 children were immunised by their family doctor. These figures are based on the assumption that all the outfits called for or purchased during the last three months have actually been used. More reliable figures are those showing that complete courses of three injections have actually been performed during the same period on 7220 children by the 48 health department diphtheria prevention stations. The goal aimed at is the immunisation of 2500 children each week in order to secure the inclusion of those under one year, who represent a total of 125,000 births per annum. During the last week reported on, ending *March 16th, through the combined effort* of physicians and public health officers, it is estimated that a total of 2385 children were immunised. By maintaining a similar rate the desired number would be protected in the course of the year, but as we have already observed, the evidence that purchases imply inoculations can only be regarded as reliable if the purchases do not diminish in subsequent months. Hitherto the children inoculated in private practice have been those advised to go to their family doctor by the health commissioners. The Commission now urge that all doctors should familiarise themselves with the technique, and should proceed to immunise all children in their own families, all those under ten in the families under their care, and all diphtheria contacts. If this advice is followed, important data should be forthcoming as to the results of preventive inoculation in a large community. All depends on the continuance of close coöperation between health officer and private practitioner. The lesson should be appreciated in other countries, especially in France, where, as our Paris correspondent noted recently, a special campaign has been set on foot by Mr. Loucheur, the Minister of Hygiene. In this country, in the absence of combined effort by the various public health services and the medical man in close touch with the life of the individual, attempts to control diphtheria have been haphazard and unequal. The disease is preventable and best attacked when, as at present, it is not very prevalent. How far the plan of campaign in New York would be practicable in London only experience could show, but as a start practitioners might be persuaded at least to familiarise themselves with the technique and to make a practice of immunising contacts and young children.

[1] THE LANCET, April 27th, p. 882.

THE IMMEDIATE PROBLEMS OF MENTAL DEFECT.

WE have already commented upon the report of the Special Committee of the Board of Education and the Board of Control, so far as it has been issued, noting as one of its most significant features the estimate of the number of mental defectives in England and Wales, made by Dr. E. O. Lewis and his assistants in their survey of six selected areas. Part III. of the report, which has been so far withheld, may appear at any moment; its imminence has been noted in the daily press and, inasmuch as it deals with the defective adult, much writing on the question of compulsory sterilisation has resulted. Those who expect to get endorsement in this part of the report of some of the suggestions which have appeared may be disappointed to find it contains nothing startling on the matter of sterilisation, dealing rather with questions of more immediate practical application.

There are grounds for deliberation which are not sufficiently appreciated. A large number of defectives owe their condition to disease or injury between conception and the age of 3 or 4, and their defects are usually held to be non-heritable. Further, the evidence furnished by Dr. Lewis and his collaborators, as well as that in other reports, shows these secondary cases to be scattered throughout the racial elements and social strata of this country. Mongols, whose plight seems to be due to germinal error, are usually sterile, but a smaller group of defects is due to germinal variation and would be heritable. These cases develop more in some family strains than in others, and one responsible observer has noted that in the family groups where these defects occur more successful individuals—winners of scholarships and so on—are also found. But the bulk of the cases which are causing real anxiety are genetically normal; they express the fact that as the conditions of life become more complex, their inferior mental attainments conduce to inefficiency, while it is these failures who tend to mate with similar failures, owing to the absence of mutual criticism. Also these are the persons who have no initiative, and who tend accordingly to be left in the isolated areas of the country in close association with each other, the more adventurous members of the community having gone where wider opportunities offer. This is a picture of a lower cultural level rather than of a pathological condition, and only when the capacities of such individuals are markedly inferior and their will dangerously weaker does the public ask for protection from them. A few of them may fall so low as to be certifiable on the present standards, but to check their multiplication by sterilisation would mean operations more widespread than seems to be generally recognised. It is hard enough to get segregation of defectives under the wise measures already provided, and it would be harder still if it were believed that sterilisation would follow—the process would not be regarded as preventive but rather as punitive.

In short, there is need for further inquiry before the difficult legislation and harsh administration implied by compulsory sterilisation are put in hand. The procedure has many strong claims to support it, but we feel that further investigation is needed before its adoption as a practical policy can be considered. The directions in which inquiry could be made are known, controls could be obtained, and in this way —with no great lapse of time—data would be forthcoming which would make the right policy far more certain.

NEW LIGHT ON SCHIZOPHRENIA.

THE monumental work of Sir Frederick Mott on the pathology of dementia præcox (schizophrenia) furnished evidence of a generalised anatomical degenerative change not only throughout the central nervous system but in the ductless glands, more especially the gonads, suprarenals, and pituitary. But in spite of these well-marked anatomical changes, repeated observations revealed very little obvious difference between the resting functions of the schizophrenic and those of the normal subject. The group of workers who have continued the investigation on the pathology of schizophrenia in the Central Laboratory of the London County Mental Hospitals have sought for evidence of abnormalities of the physiological response to conditions exerting some stress on the organism rather than for some static difference from the normal state. Once this method of investigation was adopted it was found that the schizophrenic physiology showed signs of abnormalities of response in every direction. Isabella Robertson showed that the vasomotor responses to food, drug, and postural stimuli were inverted; S. A. Mann and his co-workers detected abnormalities of the carbohydrate metabolism and a failure to respond to insulin in the presence of ingested glucose; the processes of oxidation as tested by administration of thiosulphates and other chemical methods were found to be deranged. Most of the phenomena observed were explicable on the theory of a disturbance of the acid-base equilibrium in the psychotic organism, and following up this line of thought it was found that there was evidence in the urinary post-prandial and matutinal reactions of a state of the organism resembling very strongly that which obtains in the normal individual during sleep. Since renal tests cast no suspicion on the regulating mechanism of the kidneys, it became probable that the primary disturbance of the acid-base equilibrium was to be sought in dysfunction of the respiratory centre, and it was, in fact, found that the respiratory centre of the schizophrenic resembled that of the normal sleeper in showing a depression of its response to CO_2. In a paper, published on p. 1032 of our present issue, Dr. Marsh presents further evidence of this depression of the respiratory centre in schizophrenia. Investigating a large number of cases he finds that at least 88 per cent. of them show such a depression and (which is equally important), that it seems to be a general symptom of the disease and not merely an expression of the stuporose state characteristic of so many patients. The facts now placed before us mark another step in the unfolding of a definite pathology in one great division of mental disease, though, as Dr. F. L. Golla pointed out to the Section of Psychiatry of the Royal Society of Medicine on Tuesday, it is as yet too early to draw any conclusions about the nexus between these profound biochemical changes and the disorder of conduct. Information is urgently needed concerning the state of the central nervous system with which these disturbances must be in some way connected; still less have we data on which to come to a decision on the possibility of a psychogenic origin for this class of psychosis. Nevertheless, the remissions of the psychosis occasionally associated with acute bodily disorders, and those of more temporary nature which A. S. Loevenhart has been able to achieve either by stimulating pulmonary ventilation by injection of sodium cyanide or with inhalations of Co_2, give some ground for hoping that the symptoms of dementia præcox may ultimately prove in some degree amenable to a therapy based on biochemical considerations.

CHRONIC PULMONARY SUPPURATION.

THORACIC surgery has achieved notable successes in the treatment of localised pulmonary abscesses. When an abscess, situated in the middle or outer zone of the lung, has become isolated by the formation of encircling inflammatory tissue, pneumotomy and drainage may be expected to lead to a cure. Suppuration limited to the lung parenchyma is however exceptional, for the continuity of lung tissue, bronchi, and pleura commonly leads to a wider spread of disease. Once this spread has begun there are no fixed limits to the infected area and a condition aptly described as "rabbit-burrow abscess" results. The sufferings of the patient with this condition are almost unsupportable: constant cough, fœtid breath, the expectoration of large amounts of stinking sputum, attacks of hæmoptysis, and increasing malaise make him willing to submit to any treatment that promises even a slender hope of cure. Pulmonary abscess is usually associated with an infection by spirochætes, and the expectorated pus may contain enormous numbers of these organisms, almost to the exclusion of other types. A case bearing on this fact is reported on p. 1037. The discovery of the spirochæte as the probable infecting agent led to the use of arsenical preparations in the treatment of these cases, but the results have been disappointing, nor has serum therapy been more effective. Where the physician has failed, the surgeon has met with little greater success, for the difficulty he has to face is akin to that of draining a marsh through a single dyke. Pneumotomy and drainage are insufficient, and lobectomy which involves an operative mortality of at least 40 per cent. is almost a method of despair, although Evarts-Graham has somewhat lessened the risk by the use of the cautery. The effectiveness of artificial pneumothorax depends upon securing a complete collapse of the lung, and this is usually impossible to obtain even when the pleura is free from adhesions. Should only partial collapse result, no benefit will accrue and empyema may follow. Phrenicotomy increases the stagnation in the lung without securing adequate compression. Léon-Kindberg and his colleagues think[1] thoracoplasty of value in suppuration of the upper lobe; lipiodol has, however, shown that the basal bronchi do not ungdergo effective collapse after this operation. Bronchoscopy and lavage, as practised by Chevalier Jackson, may render life supportable by periodic cleansing of the affected lung. We must, however, admit that we are at present powerless to heal, and can do but little to lessen the sufferings of the victims of pulmonary suppuration. It should therefore not be forgotten that chronic pulmonary abscess is sometimes the result of previous neglect; the slightest carelessness in operations on the upper airways may have tragic consequences, nor should the risk of lung infection from neglected sepsis in the nasopharynx be forgotten.

THE HEALTH OF THE LITTLE COUNTRY-TOWN.

THE last line of an old jingle which runs: "The devil made the little country-town," is usually interpreted as a reflection on the ethical, rather than the sanitary, standards of small communities. A recent discussion in *Tidsskrift for den Norske Laegeforening* has centred round the country-town, not as a moral sink of iniquity, but as an area in which the close contact of a few hundred or thousand persons is not compensated for, from a sanitary standpoint, by the public health machinery with which large towns are blessed. This discussion arose out of a series of papers by Dr. E. Andersen, in which he showed how much greater was the improvement of late in the public health of towns than that of country districts. His comparison was intended to promote reforms in country districts, and one of his recommendations was the employment of public health nurses who would, by gentle persuasion and infiltration in the home, see that the orders or recommendations of the local health authorities were translated into action. His conclusions as to the relative iniquity of the country in health matters were challenged by a correspondent, Dr. D. Tornöe, who argued that a factor, which conferred an undeservedly sinister reputation on the country, was the inclusion therein of the little country-town. He implied that if only strictly rural districts could be judged on their own merits, they would not be found to be so unhealthy in comparison with the large towns. In answer to this defence of the really pastoral country district, Dr. Andersen produced some interesting statistics in the *Tidsskrift* for April 15th. He showed that in the eight counties with the lowest death-rate (an average of 9·9 per 1000) 25·3 per cent. of the population lived in clusters of houses in the country—the little country-town. On the other hand, in the eight counties with the highest death-rate (an average of 11·9 per 1000) only 16·8 per cent. of the population lived in clusters. These figures do not of course by themselves acquit the little country-town of the accusation of possessing all the vices of a large town and none of the virtues of the country. But they suggest that the little country-town may not after all deserve its lurid reputation.

HYPERNEPHROMATA.

IN all clinical medicine there are no conditions more interesting than those in which the whole appearance and character of the patient are changed, and of these syndromes that associated with an epithelioma of the suprarenal cortex is perhaps the most striking. It is most common in girls, and the bronzing, hirsuties, and alteration of the figure and mentality of the patient towards the masculine type go to form a picture that, once seen, can never be forgotten. But the enthusiasm of the medical man who encounters such a case in his practice is likely to wane very rapidly when he comes to consider treatment. Of the patients under 20 from whom such tumours have been removed only a very small number have survived, and recently yet another case of sudden and unexplained death within two days of what seemed to be a perfectly simple and successful operation has been recorded in France.[1] In this case the tumour was comparatively small so that it could not be palpated, although its presence was suggested by the clinical condition. It was finally located by radiography, after the preliminary induction of a pneumo-peritoneum—a method of diagnosis not very often adopted in this country. No satisfactory explanation of the high mortality in these cases has been put forward. In the one just quoted no autopsy was allowed and the authors of the report fall back on the supposition that death was due to sudden heart failure, though they give no reason why this should have happened. In a number of the reported cases which have come to autopsy it has been noted that the opposite suprarenal gland was poorly developed, and it seems possible that death following removal of the tumour is due to a defect of adrenal secretion or some other disturbance of endocrine balance. Whatever the cause, it is undoubtedly true that the operation, though technically simple, carries an immediate high mortality quite apart from the possibility of there being undetected secondary deposits in other parts of the body, these being highly malignant tumours. It seems well worth while, therefore, to give deep X ray therapy a trial. Favourable results have been recorded in one or two cases in which the tumour has become smaller and the symptoms caused by it have disappeared.

PSYCHOLOGY OF READING.

THE relation of speech to the written word symbol remains a central meeting point of many studies. It is cognate to the problem of vision, to the neurology of aphasia, and to the practical application of such psychological functions as learning and skill in various economic activities. Even apparently simple investigations, such as that of assessing the merits of different kinds of printers' type, are hampered by our ignorance of the mental processes involved in reading. The Medical Research Council had at one time a committee on the Legibility of Type, and published the results of an experimental study on the subject conducted by Mr. R. L. Pyke.[1] For years workers on the legibility of isolated letters have clamoured for some modification in the shape of certain confusing letters of the alphabet which make for obscurity and inaccuracy. The printed word and letter are so familiar to us in every-day reading, we take in so much by their "configuration" or Gestalt, that we are blind to the waste involved in bad printing, confusing type, and the similarity of certain letters and words. This waste is not merely of time but of mental effort. It was decided, however, by the Medical Research Council that no conclusions of practical value could be anticipated without a deeper knowledge of the psychological factors underlying the power of reading than is at present available. The Committee on the Physiology of Vision, with which the Committee on the Legibility of Type was merged, therefore initiated a series of studies into the mental processes involved in whole words and sentences rather than isolated letters. The first fruits of this extended research are to hand in two detailed preliminary studies, bound together, on Errors in Reading and on the Relation of Meaning to Perception in Reading respectively by Mr. M. D. Vernon and Mr. R. W. Pickford.[2] Mr. Vernon set out to determine how far typographical errors, and especially the mutual substitution of readily confused letters, entered into the reading of various types of material. By means of the tachistoscope types of reading material of ascending order of complexity were exposed to view for short periods of time. The errors made in various groups were studied and tabulated, and the reliability of the subjects were graded carefully by Pearson's ranking method. It was found that the errors were associated with the form of certain individual letters and with the position of letters in the word, and that certain types of substitution also occurred. Other errors were found to be capable of classification into "meaningful" and "mixed and doubtful." These errors occupied a third of the total. In general it was found that where full comprehension of meaning was achieved in reading, few typographical errors occurred. Where, however, meaning was obscure, or the context was not continuous, errors of substitution or replacement took place. Mr. Vernon found, as did O. Messner, that individual differences in perception were capable of grouping into "objective" and "subjective" classes. In perceiving material in which meaning was of little importance, accuracy increased with the perceptual span, but in advance of Messner, Vernon's observation led him to mark off a broad inaccurate type from a narrow inaccurate type—i.e., in reference to the visual perceptual span. Mr. R. W. Pickford arranged three experiments to investigate the relationship between the flow of perceptual processes and the flow of meaning in reading. It was quite obvious from all the admirably arranged experiments that meaning was a very significant matter in all processes of perception, imperception, and errors. In other words, the rôle of memory and of affectivity is a very important one in all errors of speech and of reading—i.e., errors which are not traceable to gross aphasia, fatigue, poor illumination or defective type. These twin researches, therefore, are not only of interest for what they set out to establish, but also for the associated problems. Curiosity is at once aroused by Mr. Pickford's intention to attack the problem from the standpoint of Head's classification of aphasias. The question of the various forms of visual imperception and word-blindness might be profitably investigated by the same tachistoscopic methods. The temperamental factor probably involved in Messner's objective and subjective types, and Vernon's "narrow and broad inaccurates" suggests new lines of research into the psychology of temperament and its effect on accuracy—a matter of some importance to vocational guidance. Neurologists, psychologists, and educationists alike should take note of these interesting approaches to what superficially looks like a dull subject.

AUSTRALIAN SURGEONS IN CONGRESS.

WE have just had a report of the second annual meeting of the Australian College of Surgeons, which was held at Sydney from March 5th to 9th, when there was a large attendance of Fellows from all parts of the Commonwealth. On the morning of the first day demonstrations on anatomy, pathology, obstetrics and gynæcology were given at the University medical school and in the afternoon on surgery at the Royal Alexandra Hospital for Children and the Lewisham Hospital. At the former, Dr. R. B. Wade showed a number of cases of spastic paralysis and Hirschsprung's disease, illustrating the types suitable for ramisection; it is in the latter that the operation so far has given the most satisfactory results. At the Lewisham Hospital Dr. S. H. Harris demonstrated his operation for removing the prostate with complete closure and restitution of the prostatic urethra. Dr. N. D. Royle demonstrated the technique of lumbar ramisection and his new operation for cervical ramisection. On the second day at the Sydney Hospital a demonstration on skeletal traction was given in the fracture ward by Dr. C. E. Corlette, and on the pathology of bone by Dr. Keith Inglis. In the afternoon Sir Alexander MacCormick operated at St. Vincent's Hospital, where a demonstration of deep X ray therapy was given by Dr. B. Harrison. The whole of the third day was taken up at the Royal Prince Alfred hospital, including the new radium clinic and the department of urology. Three evenings were occupied in discussions at the Royal Alexandra Hospital for Children, where Sir George Syme (since deceased) presided. At the first, which was of a purely administrative character, it was decided to leave in abeyance the question of erecting a building for the College at Canberra. The proper allocation of fees between surgeon and assistant was fully discussed and referred to a subcommittee to report next year. The question of higher degrees in surgery also came up. In Australia there is now a great variety of these and an attempt at uniformity is being made throughout the Commonwealth and New Zealand. Admission to the College, following American practice, is by appointment, on the personal recommendation of a number of Fellows, but after 1932 all candidates for election must possess a higher degree in surgery. At the second evening session Dr. Colin MacKenzie showed a series of specimens illustrating the application of the comparative anatomy of the fauna of Australia to everyday surgical problems. These specimens will form the basis of the anatomical collection it is proposed to establish at Canberra. Dr. H. G. Poate opened a discussion on chronic pulmonary suppuration, Dr. Harris showed the technique of prostatectomy on the screen, and Dr. A. J. Trinca read a paper on fat necrosis of the female breast. At the third session, Mr. Julian Smith opened a discussion on the prevention and treatment of cancer and showed the Canti film. Mr. R. Graham Brown, of Brisbane, read a paper on laryngectomy for malignant disease, which led to criticism of the present distribution of radium, and it was proposed to press for a supply available to all large hospitals in Australia.

FŒTAL DEATH AFTER INDUCTION OF LABOUR BY QUININE.

THE induction of labour by medicinal means—usually consisting of a full dose of castor oil followed by quinine in three doses of grs. 10 each at hourly intervals—has proved sufficiently successful, especially at or about term, to have become generally recognised. Its merit is that no internal manipulation is required and thus no increased risk of infection. With its widespread adoption, however, occasional cases have been recorded of intra-uterine death of the fœtus attributed to the toxic effects of quinine. On p. 1058 we briefly report a preliminary communication made to the British Congress of Obstetrics and Gynæcology by Prof. W. J. Dilling and Dr. A. A. Gemmell, of Liverpool, reviewing 765 cases in which quinine was used for the induction of labour. Among them were eight cases of stillbirth which might have been due to quinine. Judging from the rate of excretion of the drug in the urine of the mother, the maximal concentration in her tissues was six to eight hours after the last dose; but a high concentration may persist for as long as 36 hours. The authors had not been able to demonstrate quinine experimentally in the fœtal tissues after administration to pregnant rabbits, or indeed in the liver and kidneys of stillborn human fœtuses born within 24 hours of the last dose to the mother. Small quantities were, however, found in the urine of infants born 6 to 12 hours after the last dose, and in the liquor amnii, and further investigation is in progress to work out the toxicity and effects of quinine on the fœtal tissues. Major S. A. McSwiney,[1] of the Eden Hospital, Calcutta, recently recorded a case of intra-uterine death and one of death of an infant 21 hours after birth, both following induction by quinine on grounds of post-maturity. In the first case the fœtal heart sounds were lost within nine hours of the last dose and before rupture of the membranes, a stillbirth following a labour of 7½ hours' duration. In the second case the child was born, deeply cyanosed, after four hours' labour and five minutes after rupture of the membranes, and died without convulsions or twitching. There was no post-mortem examination, and death is ascribed to intracranial hæmorrhage.

Torleif Torland[2] mentions other cases occurring in America, and gives two examples from his own practice of maternal idiosyncrasy to quinine, in both of which œdema and a dark purplish skin eruption were produced as well as other troublesome effects. In one, labour did not start for a week and the child when born was normal. In the other, labour began a few hours after the administration of quinine, the fœtal heart sounds being then inaudible. Sixteen hours after the giving of quinine a stillborn fœtus of 8½ lb. was delivered. On post-mortem examination blood was found in the pericardial, peritoneal, and both pleural sacs, and histologically the kidney exhibited an acute tubular and glomerular nephritis.

These cases, and others previously recorded, show that quinine in the doses commonly used for the induction of labour involves a risk of toxic effects to mother and fœtus, and to the fœtus even of death in utero. Cessation of the fœtal heart sounds is so often noted before labour, or early in labour before rupture of the membranes, that the toxic effect of the drug on the fœtal tissues would appear to be a more probable explanation than any indirect action of exciting strong uterine contraction or otherwise disturbing the physiology of labour. McSwiney's assumption of death from intracranial hæmorrhage is scarcely warranted, in the absence of post-mortem examination, in a case where the infant was born naturally five minutes after rupture of the membranes. Possibly, as suggested by Torland, there is another factor in a special susceptibility of the mother to quinine. In a discussion on the effect of the drug when given to malarious pregnant women, P. A. Maplestone[3] takes the view that in therapeutic doses it has no effect in terminating pregnancy and has rather the opposite tendency by curing the malaria which is the real cause of abortion in such cases. References are given to other papers on this aspect, and among the cases quoted are some in which unduly large doses were taken without effect on mother or child.

The subject is one that clearly calls for attention, and the further investigations of Drs. Dilling and Gemmell will be awaited with interest. Meantime it is important that the possible danger to the fœtus should be widely recognised and that cases of fœtal death after induction of labour by quinine, for which no other explanation is forthcoming, should be carefully investigated and recorded.

WE regret to record the death of Mr. Arthur Henry Cheatle, aural surgeon to King's College Hospital, on May 11th, in his sixty-third year.

THE next session of the General Medical Council will commence at 2 P.M. on Tuesday, May 28th, when Sir Donald MacAlister, the President, will take the chair and give an address. The Council will continue to sit from day to day until the termination of their business.

Prof. Henry Roy Dean, F.R.C.P., has been elected Master of Trinity Hall, Cambridge, as from June 17th. Dr. Dean, who has been Professor of Pathology in the University of Cambridge since 1922, was educated at Magdalen College, Oxford, and St. Thomas's Hospital, and formerly occupied the chairs of pathology at Sheffield and Manchester.

DONATIONS AND BEQUESTS.—Mr. Abel Chapman, of Houxty, Wark-upon-Tyne, Northumberland, left £5000 each to the Royal Victoria Hospital, Newcastle-upon-Tyne, and the Sunderland Royal Infirmary.—Mr. Robert Clyde Henderson, of West Park-road, Dundee, left £1200 to the Dundee Royal Infirmary to endow a cot to be named "John and R. C. Henderson Cot," and, after other bequests, the residue of the property to the University College, Dundee, for the foundation of bursaries.—Mr. Christopher Richard Jones, of Woodside Park, London, left £500 to the Finchley Memorial Hospital, £250 each to the Royal Northern Hospital and the London Hospital, and £100 each to the Napsbury Mental Hospital, near St. Albans, and Dr. Barnardo's Homes.—Mrs. Elizabeth Knox Ferguson, of Ardgare, Cambuslang, left £1250 to Glasgow Royal Infirmary; £500 each to the Royal Hospital for Sick Children, Glasgow, and the Association for the Relief of Incurables, Broomhill Home, Kirkintilloch, and £300 each to the Western Infirmary, Glasgow, Glasgow Ear, Nose and Throat Hospital, the Victoria Infirmary, and the Royal Cancer Hospital, Glasgow.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXXI.—THE CLINICAL SIGNIFICANCE OF THE BLOOD-PLATELETS.

PART II.*

EVEN in the present imperfect state of our knowledge it is possible to make a provisional classification of the pathological conditions associated with a diminution in the platelet count. One can distinguish between those conditions in which a thrombocytopenia occurs as a primary condition and those in which it is a secondary phenomenon. Both primary and secondary thrombocytopenias are accompanied by a tendency to purpuric hæmorrhages.

Primary Thrombocytopenias.

These are held to arise as the result either of diminished production of platelets as in diseases of the bone-marrow, or of an increased destruction of platelets by the spleen and so are associated with certain diseases of that organ. The number of platelets falls frequently below 100,000 per c.mm. and may even fall below 10,000.

To the first-named group belong the thrombocytopenias of pernicious anæmia, of aplastic anæmia, and of the leukæmias; while the second group comprises the thrombocytopenias accompanying splenomegalic conditions (Gaucher's disease and Banti's disease). These various conditions are distinguished by the changes in the other cellular elements of the blood. There is also a condition in which the thrombocytopenia is the only outstanding and diagnostic feature unaccompanied by changes in the other cellular elements of the blood, except secondary changes, due to the purpuric hæmorrhages. This is the condition of "thrombocytopenic purpura" or "essential thrombocytopenia" (Frank). This condition is held by some observers to be due always to the increased destruction of platelets by the spleen, which is usually enlarged, and has therefore been called by Kaznelson "thrombolytic purpura." In this condition splenectomy is often but not always followed by a cure. Even when splenectomy does not produce a permanent cure, it brings about a temporary improvement. In order to account for this, it has been suggested that in this latter type of case there is, in addition to the increased destruction of platelets by the spleen, also a diminished formation by the bone-marrow.

A few points concerning the thrombocytopenias associated with blood diseases are of interest.

A persistent diminution in the number of platelets always accompanies pernicious anæmia. Even during temporary remissions of the disease the platelets remain below the normal number although they show a temporary increase, so that a platelet count may be of diagnostic value. No observations appear to be on record how this thrombocytopenia reacts under liver treatment. Since it appears to be an essential part of the disease it is likely to disappear with the recovery from the disease under this treatment. If that is so, it would be of importance to investigate the effect of liver treatment in other conditions associated with a thrombocytopenia. The platelets are said to be normal in number in secondary anæmias, in chlorosis to be increased.

A thrombocytopenia has been observed by Rosenthal in both the myeloid and the lymphatic types of leukæmia. A few cases of myeloid leukæmia have been reported, however, in which there was either no change or an increase. It has been suggested that a thrombocytopenia occurs in those forms of leukæmia in which the bone-marrow is aplastic, while those in which there is an increased activity of the bone-marrow exhibit a thrombocytosis. The subject requires further investigation, which would throw light on the question of the origin of the platelets.

Secondary Thrombocytopenia.

The most important group of conditions in which the platelets show a marked diminution as a secondary effect are the acute infections, which will be treated under a separate heading. In addition, secondary thrombocytopenias have been found to occur as an immediate effect after the injection of certain drugs such as salvarsan, neoarsphenamin, of colloidal metals, and of protein, peptone, and heterologous serum.

In the case of some of the drugs and colloids, the immediate thrombocytopenia has been shown to be followed during the next few days after the injection by a rise to, or above the normal number of platelets, as a compensatory reaction. A prolonged increase in the number of platelets has been produced as a late effect by the repeated injection of such colloids as indian ink and trypan blue. This effect has been ascribed to a "blocking of the reticulo-endothelial system," but it may possibly have to be interpreted as a summation of such a compensatory effect.

When, as in the case of serum, a previous injection sensitises the organism to a subsequent injection, as in the case of heterologous serum, the thrombopenia after the second injection is intensified (anaphylactic shock). This condition is held to be due to an agglutination of the platelets by the injected material. The agglutinated platelets collect as stated above in the capillaries of the internal viscera—e.g., liver. No observations appear to have been made on the behaviour of the platelets in allergic conditions such as asthma which are held to be closely related to anaphylactic phenomena.

Platelets in Acute Infections.

In many acute infections—influenza, typhoid, endocarditis, diphtheria, scarlet fever, pneumonia—a thrombopenia at the onset of the infection has been demonstrated. This persists during the active stage of infection and is followed by a rise above the normal when the infection subsides. A very striking illustration of this phenomenon was found accidentally by one of us (R. G. B.) in a subject on whom platelet counts were being made everyday, and who developed a cold in the course of these observations.

In lobar pneumonia the number of platelets begins to diminish after the infection has been established. Immediately following the onset of the crisis the platelets begin to increase in number. This continues for several days until the normal number is greatly exceeded and is then followed by a return to the normal after about two weeks. Sequelæ following pneumonia are accompanied by a renewed diminution.

Platelets in Chronic Infections (Tuberculosis).

In pulmonary and surgical tuberculosis the blood-platelet count tends to be high and there appears to be a relation between their number and the severity of the disease. The count may be normal in a mild case, in which the disease, even if extensive, is causing little systemic disturbance. But in cases having a platelet count of 500,000–1,000,000 per c.mm., the prognostic outlook is bad. The platelet count is thus of some value in assessing the physical condition of a tuberculous patient, and may give valuable assistance in assessing the condition of a patient independent of data derived from physical signs, temperature, &c.

There is as yet insufficient information concerning platelet counts in other chronic infective diseases, and the subject is one demanding further study.

Heliotherapy and Platelets.

The stimulating effect of light on platelets in conditions associated with a thrombocytosis has not yet received a clinical application. Cases of purpura are stated to have been treated successfully with ultra-violet light. It is generally assumed that the effect of light can be replaced by the administration of irradiated ergosterol. Although this is the case for the treatment of rickets, it does not follow that it is generally true. A comparison of the effects of ultra-violet light and of irradiated ergosterol on the platelets in the various conditions associated with a thrombopenia remains to be carried out.

---

* Part I. appeared last week.

Operation and Trauma.

Surgical operations are followed by a rise in the platelets which begins at the sixth day, reaches a maximum at about the tenth day, and falls again to reach the normal in about three weeks. The same effect has been observed in fractures, but only a few cases were examined. Local sepsis is not a factor responsible for this effect.

Clinical Relationship of the Blood-platelets, Blood-coagulation, and Thrombosis.

The statements on this relationship recorded in the literature are contradictory. The statement is frequently found that in conditions with a diminished platelet count the coagulation time is normal. Most observations on the coagulation time of the blood in disease are, however, of little value, because they were made with unreliable methods. Addis has laid down the following four postulates for the conditions essential for an accurate estimation of the coagulation time by any method :—

1. The blood must be obtained under the same conditions in each experiment.
2. Its contact with a foreign body must be of the same amount and kind for each observation.
3. The end-point must be clear and definite and must indicate the same degree of coagulation.
4. All estimations must be made at the same temperature.

An important factor which has often been overlooked is indicated in the first postulate. The coagulation time may show considerable differences according to the method used in obtaining the blood (venepuncture or by pricking the finger). *The last postulate has been neglected in almost* all clinical observations on the coagulation time.

In normal persons the coagulation time if determined by a reliable method at 37–38° C. is 1 min. 45 sec. It varies so little that a change of more than 30 seconds must be considered to be significant, provided the estimations are made at the same temperature. At 20° C. the coagulation time is 5 min. 30 sec. ; at 18° C. it is 7 min. 30 sec.

It is obvious that for clinical purposes the method must be sufficiently simple to be applied at the bedside. One method which fulfils all these conditions is that of H. H. Dale and P. P. Laidlaw in which the observations can be carried out at a constant temperature. It is then found that the coagulation time is shortened when the number of platelets is raised ; it is lengthened when the platelets are diminished in number. This relationship is in agreement with the known facts concerning the part played by the platelets in blood coagulation as discussed in the first part of this paper.

It has been suggested recently that a relationship exists between the number of platelets and thrombosis. The tendency to thrombosis is increased when the platelets are increased in number. This would account for the thrombosis occurring as an after-effect of the intravenous injection of certain colloids, in the convalescence from infections, such as typhoid fever, and after operations. But since thrombosis occurs only in a small percentage of these conditions in which there is an increased number of platelets there must be additional factors determining the onset of a thrombosis which manifests itself by clinical signs. Of the possible factors which have been suggested may be mentioned : a sluggish flow of blood in the veins of the leg, which are the most frequent site of thrombosis ; local pathological changes in the endothelium ; the increase of fibrinogen, which occur after operative procedures.

The Hæmorrhagic Diathesis and Platelets.

Conditions in which the number of platelets is diminished show a tendency to spontaneous hæmorrhage.

It has, however, been found experimentally that a thrombopenia is not in itself sufficient to cause hæmorrhages, nor is a slight damage to the endothelial wall of the blood-vessels, while the two combined produce an experimental purpura. On the other hand, there are some purpuric conditions such as scurvy and Schoenlein-Henoch's purpura, in which the number of the platelets is normal or only slightly subnormal, and in which, therefore, the hæmorrhagic diathesis must be referred entirely to changes in the vessel wall. Most clinicians who have studied the subject agree that two ætiologically different types of purpura exist, which can be distinguished by the behaviour of the platelets.

According to the accepted view splenectomy is of value only in the hæmorrhagic conditions associated with a low platelet count.

Hæmophilia.—An entirely separate condition is that of hæmophilia, in which there are no spontaneous hæmorrhages, *but in which the coagulation time of* the blood is enormously prolonged. In hæmophilia the blood-platelets are not diminished in number. Numerous observations on the chemical composition of the blood plasma have failed to reveal any difference which would account for the greatly diminished coagulability of the blood. According to some observers the platelets differ from normal platelets in having lost their tendency to disintegrate when coming in contact with water wettable surfaces.

In all hæmorrhagic conditions a platelet count is indicated as a measure of differential diagnosis.

The question whether purpuric conditions present a contra-indication to operative procedures cannot be readily answered, probably owing to the great ætiological diversity of these conditions. Several observers have seen patients with purpura stand major operations and have reported cases of uncomplicated labour. Rosenthal, on the other hand, records two cases of purpura in which exsanguinating hæmorrhages have followed tonsillectomy and childbirth, and which required numerous transfusions to keep them alive.

Bleeding Time.

Bleeding time is the length of time during which a punctured wound, such as is made for blood examination, continues to bleed. Gross variations in the bleeding time are readily noticed by inspection. For purposes of comparison, the bleeding time is determined by making a puncture in the lobe of the ear and applying every 30 seconds a piece of blotting paper to the drop of blood which forms, without touching the skin.

The factors determining bleeding time are obviously more complex than those which determine coagulation time. The temperature of the skin and of the room are not controlled ; the contact with the tissues of the wound which may or may not influence the process, and the conditions and behaviour of the blood-vessels from which the blood passes out, enter as additional factors. The latter is likely to be influenced by the vaso-constrictor substance liberated by disintegrating platelets.

In a normal person the bleeding time is from 1 to 3 minutes. it is greatly delayed in such conditions as purpura hæmorrhagica and pernicious anæmia, when the number of platelets is diminished ; but the bleeding time is not *always prolonged when there is a thrombopenia, and it may* be prolonged when there is no thrombopenia. Roskam has recorded a case of purpura hæmorrhagica where the bleeding time was normal in the left ear but greatly delayed in the right ear. If future observations show that such a condition is at all frequent, it is obvious that bleeding time would be of little diagnostic value.

The statement that bleeding time may be greatly delayed in patients who show a normal coagulation time may be erroneous in view of the fact stated above that most observations on coagulation time have been carried out by defective methods.

Clot Retraction.

This is diminished when the number of platelets is diminished. It is not of sufficient importance to justify a separate vein puncture. Evans has pointed out that information on this point can be gained by washing out with water the capillary tube in which the coagulation time has been determined by Dale and Laidlaw's method immediately after the clot has formed. With a low platelet count the entire soft clot can be washed out ; with a normal or a high platelet count some part of the clot remains adherent to the sides of the tube.

Changes in Morphology and Functional Activity of the Platelets.

In conditions in which there is a great diminution in the number of platelets variations in size have been observed, such as the appearance of abnormally large platelets. Such changes can best be studied in stained blood films, but too little is known as yet to make a discussion of this point profitable from a clinical point of view.

The facility with which the platelets disintegrate when in contact with a water wettable surface may also undergo variation; as already stated the condition of hæmophilia is now held to be due to an impairment of this function. Such variations may be due to inherent differences in the platelets, or they may be the result of chemical abnormalities in the plasma. Since, as already stated, the reaction of the platelets to water wettable surfaces depends on the presence of calcium ions in the plasma, there may be other chemical factors in the environment of the platelets which influence their facility to disintegrate. A method for studying the functional activity of platelets has yet to be worked out.

Special Articles.

MODERN PHYSICAL TREATMENT IN RELATION TO RHEUMATISM.

BY R. FORTESCUE FOX, M.D., F.R.C.P.,
PRESIDENT OF THE LIGUE INTERNATIONALE CONTRE LE RHEUMATISME.

III.*—ARTIFICIAL CLIMATES.

THE geographical distribution of tropical diseases or those that are especially prevalent in northern climates clearly shows that external physical conditions, such as temperature, humidity, wind, are favourable or may even be necessary for their development. It is known that many acute diseases are limited to regions having a climate in which particular parasitic organisms can flourish.

Rheumatic diseases of all kinds and many kinds of catarrh appear to be especially prevalent in northern countries. They are more chronic and less febrile than tropical diseases. It is not unreasonable to connect their prevalence with the direct or indirect influence of external cold, just as tropical diseases are connected with external heat.

How much part may be played in the causation of these diseases by predisposition, induced by external heat or cold and other physical agencies, and how much by micro-organisms or other parasites developed and activated by the same physical agencies is not yet determined. It is, however, certain that the diseases prevalent in northern as in tropical climates only affect predisposed persons; only certain persons exposed to cold and damp develop rheumatic symptoms.

Rheumatic persons are peculiarly sensitive to atmospheric changes. A medical man, living near Edinburgh and subject to attacks of rheumatism, always experienced aches and pains if he walked across the meadows when covered by a ground fog. It is often noticed that sufferers from muscular stiffness and pain lose these symptoms when the weather becomes dry and sunny. In addition to the climatic factor microbial infection has been shown to be an important factor in some cases both of articular and of non-articular rheumatism. Many rheumatic persons are liable to local foci of infection which require local treatment. But it is well to remember that where one weed has grown before another may grow again. It is preferable to remove a rheumatic liability than an expression of it.[9]

The above considerations afford a priori grounds for the use of heat and other physical remedies in many forms of rheumatism, so employed as to counteract if possible the influence of rheumatic climates. It has been already shown that an artificial climate can be readily devised which can overcome the abnormal reactions produced, for example, by cold and damp.

The northern nations have had recourse to artificial climates from remote times, for such are their periodical intensely hot vapour baths, in which moist heat is combined with friction and switching. Recent writers confirm the old opinion that these baths are a valuable preventive of disease and fortify the resistance of the body to cold.[10] Periodical heat and mechanical stimulation form the basis of the Roman and Turkish baths. When light is added it is possible to bring the tropics into any country. The good health of the attendants in such establish-

[9] Fox: Jour. State Med., April, 1929, p. 196.

[10] Same author: Principles and Practice of Medical Hydrology, London, 1913; Kajava, Y.: Arch. Med. Hydrology, 1928, vi., 110.

nents shows that no ill-effects are produced in lwellers in cold climates by spending a large part of he day in a warm atmosphere.

There seems good reason to believe that artificial limates, in which radiation, temperature, and numidity can be varied at will, may become of great alue during periods of acute illness, from their edative and gently stimulating effects. In many orms of more chronic illness daily exposures to rtificial climates of a stimulating character are ndicated. They are especially indicated for the rigo-sensitive subjects of incipient and chronic heumatic disease, provided they are precisely dapted and dosed according to individual requirements.

A suitable course of physical treatment offers to he rheumatic sufferer a change of climate, in brief epeated doses spread over a period of weeks. The umulative impressions of heat, for example, may ffect the condition of the rheumatic subject in nany ways. *There is reason to believe that external* eat, like the internal heat of fever, may stimulate he defensive mechanism of the body. Heat, properly pplied, may increase or modify metabolism, partly, s many hold, through the endocrine system; it may promote absorption, restore a defective action of the kin, and stimulate elimination. In addition to these eneral effects applications of heat appear to have local intensive action on slow and chronic or ubacute inflammatory changes. It is often noticed hat rheumatic joints or muscles become painful and ender under treatment by hot baths and applications, rom the effect of hyperæmia upon rheumatic foci. Thus hot baths may induce both local and general reactions in cases of arthritis, somewhat analogous to those set up by protein shock.[11] At spas where large numbers of cases of articular diseases are congregated, it is a common observation that arthritis and non-articular rheumatism and gout sometimes "flare up" after certain kinds of baths. *Great care is necessary* in these cases to avoid producing too strong a reaction. This has led some authorities to recommend that the physical treatment of all serious forms of arthritis should be so regulated as to give only minimal intensive reactions. Strong reactions which are often set up when baths are combined with manipulation are especially to be avoided because they signify an aggravation of the disease and sometimes extension to other joints. For the same reason, great care is needed in the use of intensive or stimulating baths in arthritis with an active focus of infection. Similarly, such baths should never be employed concurrently with surgical treatment or with the use of protein shock or vaccines, nor yet in cases showing any degree of pyrexia. On the other hand, a purely sedative physical treatment is always safe and often beneficial. It has been observed that in cases with defective resistance a suitable course of baths or physical treatment may even increase an impaired resistance in the body and so enable a focus to be safely removed.

Modes of Action.

The action of physical treatment in rheumatic conditions may be summarised as follows:—

1. *Local action on the skin, diaphoresis.*—In many persons so affected the peripheral circulation is contracted and the skin is cold, harsh, and inactive. Under carefully graduated thermal treatment the condition of the skin and the rheumatic symptoms often show simultaneous improvement. Gentle and increasing and long-continued diaphoresis is, perhaps, the chief indication in the physical treatment of chronic rheumatism. Perspiration begins in the bath but is kept up and often greatly increased when the patient lies down in his hot wraps in a warm room. This general thermal stimulation and increased elimination by the skin undoubtedly facilitate the more local action of the bath.

2. *Production of hyperæmia* in affected joints or other tissues, so as to temporarily intensify inflammation. The intensive local action of thermal baths and applications upon chronic and subacute diseases is also a most important part of the physical treatment of rheumatism. The corresponding reactions vary widely in individual cases, but as has been already stated, the best results are usually obtained from minimal local reactions. The methods employed should be intensive in proportion to the chronicity of the disease.[12] The intensive local action of hyperthermal baths and of mud packs is made tolerable by the general stimulation and abundant diaphoresis they produce.

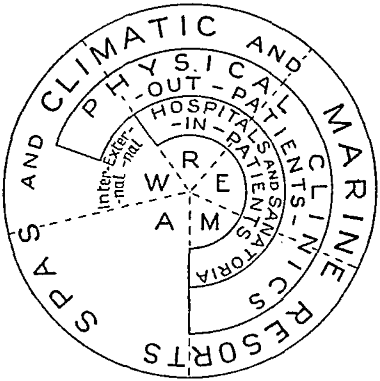

Diagram illustrating physical treatment, being the application of heat and cold and other forms of energy. A = air (climatotherapy); W = water (hydrotherapy, thalassotherapy); R = radiation (radiotherapy, heliotherapy); E = electricity (electrotherapy); M = movement (kinesitherapy).

3. *Nervous factor.*—Warmth, especially in water or vapour, is powerfully sedative. By appropriate baths pain is allayed and muscular tension and spasm are removed. For this reason it is generally easier to carry out manipulation of the muscles or passive movement of rheumatic joints either after preliminary treatment with moist heat, or whilst the limb is still immersed in still or moving water at a sufficiently high temperature. Whilst moist heat is nearly always sedative, dry heat by radiation or hot air is more stimulant. Both heat and cold, especially when accompanied by percussion as in the douche, are powerfully stimulant to the nerve centres.

4. *Resolution of exudations and deposits.*—The intensifying effect of physical treatment on sluggish inflammatory processes brings about in favourable cases, after a more acute phase, an increased tendency to resolution. If the application is too severe the inflammatory reaction is excessive and resolution is *hindered rather than helped. In the treatment of* rheumatic exudation this is especially liable to occur from inappropriate manipulation (massage). But when gentle manipulation is combined with moist heat, as in the whirlpool bath, the resolution of local deposits is favoured by general stimulation of circulation and of elimination.

Particular waters, such as sulphur waters, and certain natural thermal baths are considered with good reason to have a selective action and to increase the resorption of rheumatic deposits.[13] *It is believed*

Changes in Morphology and Functional Activity of the Platelets.

In conditions in which there is a great diminution in the number of platelets variations in size have been observed, such as the appearance of abnormally large platelets. Such changes can best be studied in stained blood films, but too little is known as yet to make a discussion of this point profitable from a clinical point of view.

The facility with which the platelets disintegrate when in contact with a water wettable surface may also undergo variation; as already stated the condition of hæmophilia is now held to be due to an impairment of this function. Such variations may be due to inherent differences in the platelets, or they may be the result of chemical abnormalities in the plasma. Since, as already stated, the reaction of the platelets to water wettable surfaces depends on the presence of calcium ions in the plasma, there may be other chemical factors in the environment of the platelets which influence their facility to disintegrate. A method for studying the functional activity of platelets has yet to be worked out.

MODERN PHYSICAL TREATMENT IN RELATION TO RHEUMATISM.

BY R. FORTESCUE FOX, M.D., F.R.C.P.,
PRESIDENT OF THE LIGUE INTERNATIONALE CONTRE LE RHEUMATISME.

III.[*]—ARTIFICIAL CLIMATES.

THE *geographical distribution of tropical diseases or* those that are especially prevalent in northern climates clearly shows that external physical conditions, such as temperature, humidity, wind, are favourable or may even be necessary for their development. It is known that many acute diseases are limited to regions having a climate in which particular parasitic organisms can flourish.

Rheumatic diseases of all kinds and many kinds of catarrh appear to be especially prevalent in northern countries. They are more chronic and less febrile than tropical diseases. It is not unreasonable to connect their prevalence with the direct or indirect influence of external cold, just as tropical diseases are connected with external heat.

How much part may be played in the causation of these diseases by predisposition, induced by external heat or cold and other physical agencies, and how much by micro-organisms or other parasites developed and activated by the same physical agencies is not yet determined. It is, however, certain that the diseases prevalent in northern as in tropical climates only affect predisposed persons; only certain persons exposed to cold and damp develop rheumatic symptoms.

Rheumatic persons are peculiarly sensitive to atmospheric changes. A medical man, living near Edinburgh and subject to attacks of rheumatism, always experienced aches and pains if he walked across the meadows when covered by a ground fog. It is often noticed that sufferers from muscular stiffness and pain lose these symptoms when the weather becomes dry and sunny. In addition to the climatic factor microbial infection has been shown to be an important factor in some cases both of articular and of non-articular rheumatism. Many rheumatic persons are liable to local foci of infection which require local treatment. But it is well to remember that where one weed has grown before another may grow again. It is preferable to remove a rheumatic liability than an expression of it.[9]

The above considerations afford a priori grounds for the use of heat and other physical remedies in many forms of rheumatism, so employed as to counteract if possible the influence of rheumatic climates. It has been already shown that an artificial climate can be readily devised which can overcome the abnormal reactions produced, for example, by cold and damp.

The northern nations have had recourse to artificial climates from remote times, for such are their periodical intensely hot vapour baths, in which moist heat is combined with friction and switching. Recent writers confirm the old opinion that these baths are a valuable preventive of disease and fortify the resistance of the body to cold.[10] Periodical heat and mechanical stimulation form the basis of the Roman and Turkish baths. When light is added it is possible to bring the tropics into any country. The good health of the attendants in such establish-to follow up a course of treatment outside. They belong also in a more specialised form to sanatoria and hydrotherapeutic establishments. Radiation, electrical energy, and manipulation have found their way into the hospitals, and in a more comprehensive form into the great spa establishments.

---

The diagram is intended to exhibit the several factors which are included in the scope of modern physical treatment and the place which such treatment may reasonably hold in the hospitals, clinics, and health resorts of the country.

In one word, we may say that there is evidence that the living machinery of the body is deranged by external physical agents, by internal chemical agents, and by bacterial poisons. The external physical agents by their action on the metabolism of the body derange it and chemical poisons are produced. The existing knowledge of these poisons is small, and the physician must trust to the tendency of the body to recover. This tendency can be helped by heat, light, waters, electricity, movement, and rest; and the hypotheses which account for the action of these physical remedies are reasonable.

CLINICS OR SPECIAL DEPARTMENTS (HOSPITAL) FOR RHEUMATISM.

A.h., available in hospital; A.c., in clinic. W.20, ward of 20 beds.

* Throughout the table an "assistant" refers to a fully qualified senior man or woman, generally a specialist in physical treatment.

Notes.—3. At Brussels the director of the Brugman Hospital is professor of physical treatment in the University. 4. At Aachen the Landesbad Hospital is maintained by industries of the Rhine provinces. 7. At Vienna Prof. Wenckebach is head of University Clinic No. 1 and the director of the physical treatment departments his assistant. 13 and 18. In these hospitals the physician in charge has no other duties in the hospital.

FIFTH INTERNATIONAL CONGRESS OF MILITARY MEDICINE AND PHARMACY.

(LONDON, MAY 6TH–11TH.)

(Concluded from p. 1002.)

SCIENTIFIC SESSIONS.

ON Thursday morning, May 9th, papers were read on

Tropical Fevers of Short Duration.

Lieut.-Colonel W. P. MACARTHUR, Surgeon-Commander S. F. DUDLEY, and Wing-Commander H. E. WHITTINGHAM collaborated in the first paper. They divided the obscure short fevers of the tropics into two main groups—atypical or abortive attacks of known diseases and fevers which have still to be described. The closer the coöperation and the more thorough the work of clinician and pathologist, they said, the fewer fevers would fall into the second group. Typhoid, paratyphoid, and undulant fever had been found masquerading in mild or abortive form under a variety of local names. Malaria often caused a low continued fever without paroxysms and with so few parasites in the blood that they were easily overlooked. Another common kind of short fever seemed to be due to a disturbance of metabolism by heat; outbreaks of this sort often followed children's parties where violent games had been played in a hot sun. Dengue and phlebotomus fever might have so few definite symptoms that they were confused with similar syndromes. Influenza was very common in the tropics but seldom accompanied by nasal catarrh, and it was often impossible to separate it with certainty from dengue and sandfly fever. The group of leptospira seemed to contain many morphologically indistinct forms which could cause clinical symptoms varying from a day or two of pyrexia with conjunctivitis and a trace of albuminuria up to severe toxæmic jaundice. These should, however, be distinguished by the blood picture. If the fever was of acute onset and the examination of films had excluded the malaria parasite or the spirochæte of relapsing fever, then a leucopenia with a relative increase of large lymphocytes pointed to phlebotomus fever or dengue, while a leucocytosis with an absolute and relative increase of polymorphonuclear leucocytes suggested the Weil's disease group. Weil's disease could be distinguished from yellow fever by the amount of albumin in the urine, which was much greater in the latter. If, despite all investigations, a pyrexia remained really "of unknown origin," it should be so labelled, to avoid the confusion of calling the same condition "tonsillitis" in one station, "myalgia" in another, and "sandfly fever" in a third.

Dr. J. C. GERARDS (Dutch East Indies) said that identification of tropical fevers by geography and duration had been replaced by detection of the causative organism, and that during recent years several non-persistent fevers had been shown to be due to closely related organisms of the spirochæte family. Yellow fever was now under control in America, thanks to the discovery of the rôle of *Aëdes argenteus*, to antimosquito and quarantine measures, and to the Rockefeller Foundation, but it remained endemic in Africa. Noguchi appeared to have found correctly that the causative organism was the *Leptospira icteroides*, which several investigators believed to be identical with the *L. icterohæmorrhagiæ* of Weil. Others, however, had proved that the yellow fever spread by the mosquito could not be caused by *L. icteroides*, and that *A. argenteus* could not transmit both leptospiræ. Yellow fever was found exclusively in tropical and subtropical zones and there was no race immunity. The virus, which took about 12 days to develop, was present and active during the whole life of the insect. Mature females only bit at night, but the young females, before fertilisation, might bite by day. The incubation period of the disease was three to six days, and the differential diagnosis included malaria, Weil's disease, and dengue. Weil's disease and other spirochætoses were not apparently due to different organisms, but varied according to the degree of virulence, dose of toxin, and individual resistance. Weil's disease was found in Japan and many parts of Europe; the leptospira probably entered the body through skin abrasions or the digestive tract. The incubation period was five to six days and the diagnosis was confirmed by the presence of the organism in the blood in early stages and in the urine later. Prophylaxis included sterilisation of dejecta, destruction of rats, and prevention of bathing. Febris hebomadis was met in Japan, especially in the early autumn. Its leptospira was distinguished from *L. icterohæmorrhagica* by serological tests and was carried by the field rat and transmitted, probably, by insect bites. It was found in the blood during the first few days and in the urine after the eighth day. The symptoms were like those of Weil's disease and there was no mortality. African epidemic spirochætosis resembled yellow fever and Weil's disease with two types, one like yellow fever and the other a pneumonia with jaundice. The spirochæte was found in the blood, urine, and sputum, and was transmitted by *A. argenteus* and spread by fleas. Certain authorities believed that there was a form of hæmoglobinuric fever due to a leptospira. The spirochætosis febrilis described by Kouwenaar at Deli resembled hæmoglobinuric fever with or without jaundice, but Baermann considered it typical Weil's disease. Papataci fever, first described by Pym in 1804, was found along the Mediterranean, in Asia Minor, Northern India, Egypt, and Central America. The symptoms resembled those of dengue, but the cause was unknown. Four clinical types had been described, and the disease was usually mild with protracted convalescence. The virus of dengue was not known, but was present in the blood two or three days before symptoms appeared. Incubation was from five to nine days, immunity short, and convalescence slow. The mosquito was infectious for 11 to 14 days after biting, but the virus was not transmitted through ova. The five-day fever of Java was thought to be a polyneuritis-astheno-neuralgic fever comparable with the astheno-myalgic fever of Bernard. Fièvre d'Ancon, a mild disease like seven-day fever, had been described by Deeks in the Panama Canal Zone in 1912. Seven-day fever was described as a sporadic endemic fever of Indian ports and was not universally accepted as a separate disease from dengue.

The following officers took part in the discussion: Dr. SACQUÉPÉE, Dr. BLANCHARD, Colonel A. VAUDEMER, Dr. CAZANOVE, and Dr. A. P. CAWADIAS, the last-named discussing the recent Greek epidemic of dengue which had somehow arisen out of many previous small ones. Many cases of three-day fever, he thought, were really dengue.

At the discussion held on Friday, May 10th, on the

State of the Teeth in Relation to Physical Fitness in the Different Military Services,

the chair was taken by Colonel J. P. HELLIWELL. A joint paper was presented by Surgeon Lieut.-Commander J. T. WOOD, Captain H. S. WOODS, and Lieut.-Colonel (temporary Wing-Commander) C. L. COLBRAN. For the purposes of the paper they regarded the teeth and their attachments as the essential tissues of an organ, the function of which was adequate mastication of food so that the maximum nourishment might be obtained from it. The dental standard for enlistment defined the minimum degree of dental efficiency considered compatible with physical fitness in the Service, and was influenced by the need for maintaining establishments at full strength, the average dental condition of the recruits available, the provisions made for treatment, the period of engagement anticipated, any special qualifications of the individual, and the advantages and disadvantages of dependence upon artificial dentures.

The authors then described the standards in force in the three Services. In the Army a natural masticating power of 50 per cent. efficiency was the minimum. In the years 1924–5–6 an average of 5·3 per cent. of recruits were rejected for the Navy for purely dental reasons, the figure for the Army being 3·5 and for the Air Force 0·5 per cent. The figure was misleading for the Navy, because dental defects were roughly weeded out by the naval recruiters before the men were presented. The average recruit for the services had a neglected mouth and had had no treatment save extraction for the relief of pain. On admission, dental treatment was begun as soon as possible and oral hygiene was taught. Thereafter he was examined periodically and treated as occasion arose. He was always examined before proceeding abroad. In the Navy and Air Force a very high standard was insisted on for submarine, diving, and flying personnel. Officers were entitled to free treatment, but not to the supply of dentures. They were systematically examined in the Air Force, but not in the Army. If a soldier lost so many natural teeth that his nutrition was threatened, the deficiency could be made good by artificial dentures, but the wearers were always potentially inefficient, as the dentures were fragile, removable, and easily misplaced or broken, while partial dentures wore the remaining teeth and made constant attention essential. Therefore the need for dentures raised a very serious problem.

Infection of the dental tissues might produce closed or open dental sepsis, or both. The effect on physical fitness depended on four factors: the virulence of the infection, the volume of toxic products absorbed, the time factor, and the body resistance. The secondary or systemic effects fell into three main groups: (1) those due to absorption via the lymphatic system, as in closed infection. These included infective arthritis, toxic heart, and toxic neuritis. (2) Those due to absorption via the alimentary system, as in open dental infection. In this case the symptoms were not usually localised and appeared as general debility, rheumatism, or anæmia. (3) Those due to direct extension—e.g., affections of the antrum, ear, nose, and throat.

The authors then reviewed a series of illustrative cases among which it was noticeable that closed dental sepsis producing severe systemic lesions usually followed conservation of pulpless teeth, often by crowning. Most of the cases were officers; those "other ranks" were men who had been admitted before adequate measures were in force for the dental care of recruits.

Captain J. M. CLARK described

The Dental Service in the Cuban Army.

At the present time, he said, even the remotest district possessed excellent surgeries, but the service had failed to keep pace with the ever-advancing science of stomatology, and was hampered by obsolete regulations. He urged the importance to an army of a vital, scientific and progressive dental corps. Dental officers must insist on the inclusion of the necessary mineral elements in the dietary and should strive to improve the race by urging eugenic measures. The Army was the permanent vital power of the nation, and through it all fit citizens should pass. Teeth influenced all the phases of army life: discipline, action, and moral and physical efficiency. Healthy teeth could only be attained by careful preventive and curative methods. Propaganda must be carried on among the men, and a hygiene service should be instituted. When once the coöperation of the soldier had been secured, almost anything could be achieved. The ideal scheme would include: a dental card for each man, periodic general inspection at short intervals, observation of the frequency of certain ailments, reports to the dental officer of the district, cleanliness, and the use of embrocations and analgesics. Every soldier should be supplied with a pocket-case containing a dentifrice, tooth brushes, dental floss, litmus, a tincture for the gums, and cotton hyssop. The officers should advise the men on the use of the case and the choice of a dentifrice according to the reaction of the saliva to litmus. Hygienic precautions might prove harmful if carelessly or unintelligently applied. Oral hygiene could not be considered separately from general hygiene, and a soldier who did not keep his teeth in proper order could not be a good soldier. In Dr. Clark's opinion a well-restored tooth was preferable to the best substitute. Were the inefficiency of soldiers to be estimated on dental lesions, the result would prove staggering.

Major A. F. MACCALLAN read a paper entitled

The Eye as a Danger Signal of Dental Sepsis.

He said he had often met iritis, cyclitis, and choroiditis, together with blepharitis and ulceration of the cornea, as the result of dental sepsis. In fact, every corneal ulcer he had ever seen had been associated with unhealthy conditions of the teeth. Cataract in young patients was often due to the teeth. The mere deposition of tartar could cause iritis. In 82 out of 100 officers requiring spectacles, there had been apical abscesses. As well as blepharitis, opacities in the lens and vitreous, visible with the slit lamp, were often signs of dental disorder. It ought not to be left to the ophthalmologist to detect bad dental surgery.

Discussion.

A paper by Dr. CARIÈS (France) was read by Lieut.-Colonel GRAVELLAT HEURY. He spoke of the benefits of the new rules introduced in the French Army in 1925. No one need now be rejected on account of dental defect. The coefficient of mastication was estimated, as part of the medical examination, according to precise rules. When it was below a certain minimum, or the nutrition was impaired, a denture was fitted.

Dr. CHARLET (France) stressed the importance of the examination of metabolism.

Colonel J. P. HELLIWELL said that the number of recruits showing any benefit from treatment under the school dental service was negligible. He summarised the research work being carried out by the British Army dental service, and said that the great majority of the ill-effects were due to the attempt to preserve pulpless teeth. The differentiation of the various kinds of sepsis in a mouth might be of great diagnostic value. The uniform method of treatment now in force in the Army should greatly improve the dental condition of the men and their knowledge of oral hygiene, as well as raising the general standard of national health.

Dr. F. WATRY (Belgium) said that the dental standard ought to be part of the general standard of physical fitness and to be determined precisely. It should be modifiable for each individual. The period of military service ought to be used to inculcate habits of oral hygiene; the responsibility of Army medical and dental officers was to the whole race.

Major E. B. WAGGETT said that the man on campaign was better off with a denture than with gaps in his mouth. There was no serious risk of broken dentures; Army biscuits could be broken by a cracker, and if each man were supplied with a small box he would not put his denture under his pillow, and so break it in the morning. The two lower canines should never be left to fix a denture if they were unhealthy. Small dentures were a source of great danger, as they were apt to be swallowed.

Dr. R. BOISSIER (France) discussed focal sepsis.

Dr. J. FILDERMAN (Belgium) pressed for the fuller recognition of the dental services.

VISIT TO HALTON.

On Wednesday afternoon a party of 400 or more visited the Royal Air Force establishments at Halton, where the mysteries of aircraft construction were explained to them. Halton is essentially a training school, with 2500 to 3000 youths in residence, the course covering a period of three years, at the end measures as decapsulation of the kidneys and decompression of the kidney by Cæsarean section.

Dr. A. L. MUDALIAR (India) read a paper on Double Monsters, including a historical survey of fused twins, with especial reference to the possibility of separation.

Prof. MILES PHILLIPS (Sheffield) read a short note on a Successful Pregnancy following X Ray Stimulation of the Ovaries after Ten Years' Amenorrhœa. The literature, he said, showed that a number of normally developed children had been born after X ray therapy directed to the ovaries in certain cases of amenorrhœa accompanied by sterility. In the case under his care menstruation had promptly begun after treatment and pregnancy had soon followed, the child being delivered by Cæsarean section. It was essential to space the X ray exposures correctly in order to prevent irradiation of the newly fertilised ovum.

Dr. SOLOMONS believed that there was a great future for this form of treatment. He had had several cases of menstruation following prolonged amenorrhœa. He believed, however, that irradiation with X rays should be left until the last, and that an effort should be made with hormonic preparations and other stimulating drugs.—Prof. ADLER had had two cases of pregnancy following stimulation of the ovaries with X rays out of 40 cases treated in this way. The dosage was difficult to decide and must be very carefully regulated. —Prof. R. W. JOHNSTONE (Edinburgh) had treated several cases of amenorrhœa and agreed with Dr. Solomons and Prof. Adler about the dosage and endocrine gland treatment. He thought that coitus should not be allowed for two or three months after the establishment of the menses because the fœtal abnormalities that occurred were probably due to fertilisation of the ovum of the first few ovulations. He also said he had had good results from treatment by diathermy.—Prof. A. H. DAVIDSON (Dublin) described a case in which a woman of 40, who had been married for 20 years without any issue had rather profuse menstruation, for the stoppage of which X rays were employed. Menstruation had been reduced almost to normal, pregnancy had followed, and the result had been normal delivery of a healthy infant at full term.—The CHAIRMAN said that too much stress must not be laid upon trying to bring about menstruation before pregnancy could supervene as many cases became pregnant in the absence of menstruation.

In the afternoon demonstration operations were performed at various Dublin hospitals. Prof. Adler demonstrated the technique of local anæsthesia for vaginal operations.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Beginning of a Social Revolution.

WHEREAS in England each poor-law area has had its workhouse and its infirmary, in Scotland the functions of these two institutions have been combined in the poorhouse sick wards. About 30 years ago Glasgow formed two of her poorhouses into hospitals, each with a medical superintendent. These hospitals were still technically poorhouses, but for the first time the governor was a medical practitioner. In Edinburgh the sick wards of the two poorhouses—Craiglockart and Craigleith—became functionally more or less separate hospitals, with medical superintendents, but there was no definite separation of hospital from poorhouse.

In 1914 the War Office commandeered the fine building at Craigleith for a war hospital and, later, the Pensions Ministry continued and took the hospital over for their own purposes. Some time ago the Pensions Ministry restored Craigleith to the parish council and now, as part of the new development, the council have constituted Craigleith into a hospital proper. At the formal reopening by Dr. Parlane Kinloch, Chief Medical Officer of the Health Departments of Scotland, the chairman of the council said that Craigleith had been opened in 1868 and, with the various additions since made, the cost was about £83,000, which, in present-day values, would be something like £200,000. The buildings occupy, roughly, 15 acres and 20 acres more are available for new undertakings. There are about 120 beds and these are regarded as the nucleus of a much larger scheme. When the City Council takes over the functions of the parish council 12 months hence, Craigleith Hospital will be one of the institutions transferred.

Dr. Kinloch said that the achievement was great in itself, but much greater in its implications was the fact that the parish council and the other local authorities responsible for health services had been engaged in examining and moulding the original proposals of the Government for a far-reaching reform of the whole of the machinery of local government. To-day the provisions of the Local Government Reform Act made it possible for the first time, and for all time, to dissociate disease and incapacity from destitution. Craigleith Hospital itself becomes symbolic of the new hospital movement in Scotland. The new statute provides full powers for the coördination of all forms of hospital and medical schools, and it is significant that the secretary of the Hospitals Liaison Committee should be an officer of the Department of Health. The new Act makes it possible for the voluntary hospitals and the official hospitals to collaborate without being trammelled by the poor-law "stigma." For the first time sickness as a cause of destitution is absolutely dissociated from the poor-law. After 20 years the primary proposal of the Minority Report is realised in a Scottish statute. This is one of the greatest reforms in Scottish medical history.

Another Milk Experiment.

Some time ago details were given in THE LANCET (Jan. 5th, p. 40) of the Scottish school milk experiment. Another test is in progress under the Edinburgh and East of Scotland College of Agriculture and the Royal (Dick) Veterinary College at the Poultry Department, Liberton. Some 88 chickens, hatched on Jan. 14th, have been divided into four groups. It is unnecessary to give details of the feeding but one essential point is that two groups have had separated milk added to the diet; the two other groups have only had water added. The conditions in the poultry pens have otherwise been the same. The results of the three months' experiment are very striking. The groups whose diet has been supplemented by separated milk show a great proportional increase in weight as against the water groups. The average gain up to the ninety-fourth day is as follows: Group I. (milk), 1176 g.; Group II. (water), 542 g. In the other two groups the figures were: Group III. (milk), 1142 g.; Group IV. (water), 557 g. In the contrasted groups the diet has, of course, been otherwise the same. The differences of size between the milk sets and the water sets are very obvious. The milk-fed chickens are large and relatively lethargic, consuming extremely little greenstuff; the water-fed chickens are much smaller and more active, and are ravenous for greenstuff. It is amusing to see how, under a slight shower of snow, the milk-fed pullets will rush to shelter, while the others follow their active open-air life. The difference in size, condition, and activity is hardly credible, and if the number and quality of eggs produced correspond to the increase in size, the results should be remarkable. There have been differences in the incidence of disease among the groups, but the details of this are not yet available in report form.

Smoke Abatement.

The annual report (1928–29) of the Scottish Branch of the Smoke Abatement League contains a striking fact—namely, that in the 13 years during which classes have been held by the branch some 947 men have been enrolled for instruction in the latest methods of stoking furnaces for steam-raising purposes and in economic fuel combustion. It has often been stated by men familiar with factory methods that, if proper stoking were adopted, there would be no smoke problem for the factories. This has been known for at least 40 years, but its application has hitherto not been encouraging, to say the least. The report urges the Secretary of State for Scotland to apply to Scotland the same principles as were applied to England in the Public Health (Smoke Abatement) Act, 1926. Why this has not been done already is difficult to explain. But one difficulty has been the methods followed at the great iron-smelting works at Coatbridge and elsewhere where, apparently, it is impossible to prevent smoke without such a radical reconstruction of plant as would wipe out the industry. In Scotland, iron and steel have been for years almost at the bottom of their prosperity and, probably, the representations of the manufacturers prevailed against any radical treatment of the smoke problem of particular areas. But improvement is only a matter of time. Meanwhile domestic smoke is the great problem, and this can be solved only by the steady displacement of crude coal by smokeless coal, by gas, and by electricity.

An interesting question has been raised by Dr. R. M. Buchanan, *bacteriologist to the Corporation of Glasgow*, who traces the decay of sandstone in buildings and monuments definitely to the action of bacteria in a smoke-polluted atmosphere.

> "The process of decay," he is reported as saying, "had hitherto been ascribed to the direct solvent action of adventitious gases in the atmosphere, arising from the combustion of coal or emanating from chemical works. On the other hand, its resemblance to an infective process was one of its chief characteristics. It was associated with many micro-organisms, some of which were capable of deriving sustenance from materials absorbable in solution from polluted atmospheres. The end-products of decay were to be regarded as the result of chemical changes induced by the growth of living organisms in the stone. However improbable at first sight it might appear, by a logical factor it was essential to the process and brought it into line with other reducing processes in nature."

This and other smoke problems were the subject of discussion at the annual meeting of the Scottish branch in Edinburgh on May 3rd.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Social Insurance Law and the Medical Syndicates.

THE conflict between the Government and the medical profession is beginning as a kind of preliminary engagement between outposts. While negotiations are being carried on in diplomatic secrecy between the leaders of the profession in Paris and the Government, the local syndicates in the country *départements* are examining the situation in which the new law is going to place them. The physicians of the Département du Nord have been the first, I believe, to pass a resolution that is in flat revolt against the law. This resolution says that the law as it actually stands is wholly incompatible with the honest and proper practice of medicine and will not give the patients the care they ought to have: "The physicians of the Département du Nord refuse their collaboration to the Insurance Law as it stands at present."

Considering that this department is one of the most important in France, by its industry, its mining districts, and its working population, whilst its physicians are known for their high standards and are strongly organised with a remarkable man, Prof. Vanverts, at their head, we may expect that the Government will take good notice of their protest. It is not unlikely that it will ask Parliament to modify the law as was promised when it was hurriedly voted for just before the last elections, the deputies being afraid to go to the polls without having decided at least upon its principles.

Failures of Whipple's Diet.

Everyone agrees that Whipple's liver diet is a wonderful cure and should be applied in all cases of anæmia, the Biermer type being the principal indication. At the last session of the Société Médicale des Hôpitaux Dr. Prosper-Emile Weil, one of the prominent hæmatologists, reported the case of one of his patients who, having been cured a first time of pernicious anæmia by Whipple's liver diet, got no benefit at all of the same diet six weeks later, and died. He observed that it should never be forgotten that exceptional cases may be encountered in which liver diet has no effect, and a similar opinion was expressed by several other members of the Society from their own experience.

Is Arteriography Permissible in Practice?

Dr. Reynaldo dos Santos has lately given a lecture before the Paris Société de Chirurgie, to which he belongs as a Portuguese associate member, on the injection into arteries of a saturated solution of sodium iodide to permit of radiographic exploration—a method already employed by Egaz Moniz of the same country, for cerebral arteries. Dr. dos Santos showed the Society splendid radiograms of arterial distribution obtained in this way, but at the next meeting there was some little disturbance over the suggestion, and one of the leading Paris surgeons, Prof. Lecène, said that certain methods of investigation should be reserved for experimental work, and he did not believe that a physician should be allowed to inject into a man's blood so caustic a substance as a saturated sodium iodide solution; he had seen lesions caused in the ureter by much weaker solutions. Many other members of the Society also held the view that this attempt, if it may be regarded as interesting from the scientific standpoint, should not be repeated and that the method should not enter into routine practice.

Prof. Roussy's Election to the Academy of Medicine.

Dr. Roussy, professor of pathological anatomy and histology in the Faculty of Medicine, has been elected a member of the Academy of Medicine of Paris. A pupil of Dejerine, with whom he described the thalamic syndrome, one of his main works has been the study of lesions of the infundibulum and the tuber cinereum, which he regards as governing the metabolism of water and fat, and responsible, by default, for Fröhlich's syndrome. He showed, with Camus, that the hypophysis is not the source of those troubles, and that previous experiments had caused lesions of both regions; whereas minute dissection made it certain that a lesion of the hypophysis could not by itself create the syndrome, whilst the destruction of the nuclei of the tubero-infundibular region was alone sufficient and necessary. Since the war Prof. Roussy has devoted his time to cancer, and it will be remembered that some weeks ago Mr. H. S. Souttar gave readers of THE LANCET [1] an account of what is being done in his cancer centre, not only for scientific work, but also in social propaganda against the disease.

Public Health Services.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 4TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 356 (last week 354); scarlet fever, 2152; diphtheria, 1028; enteric fever, 29; pneumonia, 1348; puerperal fever, 47; puerperal pyrexia, 109; cerebro-spinal fever, 18; acute poliomyelitis, 4; acute polio-encephalitis, 4; encephalitis lethargica, 23; dysentery, 10; ophthalmia neonatorum, 106. No case of cholera, plague, or typhus fever was notified during the week.

---

[1] THE LANCET, Feb. 9th, p. 300.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on May 7th-8th was as follows:—Small-pox, 338 under treatment, 12 under observation (last week 308 and 22 respectively); scarlet fever, 1518; diphtheria, 1070; enteric fever, 9; measles, 100; whooping-cough, 1027; puerperal fever, 20 (plus 10 babies); encephalitis lethargica, 80; poliomyelitis, 4; "other diseases," 61. At St. Margaret's Hospital there were 11 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 4 (0) from enteric fever, 60 (1) from measles, 10 (0) from scarlet fever, 103 (31) from whooping-cough, 38 (6) from diphtheria, 35 (7) from diarrhœa and enteritis under two years, and 102 (18) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to West Ham C.B. The death mentioned in last week's return should have been assigned to Acton M.B., and not to Brentford and Chiswick U.D. No great town reported more than three deaths from influenza, except Birmingham with 5, Wallasey, Manchester, and Sheffield with 4 each. Birmingham reported 11 deaths from measles, Manchester 8 deaths from whooping-cough. Of the 25 deaths from diarrhœa outside Greater London 8 were reported from Birmingham.

The number of stillbirths reported during the week was 251 (corresponding to a rate of 36 per 1000 births), including 56 in London.

Deaths from Small-pox.—The death assigned to Northampton C.B. in the week ended April 27th, was that of a woman of 59 years, who was notified as suffering from small-pox on April 23rd, and was removed to hospital the same day. Dr. Stephen Rowland, medical officer of health, tells us that the attack could not be called severe, but her condition was complicated by severe laryngitis. She was also suffering from extensive foul varicose ulcers of many years' standing. She gradually sank and died on April 25th, the death certificate being signed "Acute laryngitis, small-pox." She had been vaccinated in infancy and showed four faint marks.

Since January of this year over 430 cases of small-pox have occurred in the County Borough of West Ham. Two of these cases have died while under treatment for small-pox. The first case was that of a girl aged 2 years (unvaccinated), who was seen by Dr. F. Garland Collins, medical officer of health, on March 24th, and at once removed to hospital suffering from small-pox and broncho-pneumonia. The rash developed on the day of removal, but the child had been unwell and had suffered from a cough for several days. A brother of the patient, a newsboy aged 17 years, had been removed to hospital suffering from small-pox on March 12th from the same house, which was both dirty and over-crowded. The girl died six days after admission. The rash was scanty and the small-pox was of mild type. It is doubtful, Dr. Collins writes, whether or not this child would not have died from broncho-pneumonia even had it not developed small-pox.

The second death, which occurred on April 28th, was that of a woman aged 41 years. The son of this woman was one of the crew of the s.s. *Tuscania*, who arrived in West Ham after being discharged from his ship at Liverpool on April 2nd. He felt unwell on the 6th, when he was seen by a doctor. On the 8th a rash developed, and he was removed to hospital. This man had evaded vaccination when it was being performed upon members of the crew before they left the boat. The mother, who was unvaccinated and a direct contact, refused vaccination on the day the son was removed to hospital. She was taken ill on April 24th—i.e., 16 days after the removal of her son—was removed to hospital on the 26th, and died of small-pox on the 28th. Owing to the dangerous condition of the son this mother was permitted to visit him at the Small-pox Hospital on about nine occasions. On April 12th she consented to be vaccinated at the hospital; as the vaccination did not "take," she was vaccinated again on the 18th, and again with a negative result. Dr. Collins adds that not one of the 12 other direct contacts of the son who were vaccinated on the 8th contracted the disease.

DARLINGTON WAR MEMORIAL HOSPITAL.—This institution is to be enlarged by the addition of three new wards and an operating theatre at a cost of £60,000. These additions will bring up the accommodation to 150 beds.

Correspondence.

"Audi alteram partem."

THE NEW IMPORTANCE OF RADIUM.

To the Editor of THE LANCET.

SIR,—It has taken 30 years to develop a technique that yields reasonably good results in one or two groups of cancer. In these groups the routine is becoming more or less standardised, but in the greater number of cases—cancers of breast, of abdomen, and in fact in almost any position except the lip, larynx, and uterus—the results are disconcertingly erratic and the technique is still in its experimental stages.

Looking back one sees that progress has always come from institutes where intensive methods of study are possible—i.e., when there are large numbers of cases, adequate supplies of radium, *and* where accessory methods such as X rays, diathermy, and surgery are available. In this country progress has come from the Radium Institutes of London, Manchester, and the Middlesex Hospital, but it is comparatively little compared to that which has emanated from the Radiumhemmet of Stockholm or the Brussels and French clinics. We look almost in vain for any advance from individual workers and from ordinary general hospitals. In the present boom of radium the idea seems to be to scatter this beneficent agency broadcast and to overlook the fact that it requires such highly specialised technique and knowledge that it can only be used to full advantage in a few centres. We see surgeons and gynæcologists rushing across to Brussels and elsewhere and, after a week of observation, returning as experts, writing up a few cases, and imagining they are advancing scientific progress. We shall not wisely use the great gift of radium with which the country is supplying the medical profession unless we look at the history of the last 30 years and learn the lesson which is plain. To obtain the best results and to make progress it is obvious that we must centralise our resources. setting up, say, half a dozen efficiently staffed centres with subcentres as in France, perhaps, where radium can be expertly handled by those who specialise in this work and with whom it is not merely a sideline, and where the accessories—a really efficient X ray service, surgery, and diathermy—are also available. with expert and experienced workers. A correspondent in the *British Medical Journal* has already made this suggestion (April 27th, 1929).

It is argued that patients are often too ill to travel; if so they are probably beyond all hope of effective treatment, and obviously the diagnosis should have been made much earlier. Medical men who do not recognise cancer until the patient is in such an exhausted condition are certainly not likely to be competent to treat it by these newer methods. Naturally patients like being treated by their own doctors, and also prefer to remain as near home as possible, but surely these are minor considerations. and neither the feelings of the patient nor the self-sufficiency and self-interest of the medical man should stand in the way of progress. The treatment should not be for those who are in extremis and as a last resort, but applied early, when there may be a reasonable hope of success. Radiation treatment should be the first, not the last agency to be used.

A centralising scheme such as this would involve travelling to the centres, but there is no reason why funds should not be allocated to pay these expenses, as is done in Sweden, two centres serving the whole of that large country most efficiency, each case being followed up and literally almost forced to present himself for observation and further treatment at the discretion of the authorities of an institute that is really expert in the combined use of radium, X rays, diathermy, and surgery—four agencies which are under the control of one expert. Expert knowledge of radium and X rays is of far greater importance than expert surgery, which—in the surgery of access—is a comparatively simple matter. In other words, the expert who controls the treatment should be the man who has expert knowledge of the most potent weapons—i.e., radium and X rays.

In the composition of the Committee that is to control these radium resources we note that those who have done the spade work, those who are experts in these methods, are hardly represented. It is assumed that surgeons who perhaps possess a little radiological knowledge should be the controlling influence—the actual control of the resources should be in the hands of those who not only possess some knowledge of surgery, but who have training and experience in radiation therapy such as can only be acquired by years of study and experience. If this attitude of surgical predominance persists we shall make no progress, for in the treatment of cancer surgery is practically a failure and there is no progress in spite of all the advance in modern technique. We have explored all the possibilities of surgery; we are just beginning to explore the more hopeful realms of radiation treatment. Till we realise that it is surgery and not radiation treatment which should now be regarded as the refuge of the destitute we shall not progress. I am, Sir, yours faithfully,

Cambridge, May 13th, 1929. A. E. BARCLAY.

To the Editor of THE LANCET.

SIR,—The priority of the Middlesex Hospital in the use of large quantities of radium externally should not be forgotten in the discussion in your columns, as it has been by Sir Charles Gordon-Watson in your last issue. In 1920 two and a half grammes were lent to the Middlesex Hospital by the Medical Research Council, largely owing to the initiative of my predecessor, the late Dr. Cecil Lyster. The large amount of valuable experimental and clinical work done with radium tubes and a "bomb" by Prof. Lazarus-Barlow, Prof. Sidney Russ, and Dr. Helen Chambers is recorded in the 1922 report on "The Medical Uses of Radium" of the Medical Research Council (No. 62).

Later on this radium was split up and distributed to other centres, but for about two years half a gramme was available for surface use, and I was, I believe, one of the first to use such a large quantity from a distance such as six centimetres. The patients treated were mostly surgical rejects, but valuable results, in some instances still continuing good, were obtained, as recorded in the reports to the Medical Research Council, and, briefly, in your own columns.[1] The establishment of the "Radon Centre" prevented the continuance of this study at the Middlesex, but, as I said in the discussion on Dr. Max Cheval's interesting paper [2] on the Brussels four-gramme "bomb," read before the Medical Society of London on March 28th, 1928, it is to be hoped that this method will not be neglected for long in England, as it promises well not only in gynæcological but in several other departments of cancer therapy.

I am, Sir, yours faithfully,
J. H. DOUGLAS WEBSTER.

Chandos-street, London, W., May 11th, 1929.

BLOOD STANDARDS.

To the Editor of THE LANCET.

SIR,—As the Haldane instruments used at Salford Royal Hospital are prepared by the original makers, Dr. Goodhart's suggestion does not explain our difference. The standards show no variation amongst themselves, and I have tested the pipettes by the mercury method and found them exceedingly accurate. I do not attach much weight to checking a result with a second opinion, because in the Salford laboratory I have known five opinions in agreement upon a single sample. On one occasion the bloods of the laboratory staff were tested, and every stage of the estimations gone through to the satisfaction of four observers. The results of presumably normal people ranged from 79 to 89 per cent. The comparisons were made by daylight and artificial light, in each case by transmitted and reflected light.

Both Dr. Goodhart and I are firmly convinced that we are right and the discussion could be quoted by a chemist to illustrate the inaccuracies inherent in all colorimetric methods of analysis. It appears to me that the only way to test the unconscious error of different observers would be to insert various dilutions of blood and the standard into an apparatus similar to that used by ophthalmologists to detect malingerers claiming to be blind in one eye. With this device it is, I understand, impossible to say whether an object is on the right or left in actual fact, or whether two images of a single object are being seen. Such a test might provide some entertainment to the onlookers. I am, Sir, yours faithfully,

Manchester, May 10th, 1929. C. E. JENKINS.

A NEW SIGN OF MEASLES.

To the Editor of THE LANCET.

SIR,—With reference to the note in your issue of May 4th (p. 962) on the appearance of small hæmorrhages on the buccal mucous membrane in the prodromal stage of measles—a sign which Dr. Geza Pétenyi has not found mentioned hitherto in medical literature—I should like to say that I have not only frequently seen this phenomenon, but have also stated on p. 271 of my work on "Acute Infectious Diseases" (1925) that "minute hæmorrhages on the buccal mucous membrane often precede the occurrence of Koplik's spots."

I am, Sir, yours faithfully,

Western Hospital, S.W., May 3rd. J. D. ROLLESTON.

SERVICE UNIFORM.

To the Editor of THE LANCET.

SIR,—Many of us who have served and who are serving will agree with your remarks last week (p. 1000) as to the sombre effect of the service uniforms of the officers of the R.A.M.C. at the recent International Congress of Military Medicine. A smarter uniform than khaki is urgently needed for ceremonial occasions such as this, and some form of suitable full dress with a neat *shako* in lieu of the old *pickelhaube* helmet should be authorised. A grant should be made towards the cost and it should be obtainable through ordnance stores. The Navy have a suitable uniform for such occasions; why should not the Army? It is false economy too, both from the standpoint of esprit de corps and recruiting, to further withhold any longer the re-issue of full dress for ceremonial and "walking out" from our regular and territorial armies.

I am, Sir, yours faithfully,
RUSSELL STEELE,
Captain, late R.A.M.C.

Royal United Service Institution, Whitehall,
London, S.W., May 13th, 1929.

PRIMOGENITURE AND ABNORMALITIES.

To the Editor of THE LANCET.

SIR,—With reference to Dr. M. T. Macklin's article in your last issue, I should like to refer readers to my letter [1] to you of Oct. 22nd, 1927, where I endeavoured to show by a priori reasoning that Dr. Still's view was not justified. Dr. Macklin now confirms my contention a posteriori.

I am, Sir, yours faithfully,

Shortlands, Kent, May 12th, 1929. A. WOHLGEMUTH.

SUBMUCOUS RESECTION OF THE NASAL SEPTUM.

To the Editor of THE LANCET.

SIR,—In his comment on your annotation of Feb. 2nd (p. 244) Mr. Macleod Yearsley has expressed (Feb. 9th, p. 307) certain opinions about the operation, with some of which I agree and with others I do not. Mr. Yearsley has done over 1000 of these operations; I have done probably five times as many. I began *in London in 1911 and continued here, except during* visits to America, the Continent, and Britain, where I have seen the operation performed by many people.

General anæsthesia never appealed to me; I believe it unnecessary and adds to the risk of sepsis. With cocaine and adrenalin locally applied and the injection of a weak solution of neocain and adrenalin, perfect anæsthesia is secured. I had my own septum removed under local anæsthesia without pain or discomfort. The amount of cartilage and bone to be removed is *always a subject of dispute. I believe the ethmoidal* plate and the vomer should be widely removed because they are nearly always thick and irregular, and that the chief site of obstruction is far back. Mr. Yearsley has, I think, missed the principal point in removing the cartilage, which was not to tear the fibrous ligament attaching the septal cartilage to the junction of the nasal bones. If this be torn in rough handling then a depressed tip is bound to follow. Another point is to have a counter opening far back, by making a cut in one of the muco-perichondrial flaps, and so obviate the risk of a hæmatoma. I always use one catgut suture and regard this as absolutely necessary. But the incision made is *only a short vertical one*; there is no need to make the horizontal incision along the crest as performed by many. I use packing sometimes and sometimes not. We rarely see sepsis, hardly one case in 1000.

I think if Mr. Yearsley does the extensive operation which most of us think necessary he will see a few cases where the soft septum will fall to the under side in sleep, at any rate until final scarring tightens up the tissues. Our experience is that the difficulty encountered in so-called flapping is due not to the septum but to paralysis of the alæ nasi. This paralysis we combat by asking the patients to wear vulcanite dilators (specially made for each patient) during the night.

I think it is wrong to remove the enlarged posterior ends unless they are morulated. We all used to remove these poor posterior ends while taking out adenoids, and I now believe we were wrong. Mr. Yearsley probably believes as I do that the inferior turbinal is the most precious organ in the body, being the guardian of the lungs. That being so, it should be protected against the ruthless surgeon.

I am, Sir, yours faithfully,
T. A. MACGIBBON.

Christchurch, N.Z., March 26th, 1929.

PATHOLOGICAL POSTURES.

To the Editor of THE LANCET.

SIR,—I am reluctant to enter into controversy with Dr. Walshe, especially upon a subject to which he has made such valuable contributions. But I must ask to be allowed to reply to his criticism, expressed in his Oliver-Sharpey lecture which you published last week, of my views on the hemiplegic posture. I do not propose to discuss here the validity of the "appeal to phylogenesis" as an explanation of pathological postures, but I would point out that there is nothing inconsistent between a physiological and a biological explanation of a posture. Dr. Walshe's physiological interpretation of the flexed upper limb in hemiplegia is not in the least incompatible with my biological one, and is therefore not a valid argument against it. The two conceptions are in fact complementary.

Dr. Walshe is, I feel, a little unfair in extracting the quadrupedal extensor reflex from its context in my paper, for it was only one of a number of pieces of evidence in favour of my interpretation of the hemiplegic posture, and by no means stands alone. Extensor spasticity in the human upper limb is a problem of great interest and importance which otherwise Dr. Walshe does not discuss at all. My argument was that an identical posture of spastic extension of the upper limb was present in the "cerebellar fits" of Hughlings Jackson, in quadruplegia produced by lesions of the spinal cord, in the quadrupedal extensor reflex and in the normal standing attitude of the anthropoid apes. Kinnier Wilson has interpreted this posture, when it occurs in "cerebellar" or tonic fits, as decerebrate rigidity. Riddoch and Buzzard have adopted a similar interpretation of the posture in spinal quadruplegia, and I have applied it to the quadrupedal extensor reflex. Extension of the forelimb in the decerebrate animal is, as Sherrington has shown, reflex quadrupedal standing. Dr. Walshe regards such a phylogenetic explanation of extensor spasticity in the human upper limb as illegitimate. It would be interesting to hear his alternative explanation.

Lastly, Dr. Walshe himself demonstrates the difficulty of avoiding phylogenetic explanations. Referring to the tonic neck and labyrinthine reflexes in man he says: "We may state at once that these reactions belong to the group of tonic reflexes described by Magnus and de Kleijn in the decerebrate animal." Now Magnus and de Kleijn described and interpreted these reflexes in decerebrate quadrupedal animals, and they are intimately associated with quadrupedal standing. Dr. Walshe in one of his papers has shown that identical reactions are found in hemiplegia in man. What explanation except a phylogenetic one has he to offer for this?

I am, Sir, yours faithfully,
W. RUSSELL BRAIN.

Harley-street, W., May 12th, 1929.

BLOOD-SUGAR ESTIMATIONS IN THE TROPICS.

To the Editor of THE LANCET.

SIR,—Those using the Folin and Wu method for blood-sugar estimations in the tropics may have been troubled by the weak colour often developed after the addition of the molybdic acid solution to the water-cooled mixture of filtrate and alkaline copper solution removed from the water-bath. If this mixture is thoroughly cooled in *iced water* for about five minutes prior to the addition of the molybdic solution the difficulty referred to above is completely overcome. Perhaps this note may prove of some value to those who are using the Folin and Wu method in warm climates.

I am, Sir, yours faithfully,
ALBERT J. HAWE, M.B., M.R.C.S., W.A.M.S.

Gold Coast Hospital, Accra, April 26th, 1929.

SECONDARY FEVER IN SMALL-POX.

To the Editor of THE LANCET.

SIR,—As cases of small-pox are occurring from time to time it may be useful to give a personal experience which I had lately as superintendent of a small-pox hospital. Three cases of an acute discrete type, and five others of an ordinary character, were treated with the following application twice daily to all spots: calamine, grs. 15; pure lysol, ♏ 16; equal parts of white vaseline and zinc ointment to 1 oz. In none of the cases so treated was there any secondary fever; all admitted that the ointment completely removed irritation. Except for aperients and cholagogues, of which phenolphthalein, cascara evacuant, calomel, mag. sulph., and petroleum were used, no diaphoretic treatment was adopted.

I am, Sir, yours faithfully,
L. L. BURTON, F.R.C.S. Edin.

Thurleigh-road, Clapham, S.W., May 13th, 1929.

TREATMENT OF ULCERS OF THE LEG.

To the Editor of THE LANCET.

SIR,—I read with interest Dr. J. H. Young's note in your issue of May 11th on the treatment of ulcers of the leg with magnesium sulphate. This treatment, satisfactory though it is, does not appear to have any advantage over treatment with Unna's paste. Indeed it has the disadvantage that the patient is kept in bed. The treatment with Unna's paste, combined with injection of the varicose veins (if any) is ambulatory and astonishingly satisfactory. I do not think there is any particular virtue in the Unna's paste. I have used pastes of slightly different consistency and they all appear equally effective. It would seem that the crux of the matter lies in the fact that the œdematous tissues are supported and rendered non-œdematous. The only things required are a jam-jar of Unna's paste melted in a saucepan of boiling water, a wool-carrier or brush, and a couple of ordinary 2½-in. bandages. The leg is coated with paste and the bandage applied fairly tightly from the ankle upwards, more paste being worked in as one goes on. Pieces of lint can be incorporated in the bandage in the case of large ulcers. About one and a half bandages are required for a large leg. The dressing can be left on for a week even in the case of multiple large ulcers. It will naturally be a bit smelly on removal. In any case in which syphilis is suspected mercury and iodide may be given. Under this treatment the pain is relieved and the ulcers fill up and epithelialise rapidly. Later the dressing can be left on for two or three weeks.

I do not think the medical profession realises the simplicity and potency of this treatment. One sees very old ulcers on legs whose owners have taken them from hospital to hospital and the ulcers are still there. The patients are convinced that they will take them to the grave, indeed there is a widespread idea that if an old ulcer is healed up the patient will undergo rapid dissolution. In the Midlands most of these cases gravitate to institutions where they are relieved of large fees and left with their ulcers.

I am, Sir, yours faithfully,

A. ERNEST SAWDAY,
M.B., B.S. Lond., F.R.C.S. Edin.

Derby, May 11th, 1929.

THE NOMENCLATURE OF PLACENTA PRÆVIA.

To the Editor of THE LANCET.

SIR,—As the subject of placenta prævia is to be discussed at the annual meeting of the British Medical Association in July, it seems opportune to suggest that the terminology of the subject be reviewed and, if possible, standardised. The difficulty lies with the two types described variously as lateral and marginal. Whitridge Williams and Fothergill, to quote two writers, describe the type in which the placenta partially covers the os as lateral, and the type in which the placenta merely extends on to the lower uterine segment as marginal. Other writers, Johnstone and Fairbairn amongst them, refer to the former as marginal and the latter as lateral. This has given rise to confusion in the past, especially in the teaching of students, and must inevitably do so when treatment is being discussed.

It is perhaps unfortunate that the condition cannot be described under the two headings central and lateral, but the treatment is so dependent on the relationship between the edge of the placenta and that of the cervix, at the time at which it has become necessary to interfere, that it would be essential to describe, as a subdivision of the second, a third type—namely, that in which the edge of the placenta does not reach the edge of the cervix, and incidentally the type in which artificial rupture of the membranes and application of a binder is adequate treatment.

As lateral and partial have already been used to describe the same or intermediate type, may I suggest that the term lateral be dispensed with entirely in favour of the more descriptive term partial, and that the three types be referred to as central, partial, and marginal? I recognise, of course, that any classification must refer only to the state of affairs at the time of examination, as a case appearing central when the os will only admit one finger may prove to be partial when dilatation has proceeded further.

I am, Sir, yours faithfully,

E. A. GERRARD,
Resident Obstetric Surgeon, St. Mary's Hospitals,
May 13th, 1929. Manchester.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. R. W. Higgins to be Surg. Lt.-Comdr.

The following appointments are notified: Surg. Comdr. R. F. Quinton to *Emperor of India;* Surg. Lts. G. D. J. Ball to *Barham* (on transfer of flag); E. C. Downer to *Vivid;* J. J. Keevil to *Revenge;* and C. G. Rippin to *Royal Oak* (on transfer on flag).

Surg. Lt. (Short Service) G. Rorison transferred to Permanent List.

Surg. Lt. (D.): H. M. Hill to Greenwich; and L. M. Hughes to *Victory*, for R.N. Barracks, Portsmouth.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. F. Tyndale, having attained the age for compulsory retirement, is placed on ret. pay.

Maj. and Bt. Lt.-Col. W. Benson to be Lt.-Col., vice Lt.-Col. W. F. Tyndale to ret. pay.

Col. N. J. C. Rutherford, late R.A.M.C. (ret.), to be Med. Offr., The Tower of London.

Maj. L. A. B. Moore (ret., R.A.M.C. Mila.) to be Temp. Maj.

Capt. J. M. Morrison to be Maj.

Lt. on prob. W. G. Harvey is secd. under the provisions of Art. 205, Royal Warrant for Pay and Promotion, 1926.

ARMY DENTAL CORPS.

Capt. H. L. McCallum to be Maj.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. A. Roberts resigns his commn.

TERRITORIAL ARMY.

Lts. H. S. Ward and S. Orchard to be Capts.
Lt. J. B. Dedman, from Gen. List, O.T.C., to be Lt.
P. D. Thomson to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. P. E. H. Adams, having attained the age limit, relinquishes his commn. and retains his rank.

INDIAN MEDICAL SERVICE.

Lt.-Col. W. V. Coppinger to be Col.
Capt. A. M. V. Hesterlow to be Maj.

EXTENSION OF BIRMINGHAM GENERAL HOSPITAL.—A casualty department and three wards are to be built on the newly acquired portion of St. Mary's Churchyard at a cost of £47,000. This will not only relieve the congested casualty and out-patients' departments, but will provide 60 additional beds. Thirty pay-beds have recently been opened and are rapidly being taken advantage of. Owing to the constant increase in the number and difficulty of operations it has been decided to appoint two resident surgical registrars to assist the honorary surgeons with in-patients. The appeal for £5500 for radium has been completely successful. A certain quantity of radium will now be available for the production of "radon."

SALOP ORTHOPÆDIC HOSPITAL.—Proposals are being considered for the entire rebuilding of the Shropshire Orthopædic Hospital and Agnes Hunt Surgical Home. The building, which was originally erected for temporary military use, is said to be very inconvenient and in an unsatisfactory condition. A new building, facing the playing fields of Shrewsbury School, would cost £80,000. The Cripples' Training College, which has grown out of the work of the hospital, is to be housed in buildings recently purchased. The boys and girls who are being trained are taught, among other things, surgical boot making and repairing and surgical appliance making.

MEDICAL GRADUATES FOR PARLIAMENT.

IN the Parliament which was dissolved on May 10th there were 13 Members of the House of Commons with medical degrees or diplomas. Eleven of them, along with Lord Dawson and four coöpted University representatives, sat as a Parliamentary Medical Committee with Dr. F. E. Fremantle as chairman, and Dr. Drummond Shiels as hon. secretary. Lord Moynihan took his seat as a peer just before the end of the Parliamentary session.

Nominations for the new Parliament, which meets on June 30th, can be made until Monday, May 20th, but the following is a complete list of the candidates so far as we know at present. A dagger sign denotes membership of the recent House of Commons, while an asterisk indicates that the candidate contested a seat unsuccessfully at the previous General Election in 1924. Polling day for most of the constituencies is May 30th, but the election may close a little later for University seats.

Some Personal Records.

Miss **ETHEL BENTHAM**, M.D. Brux., L.R.C.P. Edin., who is once again standing in the Labour interest for East Islington, is medical officer to the Memorial Baby Clinic at North Kensington and a justice of the peace. Her special interest lies in the direction of child and maternal mortality and morbidity which she connects in the main with bad housing and faulty conditions of life, including especially the ever-present dread of unemployment. She wants to see some method of bridging the gulf of medical attendance for boys and girls between 14 and 16, a time in which she has found in her practice much damage is done for want of it.

Sir **GEORGE BERRY**, F.R.C.S. Edin., LL.D., has sat in the House of Commons since 1922, and is standing for the fourth time for one of the two Scottish University seats, the other Unionist candidate being Mr. John Buchan. He has been President of the Royal College of Surgeons of Edinburgh and of the Ophthalmological Society of the United Kingdom, and was for a number of years a member of the Edinburgh University Court. If elected he will continue to work for the educational, investigational, and other interests of medicine. As a consulting surgeon he has lived in intimate contact with general practitioners for whom he has a profound admiration.

CHARLES W. BROOK, M.A. Camb., M.R.C.S., who has been adopted as Labour candidate for Balham and Tooting, qualified in 1925, and is medical director of an artificial sunlight clinic. He is placing public health and the improvement of social services in the forefront of his election campaign. His Liberal opponent is also a medical man.

Mrs. **STELLA CHURCHILL**, M.R.C.S., D.P.H., who is standing as Labour candidate for Brentford and Chiswick, took the Natural Science Tripos at Cambridge in 1905, and is medical officer to a welfare and a sunlight clinic. It is unfortunate, she writes, that the British Medical Association will not support the candidature of medical men or women who do not bind themselves by the policy of the Association in regard to State medical services. This means, in effect, that the Association is the mouthpiece and protector only of the private general practitioner and not of the medical profession as a whole. She would like to see the policy which candidates are required to support published in full in the medical press.

J. **DOUGLAS COOKE**, M.B. Melb., F.R.C.S. Eng., who is contesting Peckham in the Conservative interest, stands for the full Baldwin programme without modification. He qualified in 1902 and has retired from practice.

C. R. **COOKE-TAYLOR**, M.R.C.S., who is standing as Liberal candidate for the Dulwich division of Camberwell, is a barrister-at-law who took his medical diplomas in 1927. This is the fourth time he has contested the seat and the sixth time he has stood for Parliament. In the forefront of his programme is the Papworth scheme for dealing with tuberculosis. He notes the activity in his own constituency as elsewhere of antivaccination propaganda.

A. **VERNON DAVIES**, O.B.E., M.B. Vict., is standing for re-election in the Royton division of Lancashire as a supporter of Mr. Baldwin. He has retired from practice and is a commissioner in the St. John Ambulance Brigade.

F. E. **FREMANTLE**, O.B.E., M.D. Oxf., F.R.C.S. Eng., F.R.C.P. Lond., who is standing again for the St. Albans Division of Hertfordshire as a Conservative, has sat in four Parliaments, and has been chairman for several years past of the non-party Parliamentary Medical Committee. His agent, Lieut.-Colonel R. J. Slaughter, would be glad to receive offers of help from readers prepared to lend cars on polling day, to speak for him at public meetings, or otherwise assist his candidature. Address: Conservative Central Committee Rooms, 2, Upper Dagnall-street, St. Albans.

HENRY C. HASLAM, M.A., M.B., D.Sc. Camb., who is standing again for the Horncastle Division of Lincolnshire, is a biochemist attached to the Pathological Laboratory, Cambridge.

SOMERVILLE HASTINGS, M.S. Lond., F.R.C.S. Eng., who sat in the Parliament of 1923–24 and is again standing as Labour candidate for the borough of Reading, is surgeon in charge of the ear and throat department at the Middlesex Hospital. In his election he is, as usual, stressing public health matters.

A. B. **HOWITT**, C.V.O., M.D. Camb., who is standing in the Conservative interest for Preston, Lancs, was Epsom Scholar at St. Thomas's Hospital, qualifying in 1906, and holding a number of hospital appointments including that of resident medical officer to St. Thomas's Home. He is son-in-law to Lord Marchamley.

A. **JOSEPH G. HUNTER**, *M.C.*, M.D., F.R.C.S. Edin., who is Liberal candidate for the county of Dumfries, is assistant surgeon to the Dumfries and Galloway Royal Infirmary and medical officer to the Dumfries Prison.

Sir **HENRY JACKSON**, M.A. Camb., D.Sc. Lond., M.B. Edin., is standing for re-election in Central Wandsworth, where he was for three years mayor. In his election programme he is stressing slum-clearance, reconditioning of old houses, and coördination of traffic in Greater London. The last-named policy would, in his judgment, relieve the congestion of our streets, reduce the appalling mortality from accidents, and ensure a steady reduction of fares.

E. G. **GRAHAM LITTLE**, B.A. Univ. Cape Good Hope, M.D., F.R.C.P. Lond., who is again standing as an Independent candidate for London University, is in charge of the Skin Department at St. Mary's Hospital, London. He has been a member of the University Senate since 1905, and was elected in 1924 with a

TREATMENT OF ULCERS OF THE LEG.

To the Editor of THE LANCET.

SIR,—I read with interest Dr. J. H. Young's note in your issue of May 11th on the treatment of ulcers of the leg with magnesium sulphate. This treatment, satisfactory though it is, does not appear to have any advantage over treatment with Unna's paste. Indeed it has the disadvantage that the patient is kept in bed. The treatment with Unna's paste, combined with injection of the varicose veins (if any) is ambulatory and astonishingly satisfactory. I do not think there is any particular virtue in the Unna's paste. I have used pastes of slightly different consistency and they all appear equally effective. It would seem that the crux of the matter lies in the fact that the œdematous tissues are supported and rendered non-œdematous. The only things required are a jam-jar of Unna's paste melted in a saucepan of boiling water, a wool-carrier or brush, and a couple of ordinary 2½-in. bandages. The leg is coated with paste and the bandage applied fairly tightly from the ankle upwards, more paste being worked in as one goes on. Pieces of lint can be incorporated in the bandage in the case of large ulcers. About one and a half bandages are required for a large leg. The dressing can be left on for a week even in the case of multiple large ulcers. It will naturally be a bit smelly on removal. In any case in which syphilis is suspected mercury and iodide may be given. Under this treatment the pain is relieved and the ulcers fill up and epithelialise rapidly. Later the dressing can be left on for two or three weeks.

I do not think the medical profession realises the simplicity and potency of this treatment. One sees very old ulcers on legs whose owners have taken them from hospital to hospital and the ulcers are still there. The patients are convinced that they will take them to the grave, indeed there is a widespread idea that if an old ulcer is healed up the patient will undergo rapid dissolution. In the Midlands most of these cases gravitate to institutions where they are relieved of large fees and left with their ulcers.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Prorogation and Dissolution.

PARLIAMENT was prorogued on Friday, May 10th, and dissolved by Royal Proclamation later in the day. The Royal Assent was given by Royal Commission to a large number of Acts including the Finance Act, the Local Government (Scotland) Act, the Pharmacy Act, the Age of Marriage Act, Infant Life (Preservation) Act, and the Artificial Cream Act. In the King's Speech reference was made to the announcement by H.M. Government of their intention of taking the necessary action for the acceptance, subject to reciprocity, of the Protocol prohibiting chemical and bacteriological methods in warfare. The Dominion Governments had announced a similar intention. Reference was also made to the inquiry into the radium requirements of the country in the light of the knowledge and experience gained as to the importance of radium in the treatment of cancer; and the decision of the Government to contribute to a fund for the acquisition of a stock of radium. It was His Majesty's earnest hope that this action might prove a substantial step forward in the campaign against one of the most distressing maladies known to mankind.

HOUSE OF COMMONS.

TUESDAY, MAY 7TH.

SCOTTISH HEALTH SERVICES.

The House went into Committee on the Scottish Estimates. On the vote for the Scottish Department of Health.

Major **ELLIOT** (Under Secretary for Scotland) said that the estimates this year were increased by £260,000. There were one or two main lines by which they could test the value received for the expenditure on the health services. The figures for infant mortality were 86 per 1000, compared with 89 per 1000 last year. The figures for ten years came out at about 92 per 1000, so that there had been a very important saving in life. The figures, however, were not satisfactory compared with those of England and other countries in the Empire. Maternal mortality remained high both in Scotland and in other countries with a high standard of living. It did not appear to yield to a general advance in the prosperity of the country as did infant mortality. The death-rate from tuberculosis was 97 per 1000 of the population this year as compared with 99 last year and 116 in 1924. Those figures compared favourably with world figures. Health benefit payments showed a disquieting tendency to increase and establish itself at a successively higher level. In the first four months of last year the total cash benefits paid out were £875,000, and for the first four months of this year they were £981,000. That was not entirely a case for reproach on the health side. In that morning's issue of the *Times* he had given an account of some tests that nature had carried out in East Africa, where two tribes had been found living under similar conditions. One consumed a great deal of milk while the other did not. The tests carried out at Aberdeen gave a similar result to that reached in East Africa, and showed that there was a marked improvement in the health of school-children by the addition of a small amount of milk to their diet. Much constructive work had been done for the prevention of disease, and in Scotland they were fortunate in possessing a close and intimate link between the Department of Health and the voluntary hospitals and medical schools associated with those hospitals. One of the great tasks of a future Government would be to make sure that full use was made of the Local Government Act. About £68,000 per annum was being spent on the Highland and Island service and no more beneficent work could be imagined. Without the provision made by this service the inhabitants of the Highlands and Islands of Scotland would be without proper medical treatment. The fund, however, had been living on its savings for some time and it would be the duty of the new Government, after the General Election, to maintain and enlarge the provision made for this important service.

Importance of Nursery Schools.

Dr. **DRUMMOND SHIELS** said that it was false economy to cut down expenditure on public health. In times of stringency other things should be sacrificed before the public health services. The 11,000 houses that had been provided in Scotland towards slum clearance was a miserable contribution to the problem. He was very glad to notice in the report of the Department the emphasis laid on the importance of dealing with children between the ages of 2 and 5 years in nursery schools. The importance of these schools was being increasingly realised. These nursery schools were not so much schools in the ordinary sense of providing education, though they might provide facilities for inculcating habits of discipline and so on. Their object was to remove children from playing in the gutter and to give them a chance of having physical defects remedied. It was true, as the report stated, that the school medical officers and other medical men were assured that tonsils, adenoids, and similar defects, which were such a nuisance and such a cause of anxiety to the parents during the ordinary school life of the children, had their beginning at that period of life, and, if they were promptly dealt with it would mean a very great improvement, not only in regard to the saving of time, but in the health of the children. There were 350,000 such children in Scotland and only by a system of nursery schools could the problem be satisfactorily tackled. He did not know what the position in Scotland generally was, but in Edinburgh plans had been made for starting one nursery school in the immediate future. A big programme of nursery schools would be put into active operation if the Labour Party came into power after the General Election. The Under Secretary for Scotland had dealt very interestingly with the problem of maternal mortality, child welfare, and infant mortality, all of which were more or less grouped together. He was glad to notice that in the report Dr. Finlayson's figures were given. He (Dr. Shiels) had given those figures in the House before, but they were so tremendously significant that they were well worth repeating. Dr. Finlayson found that, taking an average of four years from 1924 to 1927, in the case of women who received antenatal attention, the deaths in childbirth or immediately after were only 3 per 1000, whereas in the case of those who had no antenatal attention the figures were 7 per 1000. Taking 1927 by itself the figures were even more remarkable, because in the case of the women who had antenatal attention the mortality-rate was 2·4 per 1000, and in the case of those who received no antenatal attention it was as high as 11·2 per 1000. Although those figures were limited, they proved conclusively that there was a very marked difference in the deaths of mothers according to whether or not they had received attention before confinement. The antenatal centres in Scotland were neither numerous nor good enough. In the large towns like Glasgow and Edinburgh there were a certain number of such centres, but more were required, and they ought to be so situated as to be convenient of access to the women, who should not have to travel long distances. As a considerable period of waiting was in some cases inevitable the centres should be made more comfortable. Some of the centres had no suitable conditions for examination which did not encourage women to attend. It should be remembered that working women were just as sensitive and had as much delicacy as women of other classes. The Department of Health ought to urge all local authorities which had antenatal centres to see that they should be such as would encourage women to attend. Strong pressure should be put on the local authorities which had no such centres at all, because they were sure that antenatal supervision would save life.

Housing Conditions and Tuberculosis.

It was satisfactory, so far, that the figure for infant mortality was down to 86, but the figure had always been higher in Scotland than in England, and there was no question that it was due to the difference in housing conditions. The same steady progress was being made in regard to tuberculosis, but he would like to see it greater. There, again, it was really a housing question. They were spending a great deal of money on sanatoria and on the treatment of tuberculosis, but the best medical authorities believed that if they could provide decent housing conditions they could sweep away the whole problem of tuberculosis in a generation. Not very much prominence had been given to the question of venereal disease. The difficulty in regard to this disease was that they did not know whether it was decreasing, or whether they were getting down to the causes. They knew that more people were attending, and there seemed to be a very definite increase in gonorrhœa, although the evidence in regard to syphilis was that it seemed to be not increasing. They did not know whether the increase in gonorrhœa simply meant that more people were attending or whether there was an actual increase. This disease was so important and was costing the local authorities and the country so much money that until they had some method such as was suggested in the recent Edinburgh Bill of dealing with it, they would continue to have inadequate results from a very large national expenditure. The report brought out the fact that every four years, or about three times in the school life of a child, it was medically inspected. That was not enough. There should be a medical inspection of every child at least once a year, and certainly the staff would have to be increased. That would be a great economy, because if, in the course of their school life they could attend to the physical conditions of the children they could turn them out at the end not only well educated, but also physically well equipped. Attention should also be paid to systematic and daily exercises for the children at school. They could honestly congratulate Major Elliot on the interest which he had taken in the experiment with regard to milk and, probably, for its initiation. It was also a tribute to the usefulness of the Empire Marketing Board. The uniting of the two experiments, one in Scotland and the other as far off as East Africa, was not only of great scientific interest but of great practical importance. The good work which Prof. Leighton had done and the interest he had taken in this subject for many years, in encouraging the milk producers of Scotland to supply pure and cleaner milk ought to be recognised. The present nomenclature of graded milk was misleading. People thought that Grade A milk was the best quality, whereas the Certified milk was the best. He would like information as to the quality of the non-graded milk. Did the Department take steps to obtain any samples of milk, and to subject them to bacteriological examinations? It should be made a serious crime to sell tuberculous milk.

Health Insurance.

It might be said that the national health insurance scheme in Scotland was now well organised and working well. The report called attention to the fact that the action taken under the Economy Act by reducing the State grant had gravely prejudiced the possibility of extension of the dental and ophthalmic services. It was the duty of the Government to make the national health insurance system really comprehensive and to enable the contributors to it to have at their command every medical and surgical aid. At present they were thrown back on the voluntary hospitals, which were overcrowded and had not enough beds. He echoed the hope expressed by Major Elliot in regard to the new hospital services under the Local Government Bill. That section of the Bill would provide a possible development of municipal service to supplement the voluntary service, and would make it possible for the ordinary citizen to obtain the specialist advice which was absolutely essential. Medicine had become so vast in so many directions that the ordinary practitioner could not be expected—and did not pretend—to be an authority on all its branches. It was only by the hospital services, or by specialist aid, that that could be overcome. The Labour Party were sympathetic in regard to research. There was, for example, the question of influenza. Present knowledge of that disease was very limited. Research was badly needed. Measles and whooping cough, which were not very seriously regarded by the public, were actually two of the most serious diseases, but they were not making a great deal of progress in regard to them. The entire sum which this wealthy country spent on research of all kinds was only about £20,000, and it would be a tremendous thing if, by research work, even a few hundred lives could be saved in Scotland each year. He wished to emphasise the importance of proper dental treatment for children. Most local authorities in Scotland had made such provision, but two of them—Argyllshire and Bute—had no provision at all. He was very glad to hear Major Elliot's reference to the Highlands and Islands Fund. He (Dr. Shiels) had had an opportunity of seeing its work in Shetland and Orkney, and there was no question about its tremendous value and necessity. The Department of Health should put some pressure on local authorities in the North of Scotland who had failed to provide maternity and child welfare services.

Reply to the Debate.

Major ELLIOT, replying to the debate, said that the Health Department were taking active steps to deal with maternal and infant mortality. Their expenditure in the current year was 50 per cent. greater than the expenditure for which the Labour Government was responsible. With regard to the milk tests, it was a question of quality, not of quantity. Last year 2249 cattle affected by tuberculosis were slaughtered and the process of cleaning up the cattle was continually going on, and was bound to result in an improvement in public health. There was no increase in the number of school-children suffering from malnutrition compared with last year.

The vote was agreed to.

THURSDAY, MAY 9TH.

The London Lock Hospital.

Mr. PETHICK-LAWRENCE asked the Minister of Health whether he had now any information to give the House as to the reforms proposed at the London Lock Hospital.

Captain T. J. O'CONNOR asked the Minister of Health whether, having regard to the damage already done to the careers of the three women dismissed from their posts at the London Lock Hospital, he would state whether the committee of inquiry had exonerated them.—Mr. CHAMBERLAIN replied: I am glad to be able to add to the statement which I made in the House on April 30th that a conference has, I understand, been held to-day between representatives of the governing body of the hospital and of the former ladies' committee. The object of the conference was to reach agreement both on proposals made by the Board for the future management of the hospital and on the action to be taken with respect to certain former members of the staff. I am not in a position to inform the House of the results of the conference, but I think hon. Members will learn with satisfaction that it has been held, and will regard the Board's action in seeking it as evidence of their desire to promote the harmonious and successful working of the hospital.

Accidents in Coal Industry.

Mr. BATLEY asked the Secretary for Mines the number of miners employed and the number of fatal and non-fatal accidents in the coal industry for the years 1924, 1925, 1927, and 1928, respectively.—Commodore DOUGLAS KING replied: The figures are as follows:—

Year.	Mines under the Coal Mines Act, 1911.		
	Number of persons employed.	Number of persons killed.	Number of persons disabled for more than three days.
1924 ..	1,230,248	1201	195,423
1925 ..	1,117,828	1136	178,060
1927 ..	1,037,391	1128	173,449
1928 ..	951,632	989	161,790

Cost of Vaccination.

Mr. BROAD asked the Minister of Health what was the total cost of vaccination from the rates and taxes in England and Wales for the years 1923 to 1928; and the number of persons vaccinated and revaccinated at the cost of the rates during those years.—Mr. CHAMBERLAIN replied: The particulars required, so far as they are at present available, are given in the following table:—

Year ended Sept. 30th.	Successful Primary vaccinations.	Successful revaccinations.	Total.	Year ended March 31st.	Expenditure of Guardians.	Grants from Exchequer contribution accounts.	Total
					£	£	£
1923	415,549	316,641	732,190	1923	181,172	10,244	191,416
1924	331,522	89,600	421,122	1924	223,924	11,753	235,677
1925	270,755	40,939	311,694	1925	179,027	3,050	182,077
1926	279,721	54,221	333,942	1926	161,889	4,366	166,255
1927	305,005	113,117	418,122	1927	170,728	8,338	179,066

It will be observed that the figures of expenditure and of vaccinations, respectively, refer to different periods and cannot, therefore, be strictly related to one another.

Barking Hospital Sweepstake.

Mr. DAY asked the Home Secretary whether it was on his instructions that the Derby sweepstake organised in aid of the Barking Hospital Fund had been stopped by the police.—Sir W. JOYNSON-HICKS replied: It having been brought to my notice that the hospital committee had announced to all donors of 3*d.* a grand Derby draw, were sending out tickets for sale, and offering a consolation prize to the seller of most tickets, I had the promoters and the printers of the tickets warned that to proceed in this way was a breach of the law, and I was informed on April 22nd that the scheme had been abandoned.

British Hospitals Association and Radium.

Mr. BLINDELL asked the Minister of Health what response he was sending to the resolution passed at the annual meeting of the British Hospitals Association recently held in London offering the advisory services of the Association to the Ministry and the Radium Subcommittee as to the best and most convenient centres for radium treatment.—Mr. CHAMBERLAIN replied: This resolution has not yet been formally submitted to me, but I propose to bring its terms to the notice of the bodies through whom the new supply of radium will be administered as soon as they are set up.

Mental Deficiency Report.

Mr. ROBERT MORRISON asked the Minister of Health whether he had now decided to publish the adult section of the Mental Deficiency Report; and when it would be available.—Mr. CHAMBERLAIN replied: The answer is in the affirmative and the report will be published as soon as possible.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on May 11th the following degrees were conferred:—

M.B. and B.Chir.—J. L. Franklin.
B.Chir.—*A. B. Connell and C. A. Francis.
* By proxy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary comitia of the College was held on April 9th, with Sir John Rose Bradford, the President, in the chair.

Dr. Robert Stevenson Aitken, of New Zealand, was admitted to the membership, and the following, who were elected to the Fellowship on April 25th (see THE LANCET, May 4th, p. 957), were admitted to the Fellowship:—Dr. R. W. Marsden, Dr. Rupert Waterhouse, Dr. A. Gurney Yates, Dr. K. D. Wilkinson, Dr. T. L. Hardy, Dr. Geoffrey Bourne, Dr. A. C. Roxburgh, Dr. B. T. Parsons-Smith, Prof. A. W. M. Ellis, Dr. Harold Gardiner-Hill, Dr. J. H. Sheldon, Dr. J. M. H. Campbell, Prof. J. H. Dible, Dr. D. H. Paterson, Dr. Crighton Bramwell, Dr. A. F. Tredgold, Dr. Hugh Gainsborough, Dr. A. H. Douthwaite, Dr. Donald Hunter, Prof. H. M. Turnbull, and Prof. Lovatt Evans, F.R.S.

The President presented the report of the committee appointed to consider the desirability of instituting a diploma in obstetrics and gynæcology. The resolution unanimously passed by the committee was as follows:—

> "The committee is of opinion that the institution of a diploma in Obstetrics and Gynæcology, jointly with the Royal College of Surgeons, is desirable, and that it should be referred to the Committee of Management to consider the best method of meeting the broad practical needs of this department of medical science by means of such a diploma."

Dr. T. W. Eden proposed an amendment, seconded by Dr. Russell Andrews, that the question of instituting a diploma in obstetrics and gynæcology should be referred in the first place to a committee of the Obstetric Fellows of the College who should report recommendations to the President. This amendment was put to the vote and was defeated. The original resolution was then adopted.

The President announced that Dr. F. G. D. Drewitt had presented to the College an engraving of the Chelsea Physic Garden—a garden of which Dr. Drewitt had written a very charming history and which had many associations with the College.

The Treasurer proposed that a donation of 100 guineas should be made by the College to the National Radium Fund, and this was agreed to.

The President then dissolved the comitia.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At an ordinary meeting of the Council, held on May 9th, with Lord Moynihan, the President, in the chair, Sir George Makins was introduced, and the President presented him with the honorary gold medal of the College, together with a document declaratory of its award, in appreciation of his valuable services to the College, more especially in arranging and describing the series of drawings in the Army Medical War Collection. Prof. W. Blair Bell was also introduced, and, after signing the by-laws and making the required declaration, was admitted a Fellow of the College.

Prof. Charles A. Pannett was elected a member of the Court of Examiners for a period of five years.

The following, nominated by the Canadian Medical Association, were appointed to act as assessors to the examiners at the primary examination for the Fellowship to be held at Toronto on August 6th, 7th, and 9th, for which there are 30 candidates: Prof. J. P. McMurrich and Prof. C. H. Best. Sir Holburt Waring was appointed to go to Toronto in August as visitor to the Primary Fellowship Examination.

An offer by Mr. W. W. Ouless, R.A., to present to the College his portrait of Sir Arthur Keith was accepted with appreciative thanks.

Diplomas of Member were conferred upon 151 candidates (136 men and 15 women) who have passed the requisite examinations and have complied with the by-laws of the College. The names of these candidates are identical with those published in our issues of May 4th and 11th, with the exception that W. F. Skaife received his Membership in April. J. H. Boultbee, Liverpool University, received the diploma of Member, but will not receive the diploma of L.R.C.P. until a later date.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual general meeting of the Fever Hospital Medical Service Group of this society will be held at the society's house, 1, Upper Montague-street, London, W.C., on Friday, May 24th, at 3 P.M. After the election of officers Dr. W. Mair MacFarlane will open a discussion on the Uses of Scarlet Fever Antitoxin.

MEDICAL CONGRESS AT BRUSSELS.—The ninth session of the Journées Médicales de Bruxelles will be held from June 22nd–26th under the presidency of Prof. Henry Coppez. A feature of especial interest in the programme will be a visit to the new Faculty of Medicine at Brussels, which is described as the most complete and best-equipped in Europe. Particulars of the Congress may be had from the secretary-general, Dr. R. Beckers, 62, rue Froissart.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—A quarterly meeting of the College was held on May 7th, when Dr. R. A. Fleming, the President, was in the chair.

Dr. Ella Ferrier Pringle and Dr. John Miller Woodburn Morison were introduced and took their seats as Fellows.

Dr. Frederick William Woolrabe, Lieut.-Colonel John Philip Cameron, I.M.S., Dr. Helen May Russell, Major Ambuj Nath Bose, I.M.S., Dr. Andrew Rae Gilchrist, Dr. Matthew Burn, and Dr. David Rutherford Dow were elected to the Fellowship.

The Parkin prize was awarded to Dr. Harold Whitridge Davies. The Freeland Barbour Fellowship was awarded to Dr. John Smith Fraser.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Tuesday, May 21st, at 8.30 P.M., Dr. L. S. T. Burrell will give the fifth lecture arranged for the M.R.C.P. course, at 11, Chandos-street, Cavendish-square, W. He will speak on Modern Methods of Diagnosis and Treatment in Pulmonary Tuberculosis. The sixth lecture of the same course, on Tests of Hepatic and Pancreatic Functions, will be delivered by Dr. H. E. Archer on Friday, May 24th, at the same place and hour. Copies of the full syllabus, and tickets of admission may be had from the Secretary of the Fellowship, at 1, Wimpole-street, London, W. 1, together with particulars of other courses and lectures which have been arranged.

UNIVERSITY OF LONDON MEDICAL GRADUATES SOCIETY.—The annual meeting and May dinner of the society was held at the Langham Hotel on May 7th, this President, Sir StClair Thomson, being in the chair. Medical graduates of the University, he pointed out, numbered over 4000, and there was still scope for an increase in membership. The society, having been formed at the right time, before the actual construction of the University centre had begun, was ready to play its part in the development of the corporate spirit of the University. Sir Charlton Briscoe's proposal to re-elect the president for a second year of office was carried unanimously. On the proposal of Dr. Herbert Tilley, the three vice-presidents, Sir John Rose Bradford, Lord Moynihan, and Dame Mary Scharlieb, were also re-elected. Six new members of council were elected—viz., Dr. Rhoda Adamson (Leeds), Mr. Harry Platt (Manchester), Dr. Louisa Hamilton, Mr. Victor Bonney, Dr. A. M. H. Gray, and Sir Thomas Horder—completing the number of 18 for which the constitution of the society provides.

MEDICAL WOMEN'S FEDERATION.—The annual meeting was held on May 2nd at the Holborn Restaurant, London. The annual report showed a steady increase in the membership. The hon. treasurer stated that the loan funds had proved of great assistance to young practitioners.

The Council held its half-yearly meeting on May 3rd at the London School of Medicine for Women. Dr. Catherine Chisholm was elected president for a second year: Dr. A. E. Sanderson Clow, Dr. Alison Hunter, and Miss L. Martindale, vice-presidents; Dr. Jane Walker, hon. treasurer; and Miss Mabel Ramsay, hon. secretary. Amongst matters discussed was the report of the London University Committee on Co-education of Medical Students. Stress was laid on the fact that there are women medical students in Great Britain and the British Empire who need a school in London where they may receive their medical education on co-educational lines. The report of the Special Committee which gave evidence before the Government Departmental Committee on the Working of the Midwives Acts was adopted. The executive committee was instructed to prepare a list of names of medical women who are doing National Health Insurance work, so that at the next council a standing committee might be appointed and the interests of women panel practitioners better correlated. A vigorous protest was made by council members at the insertion in the *British Medical Journal* of an advertisement for an assistant (medical woman), who was asked to do light household duties in combination with professional work. A discussion took place in regard to the treatment by medical women of cases of venereal disease in hospitals and clinics, and a resolution was adopted urging that the medical officers treating female venereal disease cases, whether in hospital or clinics, should be women medical practitioners where and whenever such practitioners are available.

In the evening a dinner was given by members of the council, past and present, to Lady Berry, hon. secretary of the Federation for ten years, on her retirement.

not only well educated, but also physically well equipped. Attention should also be paid to systematic and daily exercises for the children at school. They could honestly congratulate Major Elliot on the interest which he had taken in the experiment with regard to milk and, probably, for its initiation. It was also a tribute to the usefulness of the Empire Marketing Board. The uniting of the two experiments, one in Scotland and the other as far off as East Africa, was not only of great scientific interest but of great practical importance. The good work which Prof. Leighton had done and the interest he had taken in this subject for many years, in encouraging the milk producers of Scotland to supply pure and cleaner milk ought to be recognised. The present nomenclature of graded milk was misleading. People thought that Grade A milk was the best quality, whereas the Certified milk was the best. He would like information as to the quality of the non-graded milk. Did the Department take steps to obtain any samples of milk, and to subject them to bacteriological examinations? It should be made a serious crime to sell tuberculous milk.

Health Insurance.

It might be said that the national health insurance scheme in Scotland was now well organised and working well. The report called attention to the fact that the action taken under the Economy Act by reducing the State grant had gravely prejudiced the possibility of extension of the dental and ophthalmic services. It was the duty of the Government to make the national health insurance system really comprehensive and to enable the contributors to it to have at their command every medical and surgical aid. At present they were thrown back on the voluntary hospitals, which were overcrowded and had not enough beds. He echoed the hope expressed by Major Elliot in regard to the new hospital services under the Local Government Bill. That section of the Bill would provide a possible development of municipal service to supplement the voluntary service, and would make it possible for the ordinary citizen to obtain the specialist advice which was absolutely essential. Medicine had become so vast in so many directions that the ordinary practitioner could not be expected—and did not pretend—to be an authority on all its branches. It was only by the hospital services, or by specialist aid, that that could be overcome. The Labour Party were sympathetic in regard to research. There was, for example, the question of influenza. Present knowledge of that disease was very limited. Research was badly needed. Measles and whooping cough, which were not very seriously regarded by the public, were actually two of the most serious diseases, but they were not making a great deal of progress in regard to them. The entire sum which this wealthy country spent on research of all kinds was only about £20,000, and it would be a tremendous thing if, by research work, even a few hundred lives could be saved in Scotland each year. He wished to emphasise the importance of proper dental treatment for children. Most local authorities in Scotland had made such provision, but two of them—Argyllshire and Bute—had no provision at all. He was very glad to hear Major Elliot's reference to the Highlands and Islands Fund. He (Dr. Shiels) had had an opportunity of seeing its work in Shetland and Orkney, and there was no question about its tremendous value and necessity. The Department of Health should put some pressure on local authorities in the North of Scotland who had failed to provide maternity and child welfare services.

Reply to the Debate.

Major **Elliot**, replying to the debate, said that the Health Department were taking active steps to deal with maternal and infant mortality. Their expenditure in the current year was 50 per cent. greater than the expenditure for which the Labour Government was responsible. With regard to the milk tests, it was a question of quality, not of quantity. Last year 2249 cattle affected by tuberculosis were slaughtered and the process of cleaning up the cattle was continually going on, and was bound to result in an improvement in public health. There was no increase in the number of school-children suffering from malnutrition compared with last year.

The vote was agreed to.

THURSDAY, MAY 9TH.

The London Lock Hospital.

Mr. **Pethick-Lawrence** asked the Minister of Health whether he had now any information to give the House as to the reforms proposed at the London Lock Hospital.

Captain T. J. O'Connor asked the Minister of Health whether, having regard to the damage already done to the careers of the three women dismissed from their posts at the London Lock Hospital, he would state whether the committee of inquiry had exonerated them.—Mr. **Chamberlain** replied: I am glad to be able to add to the statement which I made in the House on April 30th that a conference has, I understand, been held to-day between representatives of the governing body of the hospital and of the former ladies' committee. The object of the conference was to reach agreement both on proposals made by the Board for the future management of the hospital and on the action to be taken with respect to certain former members of the staff. I am not in a position to inform the House of the results of the conference, but I think hon. Members will learn with satisfaction that it has been held, and will regard the Board's action in seeking it as evidence of their desire to promote the harmonious and successful working of the hospital.

Accidents in Coal Industry.

Mr. **Batley** asked the Secretary for Mines the number of miners employed and the number of fatal and non-fatal accidents in the coal industry for the years 1924, 1925, 1927, and 1928, respectively.—Commodore **Douglas King** replied: The figures are as follows:—

Year.	Mines under the Coal Mines Act, 1911.		
	Number of persons employed.	Number of persons killed.	Number of persons disabled for more than three days.
1924 ..	1,230,248	1201	195,423
1925 ..	1,117,828	1136	178,060
1927 ..	1,037,391	1128	173,449
1928 ..	951,632	989	161,790

Cost of Vaccination.

Mr. **Broad** asked the Minister of Health what was the total cost of vaccination from the rates and taxes in England and Wales for the years 1923 to 1928; and the number of persons vaccinated and revaccinated at the cost of the rates during those years.—Mr. **Chamberlain** replied: The particulars required, so far as they are at present available, are given in the following table:—

Year ended Sept. 30th.	Successful Primary vaccinations.	Successful revaccinations.	Total.	Year ended March 31st.	Expenditure of Guardians.	Grants from Exchequer contribution accounts.	Total
					£	£	£
1923	415,549	316,641	732,190	1923	181,172	10,244	191,416
1924	331,522	89,600	421,122	1924	223,924	11,753	235,677
1925	270,755	40,939	311,694	1925	179,027	3,050	182,077
1926	279,721	54,221	333,942	1926	161,889	4,366	166,255
1927	305,005	113,117	418,122	1927	170,728	8,338	179,066

It will be observed that the figures of expenditure and of vaccinations, respectively, refer to different periods and cannot, therefore, be strictly related to one another.

Barking Hospital Sweepstake.

Mr. **Day** asked the Home Secretary whether it was on his instructions that the Derby sweepstake organised in aid of the Barking Hospital Fund had been stopped by the police.—Sir W. **Joynson-Hicks** replied: It having been brought to my notice that the hospital committee had announced to all donors of 3*d.* a grand Derby draw, were sending out tickets for sale, and offering a consolation prize to the seller of most tickets, I had the promoters and the printers of the tickets warned that to proceed in this way was a breach of the law, and I was informed on April 22nd that the scheme had been abandoned.

British Hospitals Association and Radium.

Mr. **Blindell** asked the Minister of Health what response he was sending to the resolution passed at the annual meeting of the British Hospitals Association recently held in London offering the advisory services of the Association to the Ministry and the Radium Subcommittee as to the best and most convenient centres for radium treatment.—Mr. **Chamberlain** replied: This resolution has not yet been formally submitted to me, but I propose to bring its terms to the notice of the bodies through whom the new supply of radium will be administered as soon as they are set up.

Mental Deficiency Report.

Mr. **Robert Morrison** asked the Minister of Health whether he had now decided to publish the adult section of the Mental Deficiency Report; and when it would be available.—Mr. **Chamberlain** replied: The answer is in the affirmative and the report will be published as soon as possible.

Medical News.

University of Cambridge.—At a congregation on May 11th the following degrees were conferred:—

M.B. and B.Chir.—J. L. Franklin.
B.Chir.—*A. B. Connell and C. A. Francis.

* By proxy.

Royal College of Physicians of London.—An extraordinary comitia of the College was held on April 9th, with Sir John Rose Bradford, the President, in the chair.

Dr. Robert Stevenson Aitken, of New Zealand, was admitted to the membership, and the following, who were elected to the Fellowship on April 25th (see The Lancet, May 4th, p. 957), were admitted to the Fellowship:—Dr. R. W. Marsden, Dr. Rupert Waterhouse, Dr. A. Gurney Yates, Dr. K. D. Wilkinson, Dr. T. L. Hardy, Dr. Geoffrey Bourne, Dr. A. C. Roxburgh, Dr. B. T. Parsons-Smith, Prof. A. W. M. Ellis, Dr. Harold Gardiner-Hill, Dr. J. H. Sheldon, Dr. J. M. H. Campbell, Prof. J. H. Dible, Dr. D. H. Paterson, Dr. Crighton Bramwell, Dr. A. F. Tredgold, Dr. Hugh Gainsborough, Dr. A. H. Douthwaite, Dr. Donald Hunter, Prof. H. M. Turnbull, and Prof. Lovatt Evans, F.R.S.

The President presented the report of the committee appointed to consider the desirability of instituting a diploma in obstetrics and gynæcology. The resolution unanimously passed by the committee was as follows:—

> "The committee is of opinion that the institution of a diploma n Obstetrics and Gynæcology, jointly with the Royal College of Surgeons, is desirable, and that it should be referred to the Committee of Management to consider the best method of meeting the broad practical needs of this department of medical science by means of such a diploma."

Dr. T. W. Eden proposed an amendment, seconded by Dr. Russell Andrews, that the question of instituting a diploma in obstetrics and gynæcology should be referred in the first place to a committee of the Obstetric Fellows of the College who should report recommendations to the President. This amendment was put to the vote and was defeated. The original resolution was then adopted.

The President announced that Dr. F. G. D. Drewitt had presented to the College an engraving of the Chelsea Physic Garden—a garden of which Dr. Drewitt had written a very charming history and which had many associations with the College.

The Treasurer proposed that a donation of 100 guineas should be made by the College to the National Radium Fund, and this was agreed to.

The President then dissolved the comitia.

Royal College of Surgeons of England.—At an ordinary meeting of the Council, held on May 9th, with Lord Moynihan, the President, in the chair, Sir George Makins was introduced, and the President presented him with the honorary gold medal of the College, together with a document declaratory of its award, in appreciation of his valuable services to the College, more especially in arranging and describing the series of drawings in the Army Medical War Collection. Prof. W. Blair Bell was also introduced, and, after signing the by-laws and making the required declaration, was admitted a Fellow of the College.

Prof. Charles A. Pannett was elected a member of the Court of Examiners for a period of five years.

The following, nominated by the Canadian Medical Association, were appointed to act as assessors to the examiners at the primary examination for the Fellowship to be held at Toronto on August 6th, 7th, and 9th, for which there are 30 candidates: Prof. J. P. McMurrich and Prof. C. H. Best. Sir Holburt Waring was appointed to go to Toronto in August as visitor to the Primary Fellowship Examination.

An offer by Mr. W. W. Ouless, R.A., to present to the College his portrait of Sir Arthur Keith was accepted with appreciative thanks.

Diplomas of Member were conferred upon 151 candidates (136 men and 15 women) who have passed the requisite examinations and have complied with the by-laws of the College. The names of these candidates are identical with those published in our issues of May 4th and 11th, with the exception that W. F. Skaife received his Membership in April. J. H. Boultbee, Liverpool University, received the diploma of Member, but will not receive the diploma of L.R.C.P. until a later date.

Society of Medical Officers of Health.—The annual general meeting of the Fever Hospital Medical Service Group of this society will be held at the society's house, 1, Upper Montague-street, London, W.C., on Friday, May 24th, at 3 P.M. After the election of officers Dr. W. Mair MacFarlane will open a discussion on the Uses of Scarlet Fever Antitoxin.

Medical Congress at Brussels.—The ninth session of the Journées Médicales de Bruxelles will be held from June 22nd-26th under the presidency of Prof. Henry Coppez. A feature of especial interest in the programme will be a visit to the new Faculty of Medicine at Brussels, which is described as the most complete and best-equipped in Europe. Particulars of the Congress may be had from the secretary-general, Dr. R. Beckers, 62, rue Froissart.

Royal College of Physicians of Edinburgh.—A quarterly meeting of the College was held on May 7th, when Dr. R. A. Fleming, the President, was in the chair.

Dr. Ella Ferrier Pringle and Dr. John Miller Woodburn Morison were introduced and took their seats as Fellows.

Dr. Frederick William Woolrabe, Lieut.-Colonel John Philip Cameron, I.M.S., Dr. Helen May Russell, Major Ambuj Nath Bose, I.M.S., Dr. Andrew Rae Gilchrist, Dr. Matthew Burn, and Dr. David Rutherford Dow were elected to the Fellowship.

The Parkin prize was awarded to Dr. Harold Whitridge Davies. The Freeland Barbour Fellowship was awarded to Dr. John Smith Fraser.

Fellowship of Medicine and Post-Graduate Medical Association.—On Tuesday, May 21st, at 8.30 P.M., Dr. L. S. T. Burrell will give the fifth lecture arranged for the M.R.C.P. course, at 11, Chandos-street, Cavendish-square, W. He will speak on Modern Methods of Diagnosis and Treatment in Pulmonary Tuberculosis. The sixth lecture of the same course, on Tests of Hepatic and Pancreatic Functions, will be delivered by Dr. H. E. Archer on Friday, May 24th, at the same place and hour. Copies of the full syllabus, and tickets of admission may be had from the Secretary of the Fellowship, at 1, Wimpole-street, London, W. 1, together with particulars of other courses and lectures which have been arranged.

University of London Medical Graduates Society.—The annual meeting and May dinner of the society was held at the Langham Hotel on May 7th, the President, Sir StClair Thomson, being in the chair. Medical graduates of the University, he pointed out, numbered over 4000, and there was still scope for an increase in membership. The society, having been formed at the right time, before the actual construction of the University centre had begun, was ready to play its part in the development of the corporate spirit of the University. Sir Charlton Briscoe's proposal to re-elect the president for a second year of office was carried unanimously. On the proposal of Dr. Herbert Tilley, the three vice-presidents, Sir John Rose Bradford, Lord Moynihan, and Dame Mary Scharlieb, were also re-elected. Six new members of council, were elected—viz., Dr. Rhoda Adamson (Leeds), Mr. Harry Platt (Manchester), Dr. Louisa Hamilton, Mr. Victor Bonney, Dr. A. M. H. Gray, and Sir Thomas Horder—completing the number of 18 for which the constitution of the society provides.

Medical Women's Federation.—The annual meeting was held on May 2nd at the Holborn Restaurant, London. The annual report showed a steady increase in the membership. The hon. treasurer stated that the loan funds had proved of great assistance to young practitioners.

The Council held its half-yearly meeting on May 3rd at the London School of Medicine for Women. Dr. Catherine Chisholm was elected president for a second year; Dr. A. E. Sanderson Clow, Dr. Alison Hunter, and Miss L. Martindale, vice-presidents; Dr. Jane Walker, hon. treasurer; and Miss Mabel Ramsay, hon. secretary. Amongst matters discussed was the report of the London University Committee on Co-education of Medical Students. Stress was laid on the fact that there are women medical students in Great Britain and the British Empire who need a school in London where they may receive their medical education on co-educational lines. The report of the Special Committee which gave evidence before the Government Departmental Committee on the Working of the Midwives Acts was adopted. The executive committee was instructed to prepare a list of names of medical women who are doing National Health Insurance work, so that at the next council a standing committee might be appointed and the interests of women panel practitioners better correlated. A vigorous protest was made by council members at the insertion in the *British Medical Journal* of an advertisement for an assistant (medical woman), who was asked to do light household duties in combination with professional work. A discussion took place in regard to the treatment by medical women of cases of venereal disease in hospitals and clinics, and a resolution was adopted urging that the medical officers treating female venereal disease cases, whether in hospital or clinics, should be women medical practitioners where and whenever such practitioners are available.

In the evening a dinner was given by members of council, past and present, to Lady Berry, hon. of the Federation for ten years, on her retirement.

London Rheumatism Clinic.—The following appointments have been made to the honorary visiting medical staff of the Clinic for the Treatment of Rheumatic Diseases, shortly to be opened in London under the auspices of the British Red Cross Society:—M. B. Ray, D.S.O., M.D., late honorary surgeon to the Harrogate Infirmary; F. D. Howitt, M.R.C.P., physician in charge of the physiotherapy and massage departments of the Prince of Wales General Hospital; C. B. Heald, C.B.E., M.R.C.P., physician in charge of the electrotherapeutic department of the Royal Free Hospital; B. S. Nissé, M.R.C.P., clinical assistant at the National Hospital for Diseases of the Heart; and W. S. C. Copeman, M.R.C.P., medical registrar at St. Mary's Hospital.

Chelsea Clinical Society.—The next meeting of this society on Friday, May 24th, is taking the form of a demonstration, organised by Messrs. Kodak, Ltd., illustrating the value of the kinema in relation to modern medicine and surgery by means of films of medical interest. Non-members (male practitioners only) are invited to this demonstration. Members of the society dine together at the Rembrandt Hotel at 7.30 P.M., before the demonstration. Application to one or other of the hon. secretaries, Mr. A. Rugg-Gunn, 49, Harley-street, W. 1, and Mr. L. A. Harwood, 90, Sloane-street, S.W. 1.

Post-graduate Work in Glasgow.—We have received a syllabus from the Glasgow Post-Graduate Medical Association (secretary, Dr. James Carslaw, 9, Woodside-terrace, C. 3) setting out the facilities for post-graduate instruction available in the summer session from June to October. These comprise a general medical course during the last fortnight of August and the first fortnight of September, and the granting of a limited number of clinical assistantships. Full particulars are to be found in the syllabus.

Medical Golfing Society.—The Spring Knock-out Tournament of this society was won by Sir Kenneth Goadby, the runner-up being Mr. O. N. Plummer. The other semi-finalists were Dr. A. Hope Gosse and Mr. Ulysses Williams. The summer meeting of the society will be held on June 20th at Walton Heath, and the Canny Ryall challenge cup for mixed foursomes (with the Ladies Medical Golfing Society) will be played for at Northwood on June 27th.

Commonwealth Fund Fellowship.—This Fund has awarded 24 Fellowships, tenable by British graduates in American Universities for two years, beginning next September. Among the recipients is Mr. E. T. C. Spooner, M.B., of Clare College, Cambridge, who will proceed to Harvard University.

Pharmaceutical Society of Great Britain.—This society announces that the Hanbury medal "for high excellence in the prosecution or promotion of original research in the natural history and chemistry of drugs" has been awarded to Dr. Henry Hurd Rusby, professor of materia medica at Columbia University, New York.

General Lying-in Hospital.—The Sixteenth Annual Post-graduate Week for Midwives will be given at this hospital in York-road, Lambeth, from May 27th–31st.

Invalid Children's Aid Association.—It is hoped that a total of £5000 will be received by this association as a result of the recent loan exhibition at Lansdowne House.

The Prime Minister of the Commonwealth of Australia has asked the Minister of Health to liberate Dame Janet Campbell, the Senior Medical Officer for Maternity and Child Welfare at the Ministry of Health, to proceed to Australia in order to advise the Government on the organisation and development of maternity and child welfare services for the benefit of the several States of the Commonwealth. In view of the special importance of these services in the interests of the Empire as a whole, the Minister has acceded to the request and has agreed to set Dame Janet Campbell free from her official duties in this country for a limited time. She will probably leave England towards the end of July.

Tavistock Clinic for Functional Nervous Disorders.—At the annual meeting of this clinic on May 8th Sir Frederick Willis, who took the chair, spoke of the need for early treatment of mental illness; and Dr. Crichton-Miller, the honorary director, said that there were about 700 patients on the active roll, and that for the fourth time in 18 months the waiting list had had to be closed. He foreshadowed enlargement of the premises if facilities for teaching and research were to be provided, and the hon. treasurer, Mr. D. O. Malcolm, spoke of an extension scheme to cost £10,000. He reported a deficit of £600 on the work of the year.

Messrs. A. Wander, Ltd., have given £10,000 to the Thankoffering Fund for the King's recovery. One-half of this donation is to be applied to the establishment of a scholarship at Westminster Hospital for research into children's diseases.

Dr. Wilhelm Roehl, head of the chemotherapeutic department of the I.G. Farbenindustrie, whose name is closely linked with germanin (Bayer 205) and plasmochin, has died of a septic infection.

Lebanon Hospital for Mental Diseases.—The thirteenth annual meeting of this hospital, which is established near Beyrout, in Syria, will be held at Friends House, Euston-road (opposite Euston Station), London, at 5 P.M., on Tuesday, May 21st. (Tea 4.30 P.M.) Dr. R. Fortescue Fox, late chairman of the General Committee, will preside, and brief accounts of the work at the hospital, illustrated by lantern slides, will be given by speakers who have lately returned from Syria. The secretary's address is 139, Marylebone-road, London, N.W. 1.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

(The Society's House and Library will be closed on Saturday, May 18th, and Monday, May 20th.)

Wednesday, May 22nd.—5 P.M., Comparative Medicine. Election of Officers and Council. Paper: Prof. F. T. G. Hobday: Surgery of the Thorax and Abdomen of Animals. A discussion will follow in which the following have been invited to take part: Mr. Leslie P. Pugh, Mr. F. Chambers, Prof. G. H. Wooldridge, Prof. J. McCunn, Mr. G. Brooke, and Prof. J. G. Wright. Surgery: Members of this Section are specially invited to attend.

Thursday.—8.30 P.M., Urology. Election of Officers and Council. Pathological Evening.

Friday.—4.30 P.M., Disease in Children. (Cases at 4.30 P.M.) Election of Officers and Council. Presidential Address: Dr. F. John Poynton: Some Phases in English Pediatrics as Viewed by a General Physician. Cases will be shown. 8 P.M., Epidemiology. Election of Officers and Council. Paper: Dr. A. Joe: Puerperal Fever. Obstetrics and Gynæcology. Members of this Section are specially invited to attend.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

Wednesday, May 22nd.—2.30 P.M. (at University College, Gower-street), Quarterly General Meeting. 3.30 P.M., Prof. Charles Spearman: Psychiatric Use of the Methods and Results of Experimental Psychology. (Maudsley Lecture).

MEDICO-LEGAL SOCIETY.

Thursday, May 23rd.—8.30 P.M. (at 11, Chandos-street, W.) Discussion on Acute Arsenical Poisoning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 20th, to Saturday, May 25th.—Medical Society Lecture Room, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Course of Instruction. Lectures on Tuesdays and Fridays at 8.30 P.M. Tues., Dr. L. S. T. Burrell: Modern Methods of Diagnosis and Treatment in Pulmonary Tuberculosis. (This lecture originally dated June 11th is exchanged with Dr. Myers's lecture originally dated May 21st.) Fri., Dr. H. E. Archer: Tests of Hepatic and Pancreatic Functions.—Queen's Hospital for Children, Hackney-road, Bethnal Green. Tues., at 3 P.M., clinical demonstration by Dr. Alice King (Chronic Lung Cases). Free.—St. Peter's Hospital, Henrietta-street, W.C. Wed., at 2 P.M., genito-urinary operation demonstration by Mr. Swift Joly. Free.—Royal Free Hospital, Gray's Inn-road, W.C. Fri., at 5 P.M., lecture-demonstration by Prof. Dame Louise McIlroy. This course consists of a series of lecture-demonstrations continuing until June 7th.—London Lock Hospital, Dean-street, W. Special course of instruction continuing until June 1st.—St. John's Hospital, Leicester-square, W.C. Clinical instruction every afternoon and evening with special lectures on Thurs. and Fri. Proportionate fees for last two weeks.—Maudsley Hospital, Denmark Hill, S.E. Course in psychological medicine. Last week.—Further particulars from the Fellowship of Medicine.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY, 49, Leicester-square, W.C.

Wednesday, May 22nd.—5.30 P.M., Dr. A. M. Memmesheimer (Tübingen): The Skin as an Organ of Protection and Immunity. (Annual Oration.) The annual dinner will be held immediately following the Oration at Kettner's Restaurant.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

TUESDAY, May 21st.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: *Clinical Demonstration.* 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

WEDNESDAY, May 22nd.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

TUESDAY, May 21st.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Adie: The Localisation of Cerebral Tumours (2)

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Blood Vessel Tumours of the Brain.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Neurosyphilis (1).

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

THURSDAY, May 23rd.—5 P.M., Prof. S. J. Cowell: Dietetics. (Fourth of six lectures.)

UNIVERSITY COLLEGE, Gower-street, London.

THURSDAY, May 23rd.—5 P.M., Mr. R. J. Lythgoe: Special Sense Physiology *(Fourth of six lectures.)*

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, May 23rd.—5 P.M., Dr. J. M. H. MacLeod: Leprosy.

FRIDAY.—5 P.M., Dr. Knowsley Sibley: Alopecia.

UNIVERSITY OF BIRMINGHAM.

THURSDAY, May 23rd.—4 P.M. (In the Medical Lecture Theatre, Edmund-street Buildings), Dr. H. Charles Cameron: Some Types of Septic Infection in the Newly-born. (First Ingleby Lecture.)

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, May 24th.—3.30 P.M., Dr. Barnes: Graves's Disease.

Appointments.

ALLOTT, H. C. W., L.A.H. Dub., L.R.C.S. Edin., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Wolston, Warwickshire.

TIBBITS, A. C., L.R.C.P. Lond., M.R.C.S., D.P.H., County Medical Officer for Nottinghamshire.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen City.—M.O.H. £1100.

Aberdeen Royal Hospital for Sick Children.—Hon. Asst. Surgeon.

Altrincham General Hospital.—H.S. At rate of £125.

Ashton-under-Lyne District Infirmary.—Hon. Asst. Radiologist.

Birmingham, City Babies Hospital.—Res. M.O. At rate of £150.

Birmingham, City Mental Hospital.—Jun. Asst. M.O. £350.

Birmingham, General Hospital.—Two Res. Surg. Regs. Each £100 to £140.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. At rate of £130.

Bolton Infirmary and Dispensary.—Res. Surg. O. £240. H.S. £150. Also Asst. H.S. £100.

Bradford Royal Infirmary.—H.S. £150.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120. Also H.S. £150.

Bootle Borough Hospital, Derby-road.—Two Jun. M.O.'s. Each at rate of £125.

Burnley, Victoria Hospital.—H.S. At rate of £125.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. At rate of £100.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Dudley, Guest Hospital and Eye Infirmary.—H.S. and Asst. H.S. £175 and £150 respectively.

Elizabeth Garrett Anderson Hospital, 144, Euston-road, N.W.—H.P., Obstetric Asst. and Three H.S.'s. Each at rate of £50.

Hertford County Hospital.—Hon. Surgeon.

Holborn and Finsbury Hospital, Archway-road, N.—Second Asst. M.O. £300.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100. Also Res. M.O. for Country Branch, Tadworth, Surrey. At rate of £250.

Hove Hospital, Sackville-road.—Res. M.O. £150.

Kensington, Fulham and Chelsea General Hospital, 194, Finborough-road, S.W.—Hon. Radiologist.

Leamington Spa, Warneford General Hospital.—Res. H.P. Also Res. H.S. Each £165.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Liverpool County Borough.—Jun. Asst. M.O. £600.

L.C.C. Mental Hospitals Service.—Eighth Asst. M.O. £300.

Lowestoft and North Suffolk Hospital.—H.S. £120.

Male Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Northern Hospital for Women, &c.—Sen. H.S. Also Jun. H.S. At rate of £130 and £100 respectively.

Manchester Victoria Memorial Jewish Hospital, Cheetham.—Hon. Phys.

Manor House Hospital, Golders Green, N.W.—Jun. H.S. At rate of £200.

Margate Royal Sea-Bathing Hospital.—H.S. At rate of £100. Also Asst. Med. Supt. £500.

Middlesex County Council.—Asst. Dental Officer. £500.

Middlesex Hospital, Middlesex School, W.—Second Demonstrator for Department of Physiology. £200.

Northampton General Hospital.—Hon. Anæsthetist.

Norwich, City of.—Asst. M.O., &c. £450.

Nottingham, General Hospital.—Res. Cas. O. At rate of £200.

Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. Physician to Dermatological Department.

Portsmouth Royal Hospital.—Sen. H.S. Also H.S. At rate of £175 and £130 respectively.

Queen's Hospital for Children, Hackney-road, E.—Cas. O. H.P. Also H.S. Each at rate of £100.

Royal Free Hospital, Gray's Inn-road, W.C.—Asst. M.O. for V.D. Clinic. £500. H.P.'s and H.S.'s. Also Obstetric District Asst. £100. Cas. O. £150.

Royal London Ophthalmic Hospital, City-road, E.C.—Out-patient Officer. £100.

St. Albans, Napsbury Mental Hospital.—Jun. Asst. M.O. £485.

St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C. Clinical Pathologist. £250.

Salford City Infectious Diseases Hospital.—Jun. Asst. Res. M.O. £200.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Additional Anæsthetist. £30.

Sheffield Royal Hospital.—Residents for temporary duty. At rate of £80.

Shrewsbury Eye, Ear and Throat Hospital.—H.S. £200.

South London Hospital for Women, South Side, Clapham Common, S.W.—Asst. Phys.

Stafford, Staffordshire General Hospital.—Hon. Surgeon.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £150. H.S. for Ophthalmic and Aural Departments. £150. Also Asst. H.P. £125.

Swansea Hospital.—H.S. £150.

Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.

Tunbridge Wells and Counties General Hospital.—H.S. £160.

Walsall General Hospital.—H.S. Also Jun. H.S. At rate of £125 and £100 respectively. Also Hon. Consultant Surgeon and Hon. Consultant Physician.

Wigan Infirmary.—Third H.S. At rate of £150.

Will Edmonds Clinical Research Fund.—Fellowship. £500.

Willesden General Hospital, N.W.—Registrars.

Windsor, King Edward VII Hospital.—Sen. and Jun. H.S.'s. At rate of £120 and £100 respectively.

Wolverhampton Poor-law Institution and Hospital.—Asst. Res. M.O. £250.

Workmen's Compensation Act.—Two Medical Practitioners, on Medical Board for Silicosis.

Zetland, County of.—School Medical Officer, &c. £700.

Births, Marriages, and Deaths.

BIRTHS.

ANDREWS.—On April 30th, at 41, Harley-street, W., to Helen and John Alban Andrews, M.C., F.R.C.S.,—a daughter.

BILLINGTON.—On May 9th, at Woodbridge, the wife of Dr. C. M. Billington, of a daughter.

CHILDS.—On May 6th, at Chalbury Lodge, Burnham-on-Sea, the wife of Dr. Reginald Childs, of a son.

DEATHS.

CHEATLE.—On May 11th, in London, Arthur Henry Cheatle, C.B.E., F.R.C.S., aged 62 years.

KEELE.—On May 9th, at Langford-place, St. John's Wood, Charles Ferdinand Keele, M.R.C.S. Eng., L.R.C.P., aged 88 years.

KENNY.—On May 11th, at The Avenue, Clifton, York, Major-General William Wallace Kenny, C.B., late A.M.S., aged 75 years.

SIDEBOTHAM.—On May 9th (Ascension Day), at his residence, Erlesdene, Bowdon, Cheshire, Edward John Sidebotham, M.A., M.B., aged 68 years.

THACKER.—On May 4th, at Nice, Cecil Robert Allen Thacker, M.A., M.D., late Fellow of Sidney Sussex College, Cambridge, aged 39 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices o Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

TREATMENT OF HÆMORRHOIDS BY INJECTION.

DR. V. J. BELLOT, Surgeon-Captain in the French Navy, reports at length in the *Archives de Médecine Navales* (1928, cxviii., 237) on the treatment of hæmorrhoids by injection, as he has practised it in the Naval Hospital at Cherbourg during the last five years. The solution he injects, drop by drop, into the pile contains 0·8 g. quinine hydrochloride and 0·4 g. urethane in 2 c.cm. of normal saline. He has done 150 cases without a failure and declares the method satisfactory alike to patients and surgeon, for it causes really no discomfort, the cure is complete, and in the most successful cases the piles are sclerosed without any more trouble.

His patients, being service people, were mostly treated in hospital. The operation, he says, should not be done when the piles are inflamed. Once that crisis has been got over and the diagnosis has been settled the patient is purged; next morning he gets an opium pill, and the operation area is shaved and sterilised with weak iodine. On the table, a cupping glass is chosen appropriate in size, and is exhausted and applied to bring down the internal piles and to swell up the external; this is the only part of the procedure that is at all painful. After further cleansing the surgeon takes in his right hand a 2 c.cm. glass syringe with its plunger graduated in minims and with a short (1 cm.) fine and very sharp needle. He then proceeds to puncture every hæmorrhoid, tag, or suspicious area, and injects single minims of the solution at each puncture, 1 cm. below the surface, the punctures being made at a distance of 1 cm. from each other, and the sphincter area being avoided. There is no need, Bellot says, to see blood in the syringe; hæmorrhage is unimportant; the drop is to be expressed steadily, but not as the needle is being withdrawn. A swab held in the left hand takes up excess solution to prevent irritation of the mucous membrane.

The area is dressed with ointment on gauze which wraps an india-rubber tube; this is left in position in the anus until the first stool, delayed by a daily opium pill, is allowed to pass, generally on the fourth day. From the moment of injection there is at once relief from pain and discomfort; the patient is no longer troubled by his anus; his injected hæmorrhoids sclerose, and often he is well enough to leave hospital on the fifth day. In more than half the cases a slough forms, as always happens, he says, after treatment by ligature or thermo-cautery. After injection, however, the slough separates easily and quickly, and the patient is probably well in three weeks, and this quite without discomfort, even in defæcation.

Cures of fissure by this method are mentioned, also of piles for an old man who could not have stood the usual operation, and two cases of prolapse were successfully dealt with. The number of patients applying to the hospital for treatment of hæmorrhoids is four times what it was before treatment by injection was introduced, and all so treated are said to have been satisfied, especially those who had experienced earlier methods. Bellot claims that he has had no failure, and those he has undertaken as ambulant cases—treated as he observes, with smaller doses—have recovered completely and without sloughing. He discusses the reports of Bensaude, Terrel, and others, and their alternative procedures, but concludes that his aim, to get men cured at a single operation and without discomfort, has been successfully attained. He therefore advises others to give this method a trial.

HAIR DYES AND THEIR APPLICATION.

THE ideal hair dye must be harmless, permanent, of a natural appearance, reproducing every possible shade, and must be unaffected by such procedures as those adopted for permanently waving the hair. So far as colour is concerned, the most satisfactory results are obtained from the coal tar dyes, but unfortunately they are all dangerous. The vegetable dyes are useful and harmless, but do not give a sufficient range, and are more difficult to apply.

An elaborate treatise[1] on the subject has recently been published. It contains a description of the hair dyes and bleaching agents, the technique which should be employed in connexion with each of them, and the risks attendant on their use. It is meant to be a practical guide to the hairdresser and the chemist, but cannot but be of interest to physicians, especially dermatologists, who are liable to be consulted, not only as to the advisability of dyeing the hair, but also with regard to the consequences. Beginning with a brief consideration of the structure and pigment of the hair, it goes on to discuss the important problems of hair-dyeing in relation to the structure of the hair itself. It is pointed out that, for the dye to be permanent, the reagents employed should be capable of passing between the overlapping scales of the cuticle into the hair cortex, and that an important factor in preventing this penetration is an excess of sebum. Consequently, before any dye is used, it is necessary that all grease and sebum should be removed by cleansers. Experience has shown that the easiest form of hair to dye is that which is straight rather than curly or wavy, and of normal texture rather than very fine or very coarse.

The dyes in common use are divided into metallic dyes, such as lead, silver, copper; vegetable dyes, such as walnut juice, henna, and indigo; and dyes of the coal tar series, which frequently contain paraphenylendiamine. Of these there is a considerable number, but none of them is quite satisfactory, and the ideal hair dye has yet to be discovered. This is especially true where a black or dark brown tint is desired. The problem of dyeing grey hair black still remains unsolved.

The technique of hair-dyeing is here described in detail. Various preliminary precautions of a practical nature are insisted upon, such as the thorough examination of the scalp to ascertain whether it is healthy and not affected by some form of dermatitis, which might be aggravated by the dye; and, where the paraphenylendiamine dyes are employed, the previous use of the Sabouraud-Rousseau test is advocated. This test consists of applying a small quantity of the dye to a patch of skin behind the ear, in order to ascertain the existence of any idiosyncrasy on the part of the individual skin to the dye. Should a severe reaction occur, the employment of such dyes is negatived.

AN APPEAL.

To the Editor of THE LANCET.

SIR,—I am interested in the case of a man who has lost his leg, but who by the use of an elaborate and expensive artificial limb has been able to obtain well-paid work. The limb is worn out but can be replaced through the kind offices of the Royal Surgical Aid Society by another one. But 140 letters are required to this end. Of these through the man's own exertions, 61 have been forthcoming, and 44 have been received through the Editor of THE LANCET. I am hoping, Sir, that you will let me publish this appeal for the residue and will allow me to indicate to those who are able to help that you will accept the letters on behalf of a case, the details of which you know.

I am, Sir, yours faithfully,
May 14th, 1929. Q.

*** The case is a thoroughly deserving one. It seems that the man must join the ranks of the unemployed unless he can obtain the limb promptly, and any R.S.A.S. letters sent here filled in with the name "H. Hankins" will be gratefully received.—ED. L.

DALRYMPLE HOUSE.

THIS valuable institution for the cure of inebriation and drug addiction has just issued its forty-fifth annual report. In 1928 it admitted 71 patients, five under the Inebriates Act and 66 private. All but four were cases of alcoholic excess. Of three suffering from delirium tremens, two recovered and one died. The remainder, except for two insane patients, one who died from diphtheria, and a fourth discharged to hospital with apoplexy, rapidly recovered and have remained in good health, an admirable result. Several patients have been readmitted, the cause being usually over-confidence and the hope that drink in moderation, or the avoidance of spirits, will do no harm. The superintendent, Dr. F. S. D. Hogg, repeats in his report the constant warning that the only hope of permanent cure for all but a negligible percentage lies in total abstinence. Of the four drug addicts two were cured, one left on private business and the other died of myeloid leukæmia. The average length of stay among private patients was seven weeks, excluding two patients who had elected to remain after their cure was complete. The report contains detailed statistics of patients discharged, and a number of views of the house and grounds; it testifies to the good work which this home is performing and the efficiency of its methods.

MEMORIAL TO A SURGEON.—A sum of 1000 guineas has been subscribed to found a bed in the children's ward of the new Northern Infirmary at Inverness in memory of the late Mr. James Luke, who was surgeon to the infirmary for 21 years.

An Address

ON

CANCER OF THE COLON.

Being the Annual Oration of the Medical Society of London, delivered on May 13th, 1929,

BY G. GREY TURNER, F.R.C.S. ENG.,
SURGEON TO THE ROYAL INFIRMARY, NEWCASTLE-UPON-TYNE;
PROFESSOR OF SURGERY IN THE UNIVERSITY OF DURHAM.

(*Concluded from page 1023.*)

THE ACTUAL MANAGEMENT OF CASES.

I hope I have already clearly shown that in my experience cases do best, and make the easiest recovery, in which there has been a preliminary drainage of the large bowel, usually by opening the cæcum. The advantages of this preliminary cæcostomy are that:—

1. It relieves obstruction, whether acute, partial, or potential.
2. It relieves the recurring distension of the colon by gas, which is so apt to occur in cases where the function of the great bowel has for some time been interfered with.
3. It allows the bowel to recover from the effect of obstruction of any degree, both as regards infection and muscle tone.
4. It permits the great bowel to empty, not necessarily entirely through the cæcostomy, but by relieving the disturbed function and by allowing relaxation of its wall.
5. It permits of irrigation of the bowel, either from the anus to the cæcostomy, or vice versa.
6. It relieves pain and enables the patient to get natural sleep and to assimilate nourishment.

Many surgeons, recognising the advantages of drainage, have sought to extend it to cases without obstruction by combining a safety-valve cæcostomy with the one-stage operation of excision. This is a plan which I also have carried out from time to time, but I do not consider it nearly so satisfactory as the preliminary drainage. If the opening into the cæcum is going to be reliable, its function as a by-pass ought to be established, and unless there is considerable tension in the bowel this cannot be expected to occur at once. I know that an opening made at the time of the resection has often sufficed, but I do want to urge that when there is the least doubt, it is much wiser to make it some days earlier.

Even in the presence of obstruction, a cæcostomy is not always efficient. I do not imagine that it will ever fail to relieve the immediate symptoms of obstruction, but quite often the bowel does not completely empty, and does not recover its normal size and tone. In these circumstances the surgeon may find an enlarged fæcal soiled, sodden, and infected intestine, even some two or three weeks after the cæcum has been opened. For these reasons a preliminary colostomy is sometimes more valuable.

If a cæcostomy functions satisfactorily and relieves the mechanical symptoms and, in spite of this, the patient does not pick up, a search must be made for the cause. Either there is unsuspected dissemination which may be suggested by a slight degree of jaundice, or there are fæcal ulcers in the bowel with localised peritonitis, or there is absorption from a sloughing growth, or from an abscess in association with the growth. All these conditions, except dissemination, are indications for a further operation rather than for waiting. This brings us to the consideration of the proper interval that should elapse between the cæcostomy and the next stage.

This depends upon the progress which is made. As long as the patient is really improving, then it seems prudent to wait. If progress hesitates after the mechanical obstruction is relieved by satisfactory drainage, then it does not seem wiser to delay for longer than two weeks because the stabilisation of the fistula will have occurred by that time, and want of recovery will be due to one of the other conditions which have been mentioned, and which are not likely to improve by further waiting.

During this period irrigation of the bowel can be carried out from the rectum and through the cæcostomy, although the former is likely to be the more successful. If this is not immediately successful, it should be repeated, and it is quite extraordinary how on one occasion fluid passed into the rectum will find its way through what subsequently proves to be a tiny channel in the growth, while on another occasion nothing can be made to traverse the intestinal canal. It does not appear that antiseptic irrigation is any more useful than irrigation by saline solution, which acts purely mechanically. It is important to give at least one dose of purgative medicine to make sure that the small bowel is thoroughly emptied, but repeated purgation in the presence of a patent cæcostomy seems to have no effect on the large bowel and is unnecessary.

The interval between the cæcostomy and the second operation should be used for endeavouring to locate the exact situation of the growth. Where this can be done it is possible that exposure to X rays or to radium emanation may be valuable, but these are methods which I have not employed, and they only occur to me as refinements which may become the established practice in the not very distant future.

A difficult class of case is the patient who arrives with a mild degree of obstruction. The symptoms are not very marked and the abdomen is not distended; in other words, there is nothing to determine that only a blind cæcostomy should be carried out. In these circumstances the best results will follow if the surgeon will open the abdomen and determine the situation and extent of the growth, with a view to its subsequent removal. Having made this investigation and determined that resection is likely to be feasible, he should do a preliminary cæcostomy or colostomy and remove the growth at a subsequent operation. If, on the other hand, the growth is clearly irremovable, or is on the borderline, then it may be wise to make a lateral anastomosis which will suffice to relieve the condition as far as possible. Sometimes I have made such an anastomosis with the intention that if the patient made an extremely good immediate recovery, then I would reopen the abdomen by direct incision over the growth, and endeavour to remove it. Such efforts have not infrequently been rewarded, and I want to refer you to a growth in the neighbourhood of the splenic flexure which, at such an operation, I found to be involving the upper jejunum, together with a portion of the stomach.

At the first operation a lateral anastomosis was made between the proximal colon and the sigmoid. During the fortnight that followed the patient made such unexpectedly good progress that I reopened the abdomen and excised the mass of growth, together with the loop of jejunum and a complete section of the stomach (Fig. 4). The patient is now, more than two years afterwards, in excellent health, having gained 2 st. in weight, and is able to follow his occupation regularly.

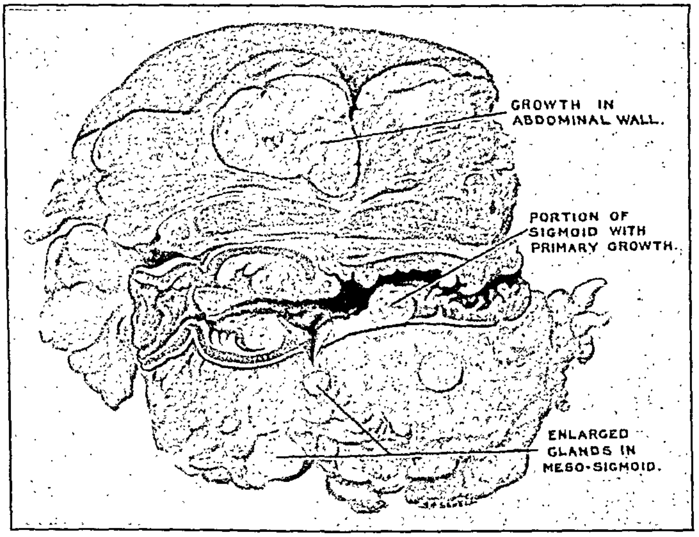
This seems a proper place to indicate the sort of preliminary investigation that must be made when the abdomen is opened. It includes first an examination of the liver for secondary deposits, and if these are absolutely definite, then I scarcely think that it is ever worth while to do more than a palliative anastomosis. At the same time I would not be easily deterred, for sometimes a simple mass in the liver may simulate a secondary deposit, and subsequent investigation, or the future history of the patient, has more than once shown that such a single mass has been an adenoma, an angioma, or an old inflammatory condition. I should much rather do what may prove to be an unnecessary resection than deny a single patient the great advantages of the removal of a malignant growth because of the fear that some indefinite lump in the liver may after all turn out to be a secondary deposit.

It is next important to examine carefully the neighbourhood of the growth for such extension as might render a radical operation unwise; especially the presence of secondary outlying nodules on the peritoneum—one of the worst of all types of dissemination.

The glands in the neighbourhood of the growth should then be carefully examined. Masses of glands close up to the growth need not be a deterrent, but a chain of glands extending far from the growth, though they need not prevent a resection being carried out, are certainly of evil omen. Sometimes a single mass of glands may be found at some distance from the growth. Under these circumstances the growth may safely be removed, and an anastomosis made, and the glands dealt with either then or subsequently by the insertion of radium. I see that my friend Mr. Clogg, confronted with such an eventuality, operated a second time and removed the glands, but this opportunity cannot often arise.

Cases in which the growth is adherent to the abdominal wall are sometimes unpromising, but such an invasion need not prevent successful removal, and I want to bring before your notice two patients in which this infiltration was of very great extent. Minor degrees of fixation to the muscles of the abdominal parietes are not infrequent, and can usually easily be dealt with, but in the patients that I have in mind the whole thickness of the abdominal wall was infiltrated, so that in both the growth made a very definite and obvious mass on the surface. In both I was able to excise the involved area of the abdominal wall, and to make a satisfactory excision of the adherent bowel. In the first case, Fig. 2, where a portion of small intestine had also to be removed, the patient is alive and free from recurrence now nine years after operation, and in the second, Figs. 5B and 6, the patient is extremely well, though more than four years have elapsed since the operation was carried out.

FIG. 6.



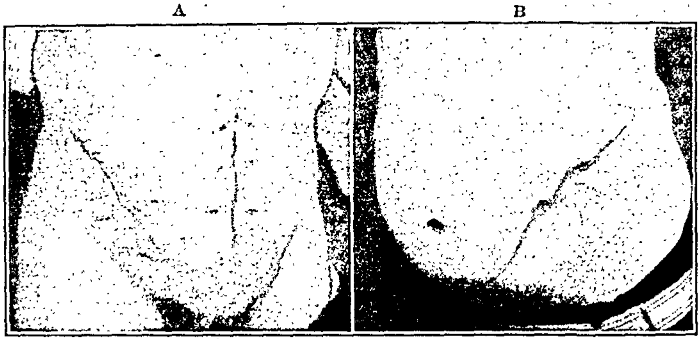
GROWTH IN ABDOMINAL WALL.
PORTION OF SIGMOID WITH PRIMARY GROWTH.
ENLARGED GLANDS IN MESO-SIGMOID.

The specimen referred to in Fig. 5B. (Case 14 in list of multiple resections.)

THE INCISION.

Having determined, by the preoperative examination, or by preliminary exploration, the situation of the growth, the selection of the optimum incision is a matter of great importance. Mobile growths in a mobile colon may be easily removed through a median or paramedian incision, but very adherent growths in the cæcal region, the hepatic or splenic flexure, or the descending colon or commencement of the sigmoid cannot be satisfactorily dealt with by this route. It is to meet these circumstances that I strongly advocate direct exposure over the situation of the growth, using the oblique or transverse muscle-cutting incisions of Rutherford Morison (Fig. 5).

FIG. 5.



To show the oblique muscle-cutting incisions employed for dealing with adherent growths. In A the growth was at the hepatic flexure. It could not be successfully mobilised from the median incision. Through the oblique incision the cæcum with an open cæcostomy and the growth were easily removed. In B the growth was in the sigmoid and had invaded a considerable area of the whole thickness of the abdominal wall. This was removed with the growth and an end-to-end union established. The specimen is shown in Fig. 6. The patient, a man of 64, is alive and well nearly five years afterwards.

If the surgeon first makes a median incision and finds that a growth favourable for removal because of the absence of dissemination is yet so fixed as to be inaccessible, he must not hesitate to make a second independent incision over the growth or he must make a cross-cut from his original one (Fig. 7A).

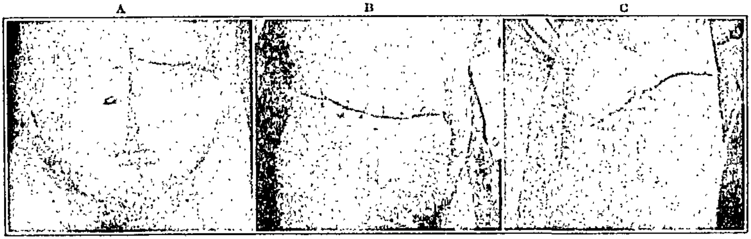
MOBILISATION.

Fixation of the growth, in the great majority of cases, is not due to malignant infiltration, but to an exaggeration of the fixation of those parts of the large bowel which has been so frequently described in the literature that has sprung up around the subject of intestinal stasis. The sort of adhesions which are responsible for the first and last kinks of Sir William Arbuthnot Lane may be congenital or they may be inflammatory, but in either case, in the presence of some localised lesion, like a bowel growth, they become much more definite and are sufficient to produce such a degree of fixation as to lead to the impression that such want of mobility is due to extension of the malignant growth. It is very rarely that the fixation to which I now refer cannot be dealt with by local interference, but unless the scissors can be freely used under the guidance of the eye it may be very baffling. It is for this reason that I consider that the operability of quite a proportion of the growths which we are now considering depends on the access which the parietal incision allows, and this is why I so strongly advocate an approach directly over the growth, rather than the traditional incision in the neighbourhood of the middle line.

The kind of fixation which is due to extension of the growth to neighbouring parts by contiguity, if it occurs on the mesenteric side, may well debar successful removal, but fortuitously it often arises away from the mesentery, and in these circumstances the extensions of the growth can often be successfully removed. I have many times cut away portions of the parietes, or an area of the peritoneum, transversalis fascia, or iliac fasciæ, or sometimes a complete section of the abdominal wall (Fig. 5B). As is shown in the list of cases of multiple excisions this sort of extension has sometimes meant the sacrifice of some part of the other viscera, and I have several times, for this reason, removed the appendages or the uterus in the female, a portion of the bladder; or a loop of small intestine; and twice a complete section of the stomach. Sometimes a slice of the stomach or duodenum, or a part of the margin of the liver has sufficed. Some of my patients who have been subjected to these extensive operations are alive and in good health several years after the operation (Fig. 8).

Separation of adhesions and the measures necessary for dealing with such extensions as I have described may mean that the mobilisation is itself a formidable matter, and I would urge the need of taking care to deal with the hæmorrhage that may occur, for I have certainly once lost a patient as the result of hæmorrhage, and possibly on other occasions such bleeding may have contributed to an unfortunate result.

FIG. 7.



A shows the incisions employed for the removal of an adherent growth of the splenic flexure. To enable mobilisation to be carried out the cross cut through the rectus had to be employed. The patient was operated upon by Paul's method and is alive and well ten years afterwards. B shows the incision used for the removal of an adherent growth of the ascending colon with many glands. The bowel from the lower ileum to the middle of the transverse colon was excised. C shows a similar incision employed for an adherent growth of the descending colon. An exploration was previously carried out through the median incision. Both B and C are recent cases.

CONDUCT OF THE RESECTION.

The actual operation of excision of a portion of the colon is seldom like the pictures one sees in works on surgery. I do not wish to say anything disparaging about the many beautiful and sometimes excellent illustrations that appear in text-books, but I do want to emphasise the very great difficulty of correctly depicting abdominal surgical procedures. I speak feelingly on this matter, because I have tried very hard to represent exactly and accurately what actually occurs, but it is extraordinarily difficult. In most books the clamps figure much too largely. I do not understand the necessity for crushing the ends of the bowel, and for my own part I am content to use clamps which merely temporarily occlude the bowel until the suturing of the ends is carefully carried out. Nor do I understand the wisdom of dividing the bowel with the cautery. No surgeon would elect to cut the bowel so near the growth as to make the use of the cautery necessary for the destruction of malignant tissue in the cut margin, but I do think that the cautery is valuable in these operations. Its usefulness is in the division of the mesentery in the neighbourhood of the lymphatics, or in those situations where the surgeon has not been able to get very far away from what is possibly an infected gland for the application of his ligatures. Under these circumstances the use of the cautery seems rational.

I have no confidence in those operations which have been proposed for the carrying out of so-called aseptic intestinal anastomosis. I have little fear of septic contamination from the contents of the bowel or its mucous surface, and I feel that if my cases have not done well it has not been because septic contamination has occurred at the time of operation. As a rule, if an anastomosis has failed there has been some fault connected with the blood-supply, or the patient has suffered from sepsis that has arisen from the sodden infected condition of the bowel and not from the exposed cut surface at the operation itself. I am at liberty to mention that Prof. John Fraser, of Edinburgh, who, with Mr. Norman Dott, was responsible for the introduction of an ingenious guillotine method of aseptic anastomosis, has himself largely given up the plan because he has found that, in the human subject at all events, it has not proved sufficiently successful.

The question often arises as to whether the anastomosis should be made by the end-to-end or the side-to-side method. This is a matter which may be safely left in the hands of the experienced surgeon, but others may welcome some guidance. Personally, I was brought up to rely on the lateral method, but I have been gradually converted to the end-to-end plan, and for the following reasons: the latter requires much less bowel, so that in a case in which it may be forseen that it will be difficult to get the ends together, more bowel can be sacrificed without jeopardising the success of the union than could be taken away if enough had to be left to make a satisfactory side-to-side anastomosis. There is much less suturing to carry out, and much less suturing to go wrong. There are no blind ends; blind ends which I have twice seen give way, and lead to a fæcal fistula, one of which required a secondary operation, and which I have no doubt on other occasions have leaked with more disastrous consequences. The end-to-end method is quicker, and this is of some moment, because it means that more time can be spent on the more important step of free mobilisation. Further, there is no temptation to scamp the suture line, and, lastly, the end-to-end union is certainly the more natural. But one freely admits that one method will not necessarily fulfil all the multitudinous indications that may arise. The surgeon should be conservative in his tastes but catholic in his methods, and should be prepared at all times to adopt any particular method that may fulfil a special indication.

This matter is often dismissed by saying that the operative measures are now sufficiently standardised. Since neither the human body nor pathological processes are standardised, I am fearful of "standardised operations." However much it may be desirable to follow some preconceived plan, the conditions found on opening the abdomen may quite preclude the possibility. In this connexion I would point out that in many of the successful cases in my series it was not possible to carry out the removal of such an amount of bowel or mesentery as would bring the operation within the accepted text-book descriptions. If the cases which I have related have convinced any of you that a lesser operation will sometimes suffice it will be some satisfaction to me.

In making the anastomosis the following are the principles which have guided me.

It must be possible to approximate the bowel ends without the least tension, and they must be able to lie in comfortable proximity before any sutures are used. The blood-supply of every part of the circumference of the cut ends must be assured. The margins of the bowel ends must be plainly seen. A water-tight junction must first be secured by through-and-through sutures, which must also arrest hæmorrhage. The first line of sutures must be buried by a peritoneal stitch which does not strangulate any of the visible blood-vessels. The line of union must be reinforced by suturing over it any of the neighbouring appendices epiplocіæ or other available tissue.

I am frightened of any method which aims at simplifying the anastomosis at the expense of any of these principles, and am suspicious of all methods which savour of sleight of hand. There is no need to hurry so important a matter, and it demands time and care for its satisfactory completion. Clamps are a convenience, not a necessity, and they must never be so strong as to crush the bowel wall.

The exact site at which it is safe to make the anastomosis must be judged by a consideration of its anatomy, its proximity to the growth, and the blood-supply. So far as the latter is concerned, I am not content to be guided by any preconceived notions as to what the blood-supply ought to be in any particular segment of the large bowel, but I make it a practice to determine by inspection and by palpation, if necessary after the clamps are loosened, that there is a sufficient blood-supply right up to the cut margin. I would like to say once again that I feel satisfied that failures to unite are usually due to starvation of the edge, caused by insufficient blood-supply, and are not entirely dependent upon infection.

PROVISION FOR DRAINAGE FROM THE SITE OF THE ANASTOMOSIS.

When the growth has been large, having a big, raw area as its bed, or has been associated with recent inflammatory disturbance, as shown by surrounding œdema, or when there is any question about the integrity of the blood-supply or the adequacy of the suturing, then will the surgeon be wise to bring a rubber strand or softened drainage-tube from the neighbourhood by the shortest route to the surface. Many times such a drain has saved a disaster for small fæcal leaks have sometimes occurred after great care has been expended at the operation. In every case such leaks have healed spontaneously.

SOME SPECIAL DIFFICULTIES.

Though most difficulties disappear with adequate exposure and mobilisation, others are due to the obesity of the subject or the situation of the growth. When there is a great deal of fat surrounding the colon the difficulties are anatomical rather than pathological, but they may prove extreme. In such cases I find it helpful to divide the layers of the mesentery, so that the vessels may be clearly seen before they are caught or surrounded by ligature. If this step is not taken they have an unhappy knack of retracting amongst the slippery fat where they are difficult to catch, and where they quickly form large hæmatomas. It is also often difficult to catch up the bowel wall for the purpose of suturing, and it is wise to separate the fat from the line of section, so that the bowel wall is clearly seen and can be safely sutured. The tags of fat which have been left are invaluable as a means of providing a local covering when used in the form of a series of grafts over the suture line.

Low sigmoid growths are very troublesome, and the surgeon has often difficulty in deciding whether or not it is wise to remove the growth and, having done so, whether to leave the patient with a permanent colotomy or attempt to make an anastomosis. I would at once say that in these cases I never contemplate an immediate anastomosis unless the patient has the advantage of a previous cæcostomy or colostomy, but with that advantage it is possible every now and again to make a successful union, although the suturing has to be done almost flush with the pelvic floor. To facilitate the removal I have found that it is best to incise the pelvic peritoneum all round half an inch away from the bowel, and by blunt stripping to separate the fat while the bowel is gently drawn upon, so that what is really a portion of the rectum is pulled up into the peritoneal cavity. A clamp is applied to the latter or it is divided without clamps, and drawn up by catch forceps, so that the sutures may be applied. After the latter have been tied, the rectum, with the suture line, retracts into the cellular tissue of the pelvis. The peritoneum, which has been previously separated, then naturally falls into position around the bowel, and can be attached by a few points of suture at a higher level than the anastomosis, in that way providing an efficient protection. In these circumstances the peritoneum must not be closely sutured around the bowel, and a drain from the neighbourhood of the anastomosis must be brought up through the parietal incision. In many of these cases, instead of endeavouring to make an anastomosis at the time that the growth is removed, the lower end of the bowel is tucked in, and the upper end brought out as a colotomy. Whichever method is adopted a large, well-oiled rubber tube must be passed from the anus into the rectum, and kept there for some days. Even when the section has to be made so close below the growth that no bowel is available for an anastomosis, the outlook is not necessarily hopeless, and I have several patients alive and well after long periods in whom these conditions have pertained.

On three occasions I have subsequently restored the continuity of the bowel by a method which is referred to by Kelly in his book on "Operative Gynæcology." The intussusception method of Rutherford Morison was devised for this class of case. It is an operation which is highly ingenious in its conception, but in actual practice I have found it difficult and uncertain and very disappointing in its results, and though it may occasionally be used it has no wide field of application.

PERITONITIS AND ABSCESSES AS COMPLICATIONS OF GROWTHS OF THE BOWEL.

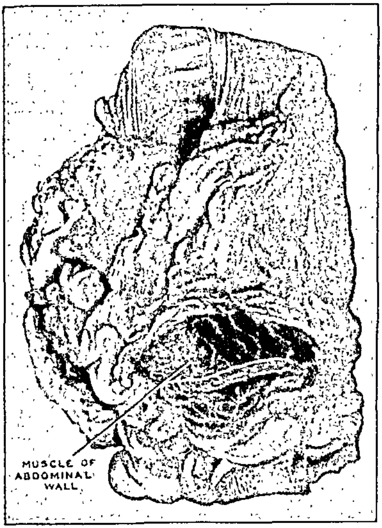
Every now and again the surgeon is confronted with a case in which a bowel growth has suddenly leaked into the peritoneum and the patient has to be operated upon as an emergency. Under these circumstances the condition is sufficiently desperate, but it need not necessarily be hopeless. In this series cases of the kind have been met with and some have been successfully overcome. Sometimes the growth has been withdrawn from the abdomen and left outside while the peritoneum and the bowel have both been drained. In others the hole in the growth has been patched by stitching omentum over it, or by stitching it to a neighbouring viscus. Or the leaking area has been brought directly to the surface through a suitable incision, and in all of these cases cæcostomy or colostomy has been performed and the peritoneum drained. In one such case a ruptured fæcal ulcer in the cæcum was used to make an anastomosis to the descending colon, the patient surviving for a sufficient length of time to justify this makeshift.

Sometimes there is peritonitis, which has arisen as a result of an infection through the wall of a growth but without an actual rupture. In these cases drainage of the peritoneum and of the bowel have similarly tided the patients over the emergency, and secondary resection operations have been successfully carried out. In fact, in these cases I believe that the patients are peculiarly resistent and will tolerate an amount of subsequent interference which in other circumstances might be ill-borne.

A definite localised abscess round a growth is another complication which occasionally first draws attention to the presence of a bowel growth, and years ago I recorded two cases (*Edinburgh Medical Journal*, December, 1909), and since that time have come across other instances—seven in all. In dealing with this complication it is probably wisest first to drain the abscess, and at a second stage to deal with the growth. I say this with some heart-searching, because I have once or twice made the mistake of carrying out the complete operation at one sitting, when I feel that had the two-stage operation been adopted the patient could quite safely have been tided over the ordeal.

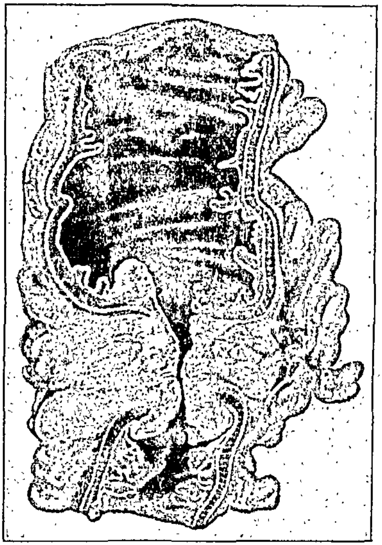
Doubtless many further improvements will be brought about in the treatment of these cases. At the time of the discussion in these rooms in 1920 nearly all the speakers bore witness to the enormous benefit which had followed the practice of not attempting the radical operation in the presence of obstruction, and of the recognition of the extreme importance of thorough mobilisation of the growth. Since then these principles have been more generally acted upon and with surprising improvement in the results. I can now only suggest that more care in the preparation of the patient along the lines suggested by Lord Moynihan, and very lucidly brought before the profession in his Harveian Oration of 1926, should be the rule. One wonders if perhaps by subjecting the growth to X rays or, in certain selected cases by the use of radium, the field of operability could be still further enlarged. These are matters which are as yet not settled, and it will perchance fall to the lot of some other orator to bring the result of experience along these lines before you. One thing I do indeed wonder with regard to malignant disease, and that is, whether we do not sometimes disseminate a comparatively innocuous growth by the manipulations which are necessary for its removal. This is suggested by the long history which sometimes precedes operative interference, and the relatively early recurrence dissemination which may follow it.

FIG. 8A.



A sigmoid growth densely adherent in the left iliac fossa and involving the parietes extensively. It was exposed and removed by an oblique muscle-cutting incision directly over it. Fig. 8B shows the growth in section. The patient is alive and well five years later.

FIG. 8B.



Same case as Fig. 8A. Shows the growth in section.

I am glad to have this opportunity of thanking those numerous medical friends who have so kindly helped me to keep in touch with their patients. I am sure that my recurring requests must often have proved a great annoyance.

In concluding this review of so important a subject, I realise acutely how very much has been left undone. A busy surgeon, with ever-increasing hospital duties and teaching responsibilities, is hard set to find the time to make use of the abundant material which passes through his hands. The coöperation of those less insistently occupied and more closely in touch with the resources of a pathological department is essential, and as I have preserved a great many of my specimens, I hope at some future time to add the result of an extended microscopical investigation in relation to the clinical results. Meanwhile, in extenuation of my manifold shortcomings, let me shelter behind these comforting words of Pope:—

> "Whoever thinks a faultless piece to see,
> Thinks what ne'er was, nor is, nor e'er shall be."

EXPERIMENTAL TREATMENT OF CANCER WITH TUBERCULIN.*

BY RAYMOND PEARL; ALAN C. SUTTON, M.D.;
AND
W. T. HOWARD, JR., M.D.

IN a paper by Pearl[1] on the relation between cancer and tuberculosis the following statement was made :—

> "After this paper had been accepted for publication on June 11th, 1928, I asked Alan C. Sutton, M.D., a member of the staff of this Institute, and that of the Johns Hopkins Hospital, to undertake during the summer the preliminary organisation of experimental work on the treatment with living tubercle bacilli and tuberculin, of transplantable cancer in rats. In the discussion of these experiments it was decided that it would be highly desirable to see what would be the result of specially treating malignant tumours in human beings with some form of tuberculin when suitable cases for such treatment could be obtained, in view of the obvious deductions which logically follow from the results of the present study of autopsy material. The ideal case for a trial would be one in which, first, a carcinoma or a sarcoma had been removed surgically, and the malignant character of the tumour definitely proved from sections of the surgical specimen; in which, second, there has been at some later date an extensive, inoperable recurrence of the same tumour, confirmed by biopsy. If in such a case the tumour retrogressed or disappeared, following special tuberculin treatment alone, the evidence would have real significance.
>
> "A small number of carefully selected cases of malignancy are now being treated by Dr. Sutton, under the direction and in consultation with the writer. Treatment of the first case began on July 10th, 1928."

It now seems desirable to report very briefly, and in an entirely preliminary way, on the progress to date of the work which we have done in treating cases of malignant disease in human beings with tuberculin. This preliminary statement will be followed in due course by a complete report presenting all the histopathological, clinical, and therapeutic data.

In the beginning stages of the trial of a new therapeutic agent for the treatment of cancer it was felt that it would be morally unjustifiable to accept for treatment any other than terminal stages of the disease, where any and all other methods of treatment had been abandoned as hopeless. Consequently all of the cases so far treated have been of this character, except one which came under treatment through unexpected circumstances in an early stage of the disease. It is our purpose to report briefly here only upon the cases which have been under treatment and study a sufficiently long time to give some reliable indication of the effect of the tuberculin therapy.

Clinical Histories.

CASE P 1.—Female, aged 52. Radical removal of left breast, May 18th, 1922. Adenocarcinoma. Partial excision of left supraclavicular lymph gland Sept. 21st, 1927. Metastatic carcinoma. X ray of chest at this time showed areas of consolidation in lower portion of right lung. Examination on July 1st, 1928, showed extensive recurrence in supraclavicular glands and extension of lung involvement. *Condition at beginning of treatment:* Patient bedridden, cyanotic, dyspnœic, with frequent attacks of severe coughing, during which the head and neck were engorged with blood, leaving her completely exhausted. Obstruction of pylorus, with 24-hour retention and daily vomiting. Her condition was rapidly and progressively getting worse. *Treatment:* Begun on July 10th, 1928, with B.F. tuberculin (bouillon filtré Denys). It has continued to the present time (April 1st, 1929). On account of the marked improvement in the patient's clinical condition, and because of the marked reduction in the size of metastatic supraclavicular glands, there was removed, surgically, a piece of one of these glands on Jan. 15th, 1929. Sections show a marked alteration as compared with material before treatment, chiefly characterised by extensive fibrosis, and œdema of residual cancer cells. *Present condition:* Patient is greatly improved. There is very little shortness of breath and that only on exertion. No cyanosis. There are only occasional mild attacks of coughing. She leads a life of moderate activity. Goes to theatre, luncheons, and climbs stairs and walks eight to ten blocks without much discomfort. Vomits only occasionally when mentally depressed, but there is no evidence of retention. Weight is constant at around 160 lb. X ray shows right lung practically clear.

CASE P 2.—Male, aged 57. Resection of pyloric end of stomach Jan. 10th, 1928. Carcinoma. On June 1st, 1928, noticed small lump in body wall wound, which continued to increase in size until on Oct. 16th, 1928, it measured 9 cm. in diameter. Its shape was that of an inverted half grape fruit. A smaller separate nodule in the lower portion of the wound measured 3 cm. in diameter. Metastatic gland in both axillæ. *Condition at beginning of treatment:* Patient emaciated and anæmic. Unable to work. *Treatment:* With B.F. tuberculin begun Oct. 17th, 1928, and has continued to the present time (April 1st, 1929). As the treatment progressed the tumour mass got progressively softer. On Feb. 1st, 1929, it began to slough over upper pole, and to drain from a central sinus. The character of this discharge indicated that hemorrhagic degeneration of the tumour mass was in progress. Because the large metastatic gland in the right axilla was apparently undergoing similar degeneration it was surgically removed on Feb. 19th, 1929. Sections show extensive œdema and vacuolation of the residual cancer cells, and congestion, hæmorrhage, œdema, and fibrosis of the stroma. Since the sloughing and drainage of the main tumour mass it has greatly diminished in size and improved in appearance. Normal epithelium has grown in over the cancerous tissue at the central drainage point and over the superficial ulcerated area at the upper pole. Unfortunately, while the central tumour was draining there was an extensive hæmorrhage one night which stopped itself, but left the patient very anæmic. *Present condition:* Tumour is approximately one-third of its maximum size. There is no evidence of new involvement. The chief concern now is the extreme anæmia following the severe hæmorrhage. This is at present improving, however, and there is now no bleeding at any point. Our impression is that the treatment was pushed too rapidly in its early stages, with a consequent too rapid disintegration of the tumour mass.

CASE P 3.—Female, aged 62. Radical removal of left breast Jan. 2nd, 1928. Adenocarcinoma. Radical dissection of metastatic left supraclavicular glands, Oct. 2nd, 1928. Partial excision of metastatic brain tumour Nov. 9th, 1928. This last operation was undertaken for the purpose of giving an opportunity to try tuberculin treatment, because the metastatic growths were rapidly progressing, and it was felt that unless a temporary stay could be obtained the patient would die from the brain metastasis before a fair trial of the tuberculin could be had. *Condition at beginning of treatment:* General condition good as to weight and blood picture. *Treatment:* With B.F. tuberculin began Oct. 30th, 1928, and has continued to the present time. *Present condition:* General nutrition still good and blood picture shows no particular change. Recently there has been gradual reappearance of brain symptoms, possibly due to pressure from œdematous reaction of residual tumour tissue following each treatment. With this thought in mind tuberculin is now being temporarily discontinued, to see whether relief of pressure symptoms will follow.

CASE P 4.—Female, aged 35. Radical amputation left breast with pectoral muscles and axillary glands, Dec. 8th, 1926. Many metastases in left axilla, especially along vessels. Medullary carcinoma. Second operation Feb. 28th, 1927, and metastatic deep cervical glands removed from left posterior cervical triangle. No tissue saved for pathological examination, or if saved was lost. On Feb. 9th. 1928, several small metastatic glands were discovered above the left clavicle. She was given courses in X ray treatment until Nov. 9th, 1928, when this therapy was discontinued because it was thought to be having a deleterious effect upon the blood picture. *Condition at beginning of treatment:* General condition excellent. Bothered only by slight cough. *Treatment:* With B.F. tuberculin begun on Nov. 16th, 1928, and continued till death. This patient exhibited a very low degree of sensitivity to tuberculin, and did not show the usual reactions following therapeutic injections. On this account the dosage was rapidly pushed up so that by Dec. 10th she was receiving 1·0 c.cm. full strength B.F. tuberculin, which was raised on Dec. 22nd to 1·5 c.cm. This was followed by a rather severe general reaction with slight elevation of temperature. From this time on, though there was no apparent reaction to increased dosage of tuberculin, the patient complained of weakness, increased cough, and substernal pressure. On Jan. 6th, 1929, she developed a right side hydrothorax. On Jan. 11th the patient died. A partial autopsy revealed a malignant pericarditis and a non-malignant polyserositis involving both pleura and peritoneum. Sections of tissue removed at autopsy showed remarkable and extensive changes in the cancer cells, particularly marked œdema of the cell body, much vacuolation, and shrinkage and degeneration of the nuclei. In view of the history it is impossible to prove that the marked alteration of the cancerous tissue observed at autopsy was solely due to the tuberculin treatment. It may have been the result of the X ray treatment, though the fact that the pericardial involvement showed the same changes perhaps makes this latter hypothesis somewhat improbable. Our general impression regarding this case, which is, however, incapable of proof, is that the dosage of tuberculin was pushed too rapidly, and brought about, on the one hand, too rapid degenerative alterations in the tumour tissue wherever located, and induced a condition of protein shock on the other hand. The unfortunate outcome led us to modify the general plan of treatment in all the cases, in the direction of not pushing the tuberculin dosage too rapidly.

---

* Preliminary Report from the Institute for Biological Research of the Johns Hopkins University, Baltimore, U.S.A.

[1] Pearl, R.: Cancer and Tuberculosis, Amer. Jour. Hyg., 1929, ix., 97.

CASE P 5.—Male, aged 38. Admitted to hospital Nov. 12th, 1928. Diagnosis (without operation or biopsy) inoperable carcinoma of rectum, with probable metastases to liver and retroperitoneal lymph glands. Secondary anæmia. Jaundice. *Condition at beginning of treatment:* General nutrition poor, had lost weight (weight = 135 lb.), marked secondary anæmia (red blood corpuscles, 2,100,000, hæmoglobin, 38 per cent.) Unable to work. *Treatment:* With B.F. tuberculin began Nov. 15th, 1928. Continued until Dec. 15th. At that time the patient felt so much better that he determined to leave the hospital and go to New Jersey for the Christmas holidays. This he did. On Dec. 28th he returned and treatment was begun again. Before leaving the hospital his blood had been built up by transfusion, but while absent he had bled profusely and became again very anæmic. Tuberculin treatment was continued until Jan. 30th, 1929. No further transfusion was given, though indicated, because he had no money to pay for it, and the hospital refused it without payment. On Feb. 1st, 1929, he was discharged from the hospital, without notice to either of the authors of this paper, because he refused a colostomy, which was advised by the hospital staff on the ground that complete occlusion of the bowel was impending. He received no further treatment. *Present condition:* On March, 20th, 1929, the patient unexpectedly turned up at the dispensary for the purpose of informing anyone interested that he was feeling well. On March 22nd his R.B.C. = 3,460,000 and Hb. = 45 per cent. He had been steadily gaining weight. On April 4th his weight was 155 lb., or 20 lb. more than on admission. Is strong. Has no bleeding. Proctoscopic examination of the rectal tumour shows now a considerable opening through it. There is no evidence of ulceration and the tumour mass is distinctly smaller than at the beginning of treatment. The jaundice disappeared shortly after treatment was begun and has never returned.

CASE P 6. Male, aged 66. In December, 1927, patient began to have attacks of gas with nausea and vomiting. From this time to May 6th, 1928, lost 25 lb. in weight. At operation, May 6th, 1928, was found to have inoperable carcinoma of stomach, so extensive that there was not enough normal stomach wall to permit any kind of anastomosis. Metastatic gland removed at operation showed adenocarcinoma. *Condition at beginning of treatment:* Emaciated, marked secondary anæmia, daily vomiting. *Treatment:* With B.F. tuberculin started Nov. 27th, 1928, and has continued to present time. Has had no other treatment. During first month of treatment did not feel so well. Thereafter marked improvement noted in stomach symptoms. Vomiting and pain practically entirely stopped. *Present condition:* Weight has stayed practically constant at around 145 lb. since beginning of treatment until recently when there was a temporary drop. It is now increasing. Stomach mass has decreased considerably from its maximum size. In early stages of treatment the anæmia became progressively worse, but is now improving. Only occasional vomiting.

CASE P 7.—Male, aged 37. In May, 1927, patient complained of a knot the size of a hen's egg on chest wall. On Dec. 1st, 1927, a biopsy was done and a diagnosis of fibrosarcoma made. Jan. 1st, 1928, courses of X ray and lead treatment were started. These were discontinued on Sept. 15th, 1928, because they had apparently produced extreme anæmia, and because the tumour involvement increased steadily unaffected by the treatment. *Condition at beginning of treatment:* Emaciated, marked secondary anæmia, just able to do a little walking outdoors each day. Considerable coughing. *Treatment:* With B.F. tuberculin begun on Nov. 27th, 1928, and has continued to present time. *Present condition:* Blood picture has improved. Has stopped coughing. Weight has stayed constant. Tumour has shown no growth during past four months, though steadily growing before that time.

Histological Changes.

Following the tuberculin treatment there are certain noteworthy changes in the tumour tissues which, in general, appear to be proportional in amount to the clinical damage suffered by the tumour. On the part *of the stroma they consist:* (1) of congestion of veins and capillaries, œdema and hæmorrhage, often attended by invasion by leucocytes—chiefly polymorphonuclear neutrophiles, lymphocytes, and plasma cells; (2) proliferation of fibroblasts; (3) hyaline change; (4) sclerosis with compression and distortion of the cancer alveoli, usually associated with atrophy *(shrinkage) of the cancer cells.*

On the part of the cancer cells the changes affect both nucleus and cytoplasm. In regard to the latter, perhaps the earliest change is swelling, associated with a loss of affinity for eosin, resulting in an appearance almost identical with that of cells in the early and midphases of mitosis. A more marked and probably later change is the appearance of larger and smaller round or oval vacuoles. In such cells, in material fixed in Zenker's fluid and stained with hæmatoxylin and eosin, there is to be seen very frequently a finely fibrillar meshwork, the spaces of which may appear empty or may contain finely granular material. In extreme degrees of vacuolation, a single vacuole may fill nearly the whole of the cell, which is often markedly swollen and distorted. Larger vacuoles may contain finely granular matter, or larger or smaller hyaline masses, deeply stained with eosin. Frequently large vacuoles are ruptured with escape of their contents. Viewed with the low power these vacuolated cells, with their condensed cytoplasmic walls, resemble cysts of certain protozoa. A second important cytoplasmic change is a form of degeneration ending in the transformation of the cytoplasm into hyaline material with marked affinity for eosin. A third change, probably associated with rupture of the cell membrane is disintegration, with the escape of finely granular material, the granules being somewhat larger than those normally present. Such cells have apparently previously undergone swelling without vacuolation.

In consequence of these changes many alveoli consist of single or a double row of cells in various stages of vacuolation, hyaline change, or granular disintegration, surrounding a large or small central cavity containing tumour cells in various stages of the above-described degenerations, cell and nuclear fragments, fine and coarse granular material, hyaline in globules or in large wavy masses, and occasionally leucocytes. The nuclear changes include swelling, with dissolution of chromatic material, hyperchromatism, shrivelling, and fragmentation.

Method of Treatment.

The tuberculin used is a bouillon filtrate from Human Strain No. 37. The method of its preparation is fully described by Willis,[3] p. 137. We are greatly indebted to Dr. Allen K. Krause for providing the tuberculin for our work. In the treatment the tuberculin is injected subcutaneously. The dosage and interval are regulated according to the sensitivity of each individual patient, as determined by intracutaneous test with O.T. There appears always to be a definite reaction in the tumour involvement, wherever located in the body, following each injection of tuberculin. Our experience indicates that during the first six weeks of treatment the dosage should be kept low. At the end of about that period there appears usually to occur a definite change for the better in the patient's condition, although up to that time little in the way of definitely observable results of the treatment is to be seen. After the first six weeks the dosage may be cautiously increased, and this appears from our present experience to be advisable. But at all times great caution must be exercised, or the patient may be killed, either by the too rapid production of toxic products from the alterations induced in the tumour tissue, or from something closely resembling allergic shock.

---

[3] Willis, H. S.: Laboratory Diagnosis and Experimental Methods in Tuberculosis; Springfield, Illinois (C. C. Thomas), 1928.

Arrangements were made on Jan. 28th, 1929, with the Harvard Medical School, and on March 19th, 1929, with St. Elizabeth's Hospital in Washington, D.C., to undertake the tuberculin treatment of series of cancerous patients in coöperation with this Institute. The work is already under way in these two institutions. Dr. Joseph C. Bloodgood also has recently started a series of cancer patients on tuberculin treatment.

This paper is a preliminary progress report only. The evidence which has so far been accumulated does not warrant any positive conclusion whatever regarding the ultimate therapeutic value of tuberculin in the treatment of cancer. The cases which have been treated are too few in number, and even in these cases the final outcome is still too uncertain to justify any far-reaching or final deductions. The clinical and histo-pathological results which have been obtained, however, taken in connexion with the positive conclusions from the study of the autopsy material already reported by Pearl (loc. cit.), are of a sufficiently promising character to warrant the continuation of the investigation. In a matter of this sort, where there is even a possibility that a therapeutic agent may be of value in the treatment of cancer, it is morally imperative that the medical profession be at once put in possession of the facts. Unquestionably the lives of some, if not all, of the patients whose histories are recounted above have been prolonged beyond the duration they would have realised had the tuberculin not been given. More than this cannot now be said. But even so much must, on humanitarian grounds, be made public to the medical profession. What is the most effective method of using tuberculin in cancer therapy, or what the effect of tuberculin would be on early cancer, and when used in combination with surgery, radium, and other modes of cancer therapy we are unable either to state or to predict, but obviously these matters want investigation, and in due time will doubtless receive it.

THE PAIN AND DISCOMFORT OF CONGESTIVE HEART FAILURE.

By K. SHIRLEY SMITH, M.B., B.Sc.,
M.R.C.P. Lond.,
MEDICAL REGISTRAR, MIDDLESEX HOSPITAL; LATE RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR DISEASES OF THE HEART, LONDON.

THE investigations described in this paper were undertaken in order to determine the incidence and nature of pain and discomfort in congestive heart failure. The pain that is presumably of cardiac origin and also that arising from the various complications attendant upon failure are considered. In the first part of this paper details are given of the analysis of the pain associated with failure in 105 patients. In the second part an attempt has been made to discover from the history, the examination, and the progress of 33 of the patients the origin and significance of the various types and grades of pain. Angina pectoris has been excluded, except that a few patients have anginal pain although suffering from some degree of congestive failure. With nine exceptions the cases were in-patients at the National Hospital for Diseases of the Heart.

The following groups of cases have been included under the term congestive failure:—

(1) Patients with *severe failure*, showing such signs as orthopnœa, enlargement of the liver, and pulmonary and other œdema.

(2) Patients with *moderate failure*, having troublesome dyspnœa and some signs of venous congestion—for example, crepitations at the bases or hepatic engorgement.

(3) Patients with slight failure, in whom *breathlessness* is observed at rest, with or without slight œdema of the feet, not previously present.

(4) Patients complaining of *anginal pain on effort*, but also showing evidence of congestive failure as above.

The Frequency and Origin of Pain in Failure.

With the aim of determining the incidence of pain in failure and its distribution according to intensity and origin, an analysis was made of the cases admitted to the National Heart Hospital over a period of six months. The following Tables show the results of this investigation. Table I. needs no explanation. Table II. shows the incidence of pain in relation to its source.

TABLE I.

Total patients admitted to the National Heart Hospital during six months		173
Number showing signs of congestive failure		105
(*a*) Number complaining of pain associated with failure	67	
(*b*) Number complaining of pain more than any other symptom	6	
(*c*) Number having or developing pain not of cardiac origin (1) alone, (2) in addition to previous pain, presumably cardiac ..	14	
(*d*) Number free from pain before and after admission	18	

TABLE II.—*Sources of Pain and Discomfort.*

(*a*) *Presumably cardiac*—that is, no other cause is found (Table I. (*a* and *b*))	73
(*b*) *Due to complications or sequelæ of failure*:—	
1. *Pulmonary and pleural*—	
(*a*) Infarction of lung	5
(*b*) Hydrothorax, primary	1
(Two patients developing hydrothorax from failure had no new pain with it.)	
(*c*) Pleurisy only—i.e., friction only	1
(In this case there were no subsequent signs suggesting further lesion, such as infarction or hydrothorax.)	
2. *Hepatic or gastric.*—Right hypochondriac or epigastric pain with hepatic enlargement ..	10
3. *Œsophageal.*—Dysphagia	1
4. *Pain of œdema*:—	
(*a*) Sacral	2
(*b*) Above ankles	1
(*c*) Antero-internal aspect of thighs	1
5. *Pain of thrombosis* of systemic veins (popliteal) ..	1
(Many patients show more than one complication associated with pain, hence the total incidence is greater than the total number of cases (14)).	

Œdema is generally regarded as painless. The complaint of pain in association with it might, at least in sacral œdema, be attributed to the discomfort of the recumbent position in bed. Yet the only patients who complained of sacral pain were found to have considerable œdema of the sacrum. One of the patients studied in detail, but not included in the above series, complained of the simultaneous onset of swelling of the legs and pain above the knees. The single instance of dysphagia in a series of 105 cases illustrates the rarity of this symptom in congestive failure. In view of the displacement of the œsophagus and the holding up at the level of the auricles of an opaque bolus, as shown by the X rays, a greater frequency of dysphagia might be expected.

Pain and discomfort may occur early or late. Early pain is almost invariably sternal and of cardiac origin, and occurs at the onset of failure. Late pain often arises from the heart, but it may be due to complications and therefore attributable to other organs.

I. *The Sternal Pain of Early Failure.*

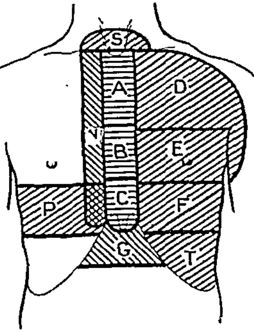
A considerable proportion of all patients complaining of pain associated with congestive failure are found to have had sternal pain on effort at some time in their history; this pain has most commonly been experienced when the reserve of the heart was diminishing—that is, when breathlessness was noticed with less and less exertion, and when slight swelling of the ankles first made its appearance in the evenings. The pain is generally midsternal, and although it may be stabbing and rather severe, it is sometimes more a dull aching pain associated with a sensation of choking or of tightness across the upper part of the chest or around the waist. Occasionally it is described as a feeling of oppression or of weight on the chest, though in such cases the symptoms amount to little more than discomfort. Concomitant breathlessness is always experienced in some measure. The sternal pain in early failure is always relieved by rest, so that patients remark that it passes off after a few minutes. There is radiation of the pain in a few cases. In some it is described as passing into the left arm (Cases 1 and 5); in others as passing straight through to the back (Case 2); and occasionally as spreading toward the left nipple (Case 3). As failure becomes established this pain is no longer felt.

It is the increasing breathlessness that is accompanied by the pain, and, similarly, the pain may diminish when the ankles begin to swell. If, from the 33 consecutive cases, the four suffering from angina pectoris are excluded, 29 remain. Of these 29 patients 13 experienced the sternal pain described above. The total of 13 excludes those patients suffering at times from sternal pain, but in whom the relation to exercise was not established. Sternal pain and tenderness on percussion over the sternum have been described by Libman[1] in subacute bacterial endocarditis. They are among the later manifestations of the disease and are therefore usually accompanied by cardiac failure. Although two or three cases of this disease were included in the 105 cases of failure studied, neither pain nor tenderness in the sternal region was observed in them.

II. *Pain Associated with Established Failure.*

Twenty-seven cases in which pain or discomfort were experienced in established failure have been classified according to the location of the pain. In order to facilitate the description of areas affected by the pain two diagrams were constructed (Figs. 1 and 2). In these the anterior and posterior aspects of the thorax were divided into the areas which were found to express best the numerous diagrams made from individual patients at the bedside. The names applied to these areas in the following description are self-explanatory, except that the term "parasternal" signifies an area lateral to the sternum and extending one inch from the sternal border.

FIG. 1.



Composite diagram showing location and distribution of pain (anterior aspect).

1. *Sternal pain* (A, B, and C) was only complained of in relation to exertion, and was never present in the patients in hospital, except when these areas were involved by pain spreading from some other region.

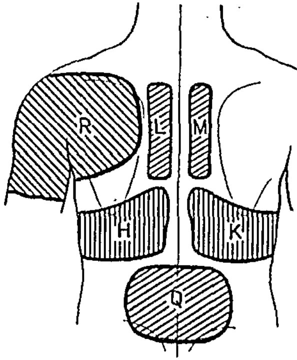
2. *Left Supramammary pain* (D) occurred only four times. The medial aspect of the upper arm was involved in all, and in two of them aortic incompetence was present.

3. *Left mammary and inframammary pains* (E and F) were more common than any others, being recorded 21 times. Of these patients 13 were fibrillating. Otherwise this group is made up of cases representing many varieties and combinations of cardiac lesions.

4. *Epigastric pain* (G) is found four times, in each case associated with considerable enlargement of the liver, and in two cases with rapid enlargement.

5. *Subscapular pain* (H and K).—(1) Bilaterally: two cases, associated with pulmonary infarction and coughing respectively. Both were cases of mitral stenosis. (2) Unilaterally: 11 cases (10 left-sided); 7 of these had mitral stenosis.

FIG. 2.



Composite diagram showing location and distribution of pain (posterior aspect).

6. *Interscapular pain* (L and M).—(1) Bilaterally: two cases; both had mitral stenosis, one had aortic incompetence as well. (2) Unilaterally: four cases (three left-sided); three had aortic incompetence.

7. *Right parasternal pain* (N).—One case: aortitis and aortic incompetence.

8. *Right inframammary pain* (P).—One case: enlarged left auricle extending to the right.

9. *Lumbo-sacral pain* (Q).—Two cases, both with much sacral œdema.

10. *Left scapular and upper arm pain* (R).—One case, in angina pectoris, by spreading from left inframammary pain.

11. *Suprasternal pain* (S).—Three cases; in two angina pectoris was present, but the suprasternal pain occurred apart from the attacks. In the third case there was hypertension.

12. *Left hypochondriac pain* (T).—Three cases; in all of these very severe failure was present, the liver being greatly enlarged while œdema involved the legs, sacrum, and lungs.

Presence or Absence of Hyperalgesia and Superficial Tenderness.

In his pioneer work on the pain of heart disease Head[2] has described local and referred pain. The former is distinguished by its restriction to the body surface immediately superficial to the organ affected, and by tenderness on pressure over the affected part. Referred pain, also investigated more from its clinical aspects by Mackenzie,[3] is characterised by *its distribution in areas remote from the origin of the pain* and by hyperalgesia of the skin as elicited by pinching. Such pain is relieved rather than exacerbated by pressure. Thirty-three cases of congestive failure in which pain was a symptom have been examined in detail for hyperalgesia of the skin and tenderness of subjacent structures. Hyperalgesia was determined by pinching the rate is falling, fibrillation is persisting, so there must be some factor beyond auricular fibrillation to account for the pain. That the pain of angina pectoris is often due to coronary disease and restriction of the blood-supply to the myocardium is not a new theory, but it has recently been further developed by Keefer and Resnik.[7] It it is true that the reduction of the oxygen-supply to the heart can produce anginal pain, the relationship between the rate of the heart and pain in failure seems explicable on the following grounds: the coronary vessels fill during diastole of the heart; when the rate increases the ratio between diastole and systole falls, the diastolic phase but not the systolic being shortened; there is thus less time for coronary filling and pain may ensue if the original blood-supply to the myocardium was only just adequate.

The association between pain and excessive rate of the heart has been further demonstrated by Barnes and Willius,[12] who have studied the occurrence of cardiac pain in paroxysmal tachycardia. Again, Schwartz [13] has shown that bouts of severe cardiac pain may arise in young adults with chronic valvular disease. In these patients the pain was always accompanied by violent and rapid beating of the heart.

(*d*) *Intracardiac Tension.*—It has been shown previously that cardiac enlargement is apt to be associated with tenderness and hyperalgesia of the chest wall, and the possibility of a causal relationship was suggested. Recent work on the occasional enlargement of the left auricle to the right may throw light upon this problem. Bedford,[14] and Bramwell and Duguid [15] have described the association between extreme left auricular dilatation to the right and pain in the right chest and axilla spreading to the right inframammary and right subscapular regions. Other cases have been observed by Labadille [16] and Mahaim.[17] This group of cases in which cardiac engorgement is a pronounced feature constitutes, as a whole, some support for the view that increasing intracardiac tension is a prominent factor in the production of the pain of established failure.

(*e*) *Coughing.*—In some instances pain in failure is partly to be attributed to coughing. In Cases 10 and 11 coughing was said to produce left inframammary pain, and in the first of these the pain spread through to the left subscapular region and tenderness developed over the affected parts. How this pain is produced seems doubtful. The onset of left-sided pain precludes the possible influences of increasing tension within the right side of the heart—an obvious result of prolonged coughing. Again, the causal relationship must be definitely established; for example, if cough results in the production of blood-stained sputum both cough and pain must then be considered as secondary to the initial event of pulmonary infarction. As cough generally arises from bronchitis this condition probably largely accounts for pain when it is retrosternal; when pain is lateral some other explanation must be sought. For example, it is obvious that much discomfort will be produced by coughing if there is hyperalgesia of the skin surface. Thus, in the light of present knowledge, pain in the left side of the chest produced or aggravated by coughing can only be ascribed to two causes—additional exertion, with concomitant increase in the pulse-rate, and repeated friction between the hypersensitive chest wall and the bed-clothes.

Factors Relieving the Pains of Failure.

The pains of failure may be relieved naturally in the course of the illness or they may yield to treatment. The following are the principal factors to be considered.

(*a*) *Establishment of Congestive Failure.*—The sternal pain of early failure is in nearly every case relieved by advancing failure, and when pulmonary and general œdema or hepatic engorgement have appeared this pain is no longer experienced.

(*b*) *Rest.*—Rest almost immediately relieves the retrosternal pain of effort. Inframammary and scapular pains are less rapidly relieved by rest and may continue but little abated after 24 or 48 hours in bed.

(*c*) *Hæmoptysis.*—The relief of thoracic pain and discomfort which sometimes follows hæmoptysis in failure may be regarded as support for the view that pain is produced by excessive tension within the lungs or right heart. This relationship is illustrated in Case 10, where the patient remarked that he generally felt better two or three days after an attack of hæmoptysis.

(*d*) *Therapeutic Measures.*—While the alleviation of pain and discomfort depend essentially upon removal of the underlying cause, some relief may be obtained by various measures. Sedatives such as bromide and chloral are useful, but the analgesics, for example, medinal, nepenthe, and liquor morphinæ hydrochloridi—may be required in severer cases and when insomnia from pain is undermining the general condition of the patient. Local applications are only to be recommended when pain is chronic and troublesome and when there is no danger of rendering an already hyperalgesic skin still more sensitive.

Angina Pectoris in Conjunction with Failure.

Among 105 patients with congestive failure only three were found to have angina pectoris. One other patient afflicted with both conditions was studied, making a total of four. Of these three were women, and the ages ranged between 43 and 57. Two of these patients were suffering from aortic incompetence. Syphilis seemed a likely ætiological factor, but in each case the Wassermann reaction was negative. In both the remaining patients there was disease of the aorta, this vessel being found higher and wider than normal on radioscopy. Negative Wassermann reactions were also given by these two patients. Three showed a systolic blood pressure of 200 or over, while that of the fourth was 145. In only one of the patients had anginal attacks occurred before the onset of dyspnœa, and in this case there was an interval of 14 months between the first attack of angina and the symptoms of early congestive failure. The history in all showed that the attacks of pain had become more severe and widespread as breathlessness became more pronounced; during treatment in hospital the attacks abated if they did not disappear.

No definite inferences can be drawn from four cases, but certain points are worthy of notice. Although the position of the pain and its radiation and relation to effort are typical of angina, there is an essential difference in the pain in these cases, since its onset is always more or less closely related to the beginning of congestive failure, and would seem therefore to depend upon morbid changes occurring in the myocardium. The complaint of dragging suprasternal pain in two of these four patients affords further proof of aortic disease, since it is generally believed that the arch of the aorta is segmentally referred to this area. This region, however, was not involved in the anginal attacks, so that no relationship is suggested between aortic disease per se and anginal pain.

Summary.

1. An analysis of 105 cases of congestive heart failure shows that only 18 escaped severe or incidental pain and discomfort. Pain was the primary complaint of 6 patients, while 67 experienced this symptom in addition to others more urgent. In 14 of the 105 patients the pain and discomfort arose from other structures than the heart.

2. Pain and discomfort due to complications or sequelæ of failure were found to be mostly pulmonary, pleural, hepatic, or gastric. Œdema, thrombosis, and œsophageal obstruction were also observed as causes of pain.

3. Pain of cardiac origin in congestive failure may be classified into: (*a*) the sternal pain of early failure; (*b*) the pain of established failure.

4. Sternal pain occurred at the onset of failure in 13 of the 20 cases analysed. It was always provoked by exertion and rapidly relieved by rest. Reasons

are given for believing this pain to be a very mild degree of angina pectoris.

5. The presence or absence of hyperalgesia and superficial tenderness were investigated in 33 cases. Only three patients experienced hyperalgesia, while superficial tenderness was present in 14. It was found that hyperalgesia and superficial tenderness were more apt to occur when the heart was much enlarged or beating rapidly.

6. The causes of pain in established failure are considered under the following heads: Exertion, cardiac rhythm, the rate of the heart, intracardiac tension, and cough.

7. Factors relieving the pains and discomfort of failure are described. These are, principally, rest, the establishment of failure, hæmoptysis, and therapeutic measures.

My thanks are due to Dr. John Parkinson and Dr. Evan Bedford for advice and criticism. For permission to use notes on patients under their care I am indebted to Dr. C. E. Lakin, physician to the Middlesex Hospital; to Dr. B. Hood, medical superintendent of the St. Marylebone Hospital, and to the honorary physicians to the National Hospital for Diseases of the Heart.

A FATAL CASE OF NÆVUS UNDERGOING MALIGNANT DEGENERATION.

BY P. CLENNELL FENWICK, C.M.G., M.D.N.Z., F.R.C.S. EDIN.,
OFFICER IN CHARGE, RADIUM AND DEEP THERAPY DEPARTMENT, CHRISTCHURCH HOSPITAL, NEW ZEALAND;
AND
J. RUSSELL WELLS, M.B.N.Z., F.R.C.S. EDIN.,
ASHBURTON.

THE radium department of Christchurch Hospital has records of malignancy following trauma in several patients. In one soldier a rodent ulcer developed over the site of a piece of shell fragment lodged in the face. In three women rodent ulcer developed in the small scar caused by a splash of hot fat, received while cooking. Sir G. Lenthal Cheatle has done much work on the relation of cancer to nerve and trophic areas, and we suggest that in the following case the slight trauma over the nævus was sufficient to destroy the trophic nerve-supply and render the area vulnerable to malignant degeneration.

The Case Described.

A young lady, aged 19 years, consulted one of us (J. R. W.) in March, 1928. She had a small nævus on the left temperofrontal region. Six weeks before seeking advice she had knocked the nævus, and from that time had noticed that it was growing larger, was irritable, and tended to bleed at the slightest touch.

Examination showed a nævoid growth, about the size of a split pea, just at the hair-line in the left temperofrontal area. It was raised above the skin but not pedunculated. Two other small nævi were present on the left *parieto-occipital region, and a large nævus, the size of the* palm of the hand, was present between the scapulæ. This had been treated with radium for 10 months five years earlier, and was partially healed. It looked angry but was apparently quiescent.

Excision of the nævus on the forehead was advised, as a transition to malignancy was feared. The growth was excised on March 12th by an elliptical incision one-quarter of an inch beyond the margins of the growth and down to the pericranial tissues. The sutures were removed on the seventh day and the wound was then soundly healed. On June 5th the patient returned, and a recurrence of the nævoid growth was found in the centre of the operation scar, and also a small swelling in front of the left ear, in or on the parotid was noted. The patient was sent to Christchurch Hospital for radium treatment. A full-strength radium plaque was applied over the forehead nævus for 15 minutes, the dose for children being ten minutes. It was impossible to say whether the firm round swelling the size of a walnut found in front of the left ear was a growth of the parotid or a lymphatic gland; it was fixed and hard, though not tender.

On July 3rd the patient returned. The nævus had shrunk to a pin-point but the swelling in front of the ear was still present. On August 21st the patient was sent again to the radium department for further consultation. The nævus had practically disappeared, but the growth over the parotid was larger and several firm glands were felt in the left posterior triangle of the neck. Immediate operation was advised. On Sept. 4th one of us (J. R. W.) removed all the glands, making a wide dissection of the whole area. The growth over the parotid was excised. The pathological report showed malignant disease, so the patient was sent to Christchurch for radium packs. On Sept. 19th a radium pack of 210 mg. of element in platinum tubes was applied at a distance of 3 cm. over the neck, and a similar pack of 50 cm. was applied over the parotid area. The time of exposure was 48 hours.

The patient returned home. No recurrence appeared in the neck or face, but secondary growths appeared below the left breast, on the right side of the neck, and in the right axilla. The liver became greatly enlarged, ascites and pleural effusion supervened, and she died on Nov. 26th, about nine months after the injury to the forehead nævus.

Pathological Report.

Dr. A. B. Pearson, the superintendent of the pathological department, examined the parotid growth, and reported as follows:—

The tissue *consists of a portion of* salivary gland and supporting connective tissues. The tissue is invaded by a tumour of malignant peritheliomatous type. The appearances in the actual tumour are extremely variable in different areas. In some parts the tissue consists of whorled masses of closely compact cells supported in a fine but scanty connective tissue stroma, and in these masses a very small blood-vessel is frequently noticed in the centre of the cell masses. In other areas the cells are grouped in lobulæ, in the centre of which well-marked vessels or sometimes large blood spaces are clearly seen. In these very vascular areas the vessels or blood spaces are lined by a layer of flattened endothelial cells supported by a thin layer of connective tissue cells which are, in turn, surrounded by a thick mass of large malignant cells. In this particular position the tumour consists entirely of this tissue of vessels with thick layers of surrounding cells. The groups or lobules seem to be in contact with each other. No connective tissue can be seen between them. In all parts the general cell features are very similar. They are usually oval in shape, with granular cytoplasm and very large oval-shaped nuclei. Very commonly they show pronounced hyperchromatic staining. Occasionally giant cells are present. These cells have one nucleus each, which is very deep-staining, but in one area groups of giant cells are present, *and these are of unusually large size and very irregular* shape. They show a very large amount of cytoplasm and contain several large irregular nuclei. Quite a number of these cells contain ingested leucocytes and dark-brown pigment. Mitotic figures in the general cell tissue are very common.

The tumour tissue shows widespread areas of necrosis and liquefaction. The tumour has invaded parts of the salivary glands, but the main growth appears to be in the lymph gland. The lymphoid tissue of the gland is completely destroyed and, in some cases, the capsule is invaded. The general features suggest a rapidly growing and highly malignant tumour.

The points of interest in this case are as follows. A very healthy girl receives a slight blow upon a small nævus and nine months later is dead of widespread malignant disease. It is, of course, recognised that nævi can take on a malignant character, but the channels by which the malignant cells are spread is sometimes uncertain. In this case the metastasis appeared to follow the lymph channels, and the pathologist mentions that large blood spaces were reproduced in the metastatic deposits. Apparently the nævoid type was reproduced—that is, a slight trauma over a nævoid area caused some change to occur in the nature of the lining cells of the nævus which altered the character of the growth from benign to malignant, and these altered cells were carried to distant parts of the body and reproduced themselves in lymph glands.

THE "CŒLIAC AFFECTION"—IDIOPATHIC STEATORRHŒAS.

BY T. E. HESS THAYSEN, M.D.,
PHYSICIAN-IN-CHIEF TO THE MEDICAL DEPARTMENT, ST. ELIZABETH HOSPITAL, COPENHAGEN.

IN describing the "cœliac affection" Gee [4] says that it "is commonest in patients between one and five years old. Sometimes from India Englishmen *return sick with the cœliac affection; seldom it is* met with in adults who have never left our island." Since Herter [7] in 1907 rediscovered the occurrence of the cœliac affection in children, describing it under the name of "intestinal infantilism," later authors have only paid attention to cases in children and have forgotten that Gee also observed this lesion in patients returning from India and in adults who had never been abroad.

The cœliac affection that attacks Englishmen in India can hardly be anything but sprue. The symptoms Gee describes as characteristic of cœliac affection—pronounced emaciation, white diarrhœa, anæmia, and muscular atrophy—are just as characteristic of both diseases as are the negative macroscopic findings in the digestive tract, which Gee emphasises in the autopsy of cases of cœliac affection. Gee does not mention the presence of stomatitis—a complication of tropical sprue that could hardly be unknown to him—probably because there are cases of tropical sprue, especially in India, in which the stomatitis is inconspicuous or absent. It might seem more difficult to identify the instances of "cœliac affection" that Gee observed in patients who had never been outside England. Of course, one cannot altogether exclude the possibility that these were cases of pancreatogenous fatty diarrhœa. Gee, however, does not mention the presence of sugar in the urine—it is present in most cases of pancreatogenous fatty diarrhœa—and he did not find the conspicuous macroscopic changes in the pancreas (atrophy, tumour) that are the cause of this disorder. Assuming, therefore, that he had the opportunity of making a post-mortem examination of these cases it is most likely that they were cases of a lesion resembling sprue. Nothing, however, is known of the occurrence of such a lesion in England in the days of Gee.

At a meeting of the Royal Society of Tropical Medicine in 1899 Thin [33] reported that two colleagues had diagnosed sprue in a patient who had never been outside his native country, and questioned the diagnosis. Manson-Bahr [13] has met with only one instance. In other countries, also, reports of a sprue-like disease in individuals who have never been in the tropics (Mense,[16] Talma [28]) were exceedingly scarce until recent years, when it has been definitely established that such a lesion really does occur, and further that it is far from being so rare as was thought. It is therefore very likely that Gee's cases of cœliac affection were instances of that sprue-resembling disease later described as non-tropical sprue. Under the term "cœliac affection" Gee includes the lesion later called cœliac disease (Miller [17]) or intestinal infantilism (Herter [7]), or "schwere Verdauungsinsufficienz des Kindes jenseits des Säuglingsalters" (Heubner [8]) together with tropical and (probably) non-tropical sprue. My object in this communication is to discuss whether these three diseases are so nearly related that one is justified in grouping them under a common designation.

Comparison of Sprue with Gee-Herter's Disease.

It is generally assumed that tropical and non-tropical sprue are the same disease, although this cannot be proved, as the ætiology and pathogenesis of both lesions are unknown. I shall therefore have to content myself with showing that Gee-Herter's disease and sprue are very nearly related and most probably identical lesions—a view that has been advanced before, on account of the conspicuous similarity in their symptomatology and course. Before I discuss the objections that have been raised against this view I shall briefly call attention to the most important points of resemblance in their clinical features and pathological anatomy. The patients have a strikingly characteristic appearance. They are markedly emaciated, their subcutaneous fat has disappeared, and their muscles are flaccid and atrophic. The large, meteoristically distended abdomen—particularly marked in children—forms a striking contrast to the thin extremities and the gaunt trunk. The skin is loose, pale, of a greyish, faded hue, without turgor, dry, often brownish. Other outstanding symptoms are: fatty diarrhœa, meteorism, anæmia, changes in the mucous membrane of the tongue, often mental disorder, achylia gastrica, and poor appetite alternating with ravenous craving for food. Organic changes in the nervous system are rarely present. A low blood-sugar curve after ingestion of glucose and abnormalities of the basal metabolism are to be found, and tetany is a frequent complication. In Gee-Herter's disease there is halisteresis which has also been demonstrated in cases of non-tropical sprue (Holst [9]).

The pathologico-anatomical findings are few, but almost identical in the two conditions. In several cases—and, it seems, more frequently in tropical than in non-tropical sprue and Gee-Herter's disease—there is enteritis or enterocolitis, and atrophy of the parenchymatous organs, with occasional fatty degeneration. These diseases occur most often in people with a previous intestinal lesion—in the tropics, especially amœbic dysentery. In some cases the disease runs an acute course with violent diarrhœa and pronounced emaciation, but the lesions—particularly in non-tropical sprue and Gee-Herter's disease—are apt to become chronic, with alternating periods of improvement and apparently unexplainable exacerbations. Tropical sprue is said to be seldom definitely cured unless the patient moves to another climate. A similar effect from change of climate may be seen in non-tropical sprue and in Gee-Herter's disease. One of my patients (No. 1) suffered constantly from steatorrhœa while at home; his stools became perfectly normal during a stay in France, and when he returned home the fatty diarrhœa set in anew. In Gee-Herter's disease also remissions have been observed when the children are moved to some other locality.

The mortality in Gee-Herter's disease is estimated by Schaap [24] at 13 per cent.; Halblützel-Weber [5] found it to be about 23 per cent. Of 23 patients with non-tropical sprue five are known to have died, but one died from an accidental complication. From tropical sprue Manson-Bahr [12] reports seven deaths in 45 patients with pronounced gastro-intestinal symptoms and stomatitis. If he had included cases with severe anæmia the death-rate would certainly have been higher. The lesions are not as clearly defined as would be desirable, since there are cases of sprue and of Gee-Herter's disease in which the fatty diarrhœa is not pronounced. Future investigations will have to decide whether such cases should be distinguished from the classical ones.

The pathogenesis is generally agreed to be an absorption-disturbance which primarily concerns the fats in the food, together with calcium salts and water and, to a lesser extent, proteins. But there is still a great deal of uncertainty with regard to the cause of this absorption disturbance. Judging from the literature, enteritis is rather frequent in tropical sprue.* If on this account the absorption disturbance is regarded as due to an intestinal lesion, even in cases where microscopic examination of the intestines gave negative results (v. d. Scheer [26]), non-tropical sprue and Gee-Herter's disease must also be considered as due to an intestinal lesion, even though it is rarer to find enteritis on microscopic examination in these conditions than in tropical sprue. Our knowledge of pathological changes in the intestines is so deficient that a lesion of the intestinal wall might easily exist without being recognised. Four fatal cases of non-tropical sprue were examined microscopically; in two of these (Blumgart,[2] Holst [9]) the intestinal wall showed no inflammatory changes; in one (Rosendahl [23]) it showed a slight, subchronic enteritis which, the author thinks, could not have been the cause of the protracted diarrhœa. Only one case (Manson-Bahr [15]) from Palestine showed definite colitis. It should be borne in mind that acute and chronic enteritis are very common lesions in the tropics. On the whole I agree with those who are sceptical of enteritis as the cause of these diseases.

Non-tropical sprue.

Objections to the Identification of Sprue and Gee-Herter's Disease.

In a discussion at the Royal Society of Tropical Medicine Reginald Miller [18] is reported as follows: "Owing to insufficient knowledge of the two diseases there was no agreement as to whether cœliac disease was the same as sprue, but there were notable differences. Cœliac disease always originated in childhood and, even without treatment, there was amelioration as maturity was reached. It was very seldom fatal, and did not occur in epidemics. Among children the essential feature of the disease was disorder of fat absorption, and it has nothing to do with intestinal disease, in many cases there being no diarrhœa and usually no ulceration of the tongue." In the same discussion Arthur Powell [21] emphasises the following points: "In sprue post-mortem examination invariably revealed a shrinkage of the liver and great attenuation of the stomach with loss of epithelium; these conditions were not observed in cœliac disease, which was characterised by enlarged spleen and great pain in the stomach. Vomiting was more frequent in cœliac disease than in sprue. In cœliac disease the appetite was poor and capricious, whereas in sprue it was the opposite. There was a tendency to dropsy in cœliac disease, while there was shrinkage of the body in sprue." Schaap,[24] who has described three cases of Gee-Herter's disease, states :—

> "La maladie cœliaque a également des rapports avec la spruo (l'aspect et la constitution chimique des fèces, l'anémie), pourtant la glossite aphteuse typique qui mène a l'atrophie fait défaut, bien que la langue dans la maladie cœliaque puisse présenter aussi des anomalies moins accentuées."

In discussing the differential diagnosis between sprue and Gee-Herter's disease, Lehndorff and Mautner [11] declare :—

> "Die Frage der Differentialdiagnose zwischen Coeliakie und Sprue hat bei der Seltenheit der letzteren in Europa für uns nicht viel Bedeutung. Die klinische Aehnlichkeit beschränkt sich auf die groben Züge der Krankheit, rezidivierende Diarrhoeen von jahrelanger Dauer, abnorm lichte Fettstühle, eine kleine Leber in einem sehr grossen aufgetriebenen Abdomen, allgemeine Schwäche und Gewichtsverlust; gemeinsam ist ferner beiden Affectionen *die negative Kalkbilanz und die Häufigkeit einer* komplizierenden Tetanie. Die für die Sprue charakteristische Mundaffection, eine Glossitis mit aphthösen Geschwüren an der Zunge, kommt bei der Coeliakie nicht vor. Ein weiterer Differenzpunkt besteht darin, dass die Sprue in einzelnen Gegenden epidemisch auftritt, die Coeliakie ist ausschliesslich ein Leiden der frühen Kindheit, während die tropischen Aphthen fast nur Erwachsene befallen."

Thus all the authors cited are agreed that there are such great differences between sprue and Gee-

---

* Several of the microscopic changes described are due to autolysis.

Herter's disease that the two lesions cannot be taken as identical. But the arguments advanced against this view are somewhat conflicting. Miller[17] and Lehndorff and Mautner[11] emphasise that typical aphthous stomatitis is not met with in Gee-Herter's disease, whereas Schaap[24] emphasises that similar, although less pronounced, changes do occur in Gee-Herter's disease. The last author is decidedly wrong when he states that atrophic glossitis does not occur in Gee-Herter's disease. Powell[21] finds that shrinkage of the liver, which is typical of sprue, does not occur in Gee-Herter's disease, in which, on the other hand, there is enlargement of the spleen. In this, however, he is in conflict with other authors, who lay particular stress upon the liver dullness being diminished and the spleen shrunken in Gee-Herter's disease. That difference in the appetite which Powell mentions does not exist; nobody else has been able to observe it. The occasional appearance of œdema of the face and hands in children with Gee-Herter's disease does not constitute any essential difference between this disease and sprue; it may obviously be regarded as "hunger-œdema." In this connexion I may add that the thinning of the stomach wall with loss of epithelium, which Powell takes to be characteristic of sprue, is a purely post-mortem phenomenon.

The greatest difficulty in recognising sprue and Gee-Herter's disease as nearly related—probably identical—conditions originates, I think, from the view that sprue is a wholly tropical disease that only attacks adults, and that Gee-Herter's disease is a disease of temperate zones that only attacks children—an idea that is definitely expressed by Lehndorff and Mautner. Sprue is not a wholly tropical disease. The literature contains, to my knowledge, records of 23 cases of sprue which developed in temperate climates in patients who had never been in the tropics. These were: 3 in Holland (Nolen,[20] v. d. Scheer,[27] Talma[28]), 7 in Germany (Hegler,[6] Mense,[16] Richartz,[22] Schäffer,[26] Wilfert[34]), 1 in England (Manson-Bahr[13]), 1 in Norway (Rosendahl[23]), 9 in Denmark (Holst,[9] Thaysen[31]), 2 in the northern United States (Blumgart,[2] Lambright[10]). The disease is also met with in Morocco (Begg[1]) and Palestine (Manson-Bahr[14]). One is therefore fully justified in claiming that sprue is not exclusively a tropical disease and that it probably occurs in any country, even though it is most frequent in some countries with a tropical climate. This fact, which will undoubtedly be further established in the future, makes it necessary once more to discuss the question of the near relationship between sprue and Gee-Herter's disease.

With regard to the second main objection against this view—namely, that sprue attacks only adults and Gee-Herter's disease only children—I quote some observations by Manson-Bahr.[15] In his excellent book, "A Report on Researches on Sprue in Ceylon," he writes (p. 23) as follows:—

> "It is generally stated that sprue is seldom seen in Europeans below middle age. Nevertheless, it may develop *at any age, even in children* of European parentage. Van der Burg states that he has recognised the disease in children of 1½ to 4 years of age, though it is as a general rule extremely rare in young adults. The oldest man I saw in Ceylon suffering from sprue symptoms was a burgher of 76 years of age, the oldest European a man of 70; the youngest was a boy of 13 of mixed parentage. I have, however, reason to believe that the disease occurs in natives at a still earlier age. I saw a Tamil boy of 8 who presented typical sprue symptoms, of which he died four months later."

In the tropics sprue thus attacks children too, and one of the reasons why it is diagnosed so seldom may probably be that in children it usually has an acute and fatal course and does not develop into the more chronic Gee-Herter's disease, which is always regarded as a "disease of luxury." Heubner[8] emphasises that most of the cases of Gee-Herter's disease occur in the socially well-to-do classes.

Table I. contains the cases of non-tropical sprue and the cases—known to me—of Gee-Herter's disease in older children in which there is some information as to the onset of the disease. Of course, I realise that the onset in such cases is a difficult question to settle. Table I. shows that of 11 cases of non-tropical sprue four developed before the age of 20 years, and one of these even occurred in a child of 11 years. Among six cases of Gee-Herter's disease one began at the age of 13 years and two at the age of about 10 years. Though it is true that in the great majority of cases Gee-Herter's disease develops in the earliest years of life, it may also make its first appearance at a more advanced age; and even if most instances of sprue occur in adults, it may also develop in children. We find all ages represented—possibly with the exception of puberty (13–15 years), which recalls the fact that Miller and other authors state that children with Gee-Herter's disease improve when they reach puberty. On the whole these data go to show that it is impracticable to maintain the greatly emphasised difference between sprue and Gee-Herter's disease—namely, that the first is seen only in adults and the latter in children only. Gee is right, I think, when he introduces his paper on the "cœliac affection" with the following words, which have since been forgotten or overlooked: "There is a kind of chronic indigestion met with in persons of all ages, yet is especially apt to affect children between one and five years old."

Aphthous Stomatitis in Sprue.

In a discussion at the Royal Society of Tropical Medicine the condition of the tongue was particularly mentioned. Thin pointed out that there are two forms of sprue: one, especially frequent in the Indian archipelagos, is characterised by very marked changes in the mouth and tongue; the other, common in India, is characterised by violent diarrhœa, while the tongue does not undergo any change before the later stages of the disease. The tongue and oral cavity may be free from inflammatory alterations, even when the disease has persisted for several years. Tropical physicians, as far as I know, agree that alterations of the tongue in sprue are inconstant in occurrence and extent, and that there are forms of sprue—the well-known hill-diarrhœa, for instance—which are not complicated by aphthous stomatitis. Schaap[24] states that the tongue in Gee-Herter's disease may show similar changes to those of sprue; and Lehndorff and Mautner[11] point out that the tongue in Gee-Herter's disease is the site of a diffuse red irritation. Common to both diseases is the frequent occurrence of smooth atrophy of the tongue. The aphthous stomatitis in non-tropical sprue is not as a rule very conspicuous and shows but slight aphtha formation; it is not infrequently absent in the acute attacks. In this respect non-tropical sprue bears more resemblance to the sprue of India.

Considering the non-specific character of this stomatitis and its occurrence as a secondary phenomenon (v. d. Scheer[26]) in a group of diseases whose main symptom is fatty diarrhœa, I cannot see any reason for denying the near relationship—and even identity—of sprue and Gee-Herter's disease on the basis of a difference in the appearance and extent of the stomatitis.

To the above-mentioned symptoms common to sprue and Gee-Herter's disease I may add two more—the low blood-sugar curve and the abnormal basal metabolism. Ingestion of glucose (about 60 g. in adults, 1 g. per kilo in children) gives a rise of the blood-sugar curve amounting to about 60 or 70 mg. per cent. when the rise is defined as the difference between the highest blood-sugar value obtained and the fasting value, and provided that Hagedorn and Norman Jensen's technique is used and the blood samples are taken every 10 or 15 minutes. Even under these conditions, however, the rise of blood sugar varies somewhat, both in different normal individuals and in the same individuals on different days. A low blood-sugar curve—that is, a curve with a rise of 40 mg. per cent. or less—is found as an inconstant phenomenon in about 5 per cent. of the blood-sugar curves of normal individuals. I have *demonstrated that such a low blood-sugar curve is* considerably more frequent (50 per cent.) in sprue and Gee-Herter's disease than in normal people (Figs. 1, 2, 3, and 4).

TABLE II.—*Blood-sugar and Basal Metabolism in Sprue and Gee-Herter's Disease.*

No.	Age. Sex.	Date of examination.	Blood-sugar rise in mg. per cent.	Date of examination.	Basal metabolism (Benedict) per cent.	Remarks.

13					Normal.	G.-H. dis. (Lehndorff-Mautner).
14	47 M.	12/8/27	21	16/5/28	+12·6	Tropical sprue.
		3/1/28	51		+13·6	Tetany.
15	49 M.	12/1/25	63			Tropical sprue.

Diarr. = diarrhœa. Hyp. = hyperchromic.
G.-H. dis. = Gee-Herter's disease.

Table II. gives a survey of the blood-sugar findings in 12 patients. Nos. 6 and 7 had almost recovered and their blood-sugar curves were normal. Of the remaining ten patients eight (Nos. 1, 2, 4, 5, 8, 9, 10, 14) showed a low blood-sugar curve. In three cases (Nos. 1, 2, 14), however, the low blood-sugar curve was less constant, as examinations here sometimes showed a rise higher than 40 mg. per cent. Nevertheless, in all cases the higher rise occurred at times when the condition of the patient had improved considerably. Patient No. 5 likewise shows a higher rise in a good period (about 40 mg. per cent.) than was found on the three preceding examinations, which all were made during a poor period. These findings, together with the normal blood-sugar curves in greatly improved patients (Nos. 6 and 7), indicate that this abnormality subsides with recovery. Investigations that are still being carried on to explain how the low blood-sugar curve is brought about have shown its origin to be the same in sprue as in Gee-Herter's disease, and that it is not due to lowered absorption of the ingested glucose.[34]

The other metabolic abnormality common to sprue and Gee-Herter's disease is change in the basal metabolism. Of 12 patients examined one case of Gee-Herter's disease has once shown a normal basal metabolism (Lehndorff and Mautner), two cases of non-tropical sprue (Nos. 2 and 8) showed the basal metabolism to be lowered as much as 18 per cent., while the remaining cases showed an increase of the basal metabolism reaching as high as 43 per cent.

The objections, therefore, that have been raised against the view that sprue and Gee-Herter's disease are nearly related—probably identical—diseases are of no significance, and the low blood-sugar curve and the abnormal basal metabolism contribute further towards establishing the identity of these two lesions.

Conclusions.

The recognition and correct interpretation of non-tropical sprue forms the connexion between Gee-Herter's disease and tropical sprue and contributes towards establishing the near relationship, nay, the probable identity, of these diseases. Judging from the clinical manifestations, Gee-Herter's disease is just as identical with tropical sprue as is non-tropical sprue; the most conspicuous differences—infantilism, the rare occurrence of a pernicious blood picture and the frequence of halisteresis in Gee-Herter's disease—are readily explained by the fact that this disease is described in children. No one has suggested that these symptoms argue against the identity of these diseases. Gee is most likely right in grouping these conditions under one term—"the cœliac affection"—as representing the same lesion, but as long as their ætiology is unknown and their pathogenesis is obscure, it might be more correct to classify them as a special group of diseases, so as to emphasise their near relationship rather than to insist on an identity no one can prove. I have called this group "the idiopathic steatorrhœas" in order to emphasise that the chief symptom of the disease in its origin differs from those of the better-known forms of steatorrhœa: the pancreatogenous, the acholic, and, most likely, also of the enterogenous fatty diarrhœa.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

AT a meeting of this Section held on May 17th the chair was taken by Dr. J. S. FAIRBAIRN, the President, and a short note was communicated by Mr. HERBERT SPENCER on

A Straight Rod Pelvimeter.

This, he said, was a simple instrument which, when carefully used in a patient fixed on a level steady table, gave an accurate measurement of the true conjugate. The device consisted of a straight rod, pointed at one end and rounded at the other, with two uprights.

Mr. G. I. STRACHAN then read a paper on

Contra-indications to Irradiation in Carcinoma of the Cervix.

He said that such impressive results had been obtained by certain workers that in a number of centres radium was now used exclusively, but opinion was sharply divided on the wisdom of this procedure. In inoperable cases radium was now used to the exclusion of other methods and in many instances growths had disappeared temporarily or permanently. The idea had therefore got abroad that any inoperable case could be treated with radium. This was incorrect; unless cases were properly selected the patient might be made worse. There were five definite contra-indications.

1. An extreme degree of general emaciation and cachexia usually meant a foul surface to the growth, extreme anæmia, and massive extensions; in these cases radium was likely to produce a rapid deterioration and early death.

2. Extreme anæmia with a red cell count of less than three millions or a hæmoglobin index below 40 contra-indicated radium, which in itself tended to produce some anæmia.

3. Extensions and metastases might be contra-indications. Radium should not be applied if hydronephrosis or pyonephrosis was suggested by the presence of a tender swelling in the loin, for this implied ureteral involvement and obstruction, and radium would only increase the obstruction by causing fibrosis in the broad ligaments. Extensions to bladder or rectum, as shown by frequency, dysuria, rectal tenesmus, or induration and fixation, would require the insertion of radium needles dangerously close to bladder or rectal wall, hastening fistula formation. Fistulæ were absolute contra-indications, for radium caused sloughing and enlarged the opening.

4. Any inflammatory pelvic lesion, such as a foul sloughing condition of the growth, would mean massive necrosis under radium, with toxæmia and the likelihood of pelvic parametritis or peritonitis. Pyometra was equally important, and an attempt should always be made to pass a sound through the cervical canal before radium was inserted. If a thin stream of pus escaped the uterus should be drained before inserting radium. There was risk of peritonitis if radium was used in the presence of salpingitis, pyosalpinx, or pelvic abscess. Suspicion should be aroused by severe pelvic pain, tenderness and fullness in one or both lateral fornices or behind, with a persistent temperature up to 101°F. These inflammatory complications were more common than was generally recognised, and were difficult to feel even under anæsthesia if there was much parametric thickening.

5. Where the whole pelvis was caked and infiltrated by extension a local remedy like radium could do little good, and it was better to leave the patient in peace.

6. Any evidence of impaired metabolism, especially defective excretion of nitrogenous waste products, was a danger signal, and radium should be withheld.

These contra-indications were of two types—the temporary, which cleared up under appropriate treatment, and the permanent ones like ureteric involvement or extension to bladder and rectum. In the former case radium could be applied when the contra-indication had been removed. An indiscriminate application of radium to these cases had led to unfortunate and sometimes disastrous results. Radium should only be used by those who had had special study and experience.

The PRESIDENT agreed that grave cachexia was a very important contra-indication.

Mr. MALCOLM DONALDSON feared lest the wave of enthusiasm for radium should result in a following wave of depression and depreciation.

Dr. EDGAR HAYDON spoke of the serious anxieties of the irradiator, and mentioned that a small surface dose would often enable him to find the cervical canal amidst much sloughing. The dangers of salpingitis could not, he thought, be over-estimated.

Mr. VICTOR BONNEY read a paper on the

Results of Surgery Compared with the Results of Radium in Carcinoma of the Cervix.

Up to the end of 1923 he had performed Wertheim's operation for carcinoma of the cervix on 265 patients out of 420 seen. There were 105 five-year survivals, so that his relative cure-rate was 39·6 per cent. and his absolute cure-rate 25 per cent., and these figures would be higher but that for the purposes of the present comparison he had reckoned as dead of cancer 21 cases who had either been lost sight of or died of some other disease before their five-year cure period was up. Of the 265 patients operated on the regional glands removed were carcinomatous in 113 and not carcinomatous in 152, giving a gland-involvement rate of 42 per cent. Of the 113 whose glands were carcinomatous, 27 survived their operations five or more years, a cure-rate of 23·8 per cent., whilst of the 152 whose glands were not carcinomatous, 78 survived their operations five or more years, a cure-rate of 51·3 per cent.

In comparing the results of surgery with those at present obtainable by radium it was necessary to emphasise what was not generally appreciated—that the scope of radium applied from the vagina was no wider than that of surgery, because radium applied that way did not reach out to the regional glands. Out of every hundred unselected patients presenting themselves at a radium clinic roughly 40 were certainly beyond the scope of radium, for at least that number had carcinomatous glands by the time they presented themselves. On the other hand, out of every hundred unselected patients presenting themselves at a surgical clinic, roughly 40 also were beyond the scope of surgery on account of gross extension of the growth to parts operatively irremovable. These two groups of 40, however, were not identical, for that which was beyond the scope of radium included certain cases not beyond the scope of surgery, and that which was beyond the scope of surgery included certain cases not beyond the scope of radium. The surgeon could distinguish the 40 per cent. beyond the scope of surgery, for he could open the abdomen to make sure, but the radiologist was at the disadvantage that he could not detect the cases that made up the 40 per cent. refractory to radium and hence had to treat them, though all unknown to him, failure was fore-fated.

By either method, therefore, only somewhere about 60 cases out of every 100 presenting themselves unselected beforehand could be treated with more or less chance of success.

Results Compared.

The radiological figures he would contrast with his own five-year results were those of Heyman from the Radiumhemmet at Stockholm and those of Gray Ward from the Women's Hospital, New York, for they were the most favourable to radium yet published. Heyman's figures related to the cases he treated from

1920 to 1923—i.e., after operative treatment had been abandoned by the Swedish surgeons, so that they represented an unselected series, and the same applied to Gray Ward's as he had abandoned operation.

It had been objected that comparison between surgery and radium was vitiated because radiological clinics got sent to them a larger proportion of patients with advanced disease than did surgical clinics, but this objection disappeared in communities where operation had been entirely superseded by radium, for the cases then presented to the radium clinic became as representative of the cases in the community at large, as were the cases attending a gynæcological clinic. That the average advancement of the growths in Heyman's and Gray Ward's cases was about the same as that of the cases presenting themselves at an ordinary gynæcological clinic was shown by the fact that the proportion of cases *in extremis* (i.e., unsuitable for radium) in their series was no larger than that encountered by the gynæcologist.

The comparative figures were as shown in Table I.:—

TABLE I.

—	Cases seen.	Five-year survivals.	Absolute cure-rate (per cent.).	Cases treated.	Five-year survivals.	Relative cure-rate (per cent.).
Bonney ..	420	105	25	265 operations	105	39·6
Heyman ..	467	106	22.7	444 radiated	106	23·8
Gray Ward ..	138	31	22·4	134 "	31	23·1

The last of these comparisons was unfair to radium. for he, the speaker, had operated on only 63 per cent. *of his patients, whilst Heyman had radiated 95 per* cent. of his, and Gray Ward 97 per cent. of his, and it was obvious that the cure-rate would be the higher the smaller the percentage of cases treated.

The Radiological Operability Rate.

In the endeavour to make comparable the results attained respectively by surgery and radium, the patients treated by radium had been clinically classified into four groups of which the first two comprised those in whom the growth was limited to, or had only slightly passed beyond, the cervix. These cases were termed "operable," and their proportion to the total number of cases radiated had been called the "radiological operability rate." It bore, however, no relation to the operability rate of surgery, which was the proportion the number of patients operated on bore to the total number of cases presenting themselves. Moreover, operation was by no means always barred by wide extension of the growth, and the result was that the "radiological operability rate" was always much lower than the surgical operability rate, so that when the results of the cases styled "operable" by the radiologist were contrasted with the results of the cases operated on by the surgeon the latter were prejudiced, as shown in *Table II.*

TABLE II.

—	Cases treated.	Percentage of total cases.	Five-year survivals.	Cure-rate (per cent.).
Bonney ..	265 operated on	63	105	39·6
Heyman ..	186 } Cl.1 and 2 {	39	76	40·8
Gray Ward..	32 } radiated {	23	17	53·1

Results in Gland-free Cases.

It was possible, however, to make a much fairer comparison by contrasting the results he, the speaker, had obtained in his group of gland-free cases operated on, which represented a selection of 36 per cent. from all the cases he had seen, with the results Heyman and Gray Ward had obtained from their class 1 and 2 cases which represented a selection of 39 per cent. and 23 per cent. from all the cases they had seen respectively (Table III.).

TABLE III.

Gland-free cases operated on.	Per cent. of all cases.	Five-year survivals.	Cure-rate (per cent.).
Bonney: 162	36	78	51·3
Class 1 and 2: Cases radiated.			
Heyman: 186	39	76	40·8
Gray Ward: 32	23	17	53·1

There was a further method of statistical comparison that had the advantage of throwing some light on the question as to which cases are most likely to be cured by operation and which by radium. Out of every 100 patients presenting themselves to Heyman and Gray Ward respectively, only 60 (i.e., those whose glands were uninvolved at the time they presented themselves) were within the scope of radium treatment, whilst of those who presented themselves to him, the speaker, 63 out of every 100 were able to be operated on. Out of the 444 cases presented to Heyman, therefore, only 266 were in reality treatable by radium with any chance of success, and of Gray Ward's 130 only 82. Regarded in this way the figures worked out as shown in Table IV.

TABLE IV.

Cases presented.	Cases within scope.	Percentage of total cases.	Five-year survivals.	"Scope" cure (per cent.)
Bonney: 420 ..	265	63	105	39·6
Heyman: 467 ..	280	60	106	37·8
Gray Ward: 138 ..	82	60	31	37·7

This calculation showed that supposing it were possible to limit the use of radium to cases in which the glands were uninvolved the percentage of cures it would effect relative to the number radiated would be about the same as those effectable by surgery operating on both gland-free and gland-involved cases relative to the number operated on. Moreover, if one assumed for simplicity a gland-involvement rate of 40 per cent. for all the cases presented to himself, Heyman, and Gray Ward, then of the 420 cases presented to him 252 were gland-free and of these he cured 78, whilst Heyman, out of 266 gland-free cases, cured 106 and Gray Ward out of 82 cured 31, showing that if there were no such thing as glandular involvement radium would give better results than surgery. It was on the gland-involved cases that surgery attained its numerical superiority in absolute-cure-rate over radium, for all these cases were beyond the scope of the latter. Table V. made this clear:—

TABLE V.

—	Total cases seen.	Gland-uninvolved cases = 60%.	Cures.	Rate (per cent.).	Total cases seen.	Gland-involved cases = 40%.	Cures.	Rate (per cent.).
Bonney ..	420	252	78	30·9	420	168	27	16
Heyman ..	467	280	106	37·8	467	187	0	—
Gray Ward	138	82	31	37·7	138	56	0	—

Conclusions.

The figures and considerations he had put before them showed that the results he had obtained by Wertheim's operation were numerically better than those obtained by Heyman and Gray Ward by radium. It should, moreover, be remembered that, owing to the facilities enjoyed by the Radiumhemmet, none of Heyman's patients had been lost sight of, whereas he had lost sight of 13 patients, all of whom were counted for the purposes of this comparison as having died of recurrence. If amongst these 13 cases lost sight of there were only 5 five-year survivals (which was probably an under-estimate) he had really cured 110 out of the 265 cases he had operated upon. Moreover, his figures included patients operated on many years ago when his operative mortality-rate was 20 per cent. instead of 11 per cent. as it stood to-day for his last 100 cases.

Inoperable Cases.

He had kept no record of the 155 cases which he had to abandon as inoperable. Some were abandoned before radium came on the scene, and though many of those who came after were treated with radium it was at a time when the results of radium therapy were far different from what they are now. But the point was that, had he been able to treat these abandoned cases by radium in the same manner as they would be treated now, a certain proportion of them would have been cured. Heyman, between 1914 and 1916, had 17 cures out of 97 "inoperable" cases treated by radium; so that out of his, the speaker's, 155 inoperable cases somewhere between 15 and 20 should have been cured, which, together with five cures out of the 13 cases lost sight of, would have raised the total number of cures effected by him from 105 to between 125 and 130 out of the 420 cases originally presenting themselves—a result far superior to anything afforded up to the present by radium treatment alone.

Mr. Bonney said that he had dealt solely with the results of operation on the one hand and radium applied from the vagina on the other, for no evidence was yet available as to the results capable of being attained by radium applied through the abdomen as well as through the vagina, or of radium applied through the vagina in combination with operative extirpation of the regional glands. The latter appeared to him to combine the advantage surgery possessed in being able to reach out to the regional glands with the advantage that radium possessed in being able to ablate the local growth without resulting deformity and without injury to the bladder and rectum when these were involved. A good many years, however, must elapse before judgment on these matters could be passed. At the present time, in spite of the improved results of radium treatment, a greater number of lives could be saved by subjecting to operation all patients whose growths were removable by an expert in this branch of surgery, and treating the remainder by radium, than by using radium to the exclusion of surgery.

Discussion.

The PRESIDENT said he was glad Mr. Bonney had made out such a good case for surgery, since there was a danger that the pendulum would swing too violently to the side of radium.

Dr. SIDNEY FORSDIKE said that Mr. Bonney's figures were not comparable with any save those of the Wertheim clinic, but was he content with a 25 per cent. cure rate? Surgery had shot its bolt in the treatment of carcinoma of the cervix, but there was no doubt that the pendulum was swinging too rapidly. The practitioner who wished to apply radium must study for several years if he wanted satisfactory results. In a certain percentage of cases, where the only finding after treatment was a thickening in the vaginal roof, recurrence took place high up in the pelvic glands; for these radium must fail.

Dr. A. J. WRIGLEY showed graphs of the results obtained at St. Thomas's Hospital on 148 cases treated from 1918–1922. The five-year cure rate was 15 per cent. Eighteen per cent. of the cases had been considered operable, 20 per cent. borderline, and the rest inoperable. The end-results for the operable and borderline cases were about 10 per cent. better than Heyman's, but so much depended on the estimate of operability that this figure did not count for much. Cases had been treated either by Wertheim's operation or by total hysterectomy followed by radium. The former group showed slightly better results for the borderline cases, and the latter for the "operable." Of the inoperable, those untreated were all dead in 18 months, and most of them in 6 months. Of those treated with radium, half lived four months longer, but of the minority who survived the rate lengthened to four and a half years. Radium needles had only been in use three and a half years, but the survival rate curve, if continued to the five years, would be a little below Heyman's 13 per cent.

Mr. HERBERT SPENCER stressed the importance of knowing the meaning of "operability."

Mr. DONALDSON said that it was very difficult indeed to compare results of radiation and operation, and that only the absolute cure rates were comparable. It was a very big assumption that the same type of case went to Bonney as to Heyman. Radium was in its infancy, and much better figures would be obtained in the course of the next five years.

Mr. WILLIAM GILLIATT said that since 1923 he had treated all cases with radium, submitting the operable one to a Wertheim operation four to six months later. He had been struck by the small amount of operative difficulty caused by the radium. The patients did much better than those not treated by radium, and the fear of vaginal complications was much reduced.

Mr. D. C. L. FITZWILLIAMS said that Mr. Bonney's figures had proved that radium did almost as well as surgery, and, moreover, it must be remembered that radium figures were based on the work of pioneers. The operative and survival rates obtained by Lawson Tait would shock any hospital board to-day. The great radium centres had become stereotyped; radium ought to be distributed to many more centres and the advance would then be rapid.

Reply.

Mr. BONNEY, in reply, said he had tried to put the case fairly. His figures were not exceptional. The surgeon needed to treat a much smaller proportion of the cases presented to him than did the radiologist in order to obtain the same number of cures, and from the unoperated-on remainder rather over 10 per cent. of cures could be obtained by radium according to the latest figures of Heyman that he had given, whereas the radiologist had no residuum, having used up his stock of material in obtaining his results. The wave of enthusiasm for radium was very foolish and bound to be followed by disappointment. Far greater skill was required to get good surgical results than to get good radiological results. He had only one standard of operability—could he get the thing out?—and he operated up to the limits of possibility. The choice was not between surgery and radium but between surgery with radium and radium alone. His own operability rate was founded on an accurate computation at a time when the cases presented to him and Mr. Comyns Berkeley formed a sample of the cases in the community at large.

SECTION OF TROPICAL MEDICINE.

AT a meeting of this Section held on May 15th the chair was taken by Dr. J. B. CHRISTOPHERSON, the President. The Secretary, Dr. W. BROUGHTON-ALCOCK, communicated a paper by Prof. A. BESREDKA on

VACCINE THERAPY.

The power of antivirus to act directly and specifically on receptive skin cells had been shown, he said, by the well-known experiments on anthrax, and its value had now been extended to the cells of the alimentary tract. Vaccine treatment by the mouth had reduced the morbidity and mortality from dysentery when used prophylactically and therapeutically. It was as effective as serum, if not more so; it was never contra-indicated, was easily applied, and caused no unfavourable results. Of 3000 men treated in the Rhine Army none contracted dysentery, while 471 cases occurred among untreated men. For typhoid, oral vaccine had taken its place as ordinary practice. Of 4140 men treated with oral antivirus preceded by bile, not one developed typhoid; of 549 treated without bile 0·07 per cent. were affected. Oral vaccination was the only method adapted to rapid immunisation of large communities. Therapeutically applied, it could prevent the gradual encroachment of the *Bacillus typhosus* on cells which were still healthy, and cut short the period of illness. Moreover, the patient so treated would not become a carrier. Extensive experiments in Russia, Germany, France, and India had shown that the treatment was equally valuable for cholera and entero-colitis. Our ignorance of the intestinal flora in the latter condition was a great obstacle to progress, but the results were too good to be disregarded. Chronic diarrhœa in children yielded rapidly to oral antivirus, and the results in severe colitis were notable. Very good results had been obtained in pyelonephritis, but when a renal lesion was present as well as intestinal disorder, the oral treatment should be supplemented by instillation of antivirus into the renal pelvis and bladder. Of 31 cases of pyelonephritis, most of them previously treated unsuccessfully with hexamine and stock subcutaneous vaccine, only 11 had proved resistant to antivirus. Acute cystitis was relieved after four or five instillations, but chronic cystitis required 10 to 15 daily treatments. The results in urinary sepsis were very good and occasionally even remarkable.

Antivirus in the Eye, Nose, Throat, and Ear.

The eye had a greater degree of autonomy than any other organ; eye diseases rarely influenced the rest of the body, and the eyes were usually unaffected by general immunities. Immunity of the cornea did not even extend to the anterior chamber, but was confined to the cells which had actually been in contact with the immunising agent. Ordinary inoculation was useless to the ophthalmologist, so that he welcomed local immunisation which, used systematically and early, would undoubtedly save many eyes. The best results had been obtained in blepharitis, conjunctivitis, ulceration of the cornea, and dacryocystitis. Sometimes a temporary aggravation followed the treatment, but this could be overcome by bathing with sterilised water and was usually followed by speedy and complete recovery. Simple instillation usually gave good results, but the antivirus could also be applied on a pomade with vaseline and lanoline. Autogenous preparations were better than stock ones. Local vaccine had a startling effect on furunculosis of the ear; the introduction of a wad of cotton-wool soaked in antivirus immediately reduced the pain, while swelling and redness disappeared in a few days and the expulsion of the core was accelerated. For otitis media 10–15 drops should be instilled into the ear, and a gauze lampwick soaked in vaccine should then be put in place. One case of chronic otitis media had been cured in 20 days, and it was reasonable to hope for more results when the flora of this condition was better known. In nasal infections subcutaneous vaccine was useless, and disinfectants could not be expected to do good when they acted on the surface only and weakened the mucous membrane. Local vaccine treatment was, however, very successful; it established a strong osmotic drainage as soon as the wicks were withdrawn together with the accumulated pus. This hypersecretion swept all before it and shortened both acute and chronic stages of sinus disease. Where surgery was unavoidable, pre- or post-operative use of the virus was valuable. Ozæna was usually regarded as insusceptible to treatment, but antivirus had given very favourable results. For chronic laryngitis the treatment could be applied directly by means of a vapouriser several times daily. Intratracheal applications were being more and more used, especially for pulmonary gangrene and bronchiectasis. Some day it might be possible to dry up, if not to cure, tuberculosis. Ulcerative stomatitis, gingivo-stomatitis, suppurative gingivitis, glossitis, acute periostitis with abscess, and alveolitis after extraction could all be treated by injection of antivirus into the tissues or by dressings. Neuralgia was stopped in about two hours, always within 12 hours; suppuration cleared up in a few days and splinters were expelled. Antivirus acted with peculiar speed and thoroughness where classical treatment was useless or very slow in action. The results of its use in pyorrhœa alveolaris had been very satisfactory.

Antivirus in Gynæcology and Dermatology.

The use of antivirus in pelvic conditions was in its infancy and each worker had his own way of applying it. Improvement had been recorded in metritis, alone or with extensions to surrounding parts. For the former, ovules or compresses were applied to the cervix, and for the later intradermic antivirus was applied to the lower abdomen. It could be used preventively or curatively for puerperal conditions and for mastitis. It provided the most rational procedure for the prevention of breast abscess. It gave most encouraging results in pyodermatitis, lessening suffering, permitting return to ordinary life, and guarding against relapse. Hundreds of boils and carbuncles had been treated by antivirus, on dressings or intracutaneously. Impetiginous abscess, sycosis, acne, sores, burns, and erysipelas yielded to it. Buboes were better in 24 hours and healed in four days if they were punctured and the released pus replaced by antivirus. Soft chancre turned to a healthy looking sore. Local vaccine treatment of urethritis encountered difficulties on account of the anatomy of the parts. Results had been uneven in the male, but good in the female, even after other methods had proved useless. Antivirus therapy was being used more and more in surgical cases before, during, and after operation, especially for intervention in septic organs. It had also endless scope in veterinary practice.

The Case against Antivirus.

General W. F. **Harvey** said it was difficult to know exactly what Prof. Besredka meant by antivirus; sometimes he spoke of it as specific; sometimes as non-specific; sometimes as if it acted on the cells, and at other times as if on the bacteria; sometimes as if it were dead; and at other times as if it were living and capable of multiplying and penetrating tissues. The method had been used in the army for gonorrhœa, and centrifugalised washings of young cultures had been found better than old ones. Intradermic use was giving quite good results. Oral vaccination for intestinal disorders had been tried in the army 20 years ago, and the investigators had at that time concluded that the production of antibodies in the blood was very irregular; agglutinins were never produced. Antivirus had been used for dysentery in the Shanghai Expeditionary Force, but unfortunately the method was so harmless that nobody would consent to act as controls, and the 5000 men had all had it. In the first season there had been 28 cases of dysentery, and in the second season 48 cases of proved dysentery and 400 of enteritis. These patients had undoubtedly had antivirus, so that the protection was not complete.

Prof. **Alexander Fleming** agreed that it was difficult to discover what antivirus was. Prof. Besredka seemed to ascribe the inhibitory action of old broth culture to some specific antibody; in the past it had been thought to be due to exhaustion of food substances or accumulation of waste products. In some cases the latter was undoubtedly the cause. There were probably many factors contributing to the end-result. Prof. Besredka seemed to expect antivirus to penetrate where antiseptics would not go—e.g., to the nasal submucosa—and spoke of an "osmotic drainage," which suggested a process other than that of immunisation. He claimed wonderful results for this exhausted broth, but relied chiefly on clinical reports by workers not under his own supervision. Clinical reports, as every advertiser knew, could be obtained. A number of people had produced evidence that applications of ordinary broth had the same effect as antivirus, both acting by attracting phagocytes in large numbers. Prof. Fleming had recently grown a certain mould in broth and found that after about ten days the broth developed an inhibitory action on pyogenic cocci, even in considerable dilutions. The results of applying this broth to suppurative conditions were as good as, if not better than, those cited by Prof. Besredka. There was no specific immunising effect at all. The medium used in antivirus treatment might have more implications than any specific immunising action.

Prof. J. C. G. Ledingham contributed a paper (read by the President) in which he said that only the experienced clinician, trained to evaluate data from many therapies, could wisely assess Prof. Besredka's results. In scarcely a single particular had his views of the action of antivirus been accepted. The skin of laboratory animals could be so treated by specific and non-specific means as to withstand and localise infections of low virulence. If the infection were highly virulent only the specific antibody would produce immunity. Poultices impregnated with ordinary broth could make a skin area an unsuitable medium for any infection. Their action was probably twofold: increase of vascularity, bringing more antibody from the general circulation, and stimulus to the local reticulo-endothelial cells by the small amount of antigen present. The local defences at various points varied greatly in intensity, but all parts were vulnerable if a sufficient dose of infection were introduced. Oral vaccination could give some immunity against intestinal infections, but it was doubtful if this could compare with an adequate dose of vaccine subcutaneously.

Dr. Graham Forbes said that many people had been unable to repeat Prof. Besredka's results with dysentery, but rhino-inoculation gave better results and was especially suitable for hypersensitive and delicate infants. It might prove valuable for nasal diphtheria and carriers.

Dr. Dennis Embleton said he had tried repeatedly to obtain results from antivirus treatment and had failed. The paper had consisted of extravagant claims for treatment and some claims for prophylaxis; these two parts should have been kept separate. The work had not been brought forward in a scientific manner; claims had been based on small series of cases. The paper ought not to have been brought forward and fathered by the Society in this way, for it might carry weight with people who could not judge and estimate the value of the work.

Dr. Broughton-Alcock remarked that antivirus had had an extensive trial and there was a good deal of literature about it.

Dr. H. S. Stannus commented on the lack of first-hand information about antivirus and said there should be more before the method was condemned, and Dr. Embleton explained that he had not intended to condemn the method, but only its form of presentation that evening, which was not such as to carry conviction.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

A meeting of this Society was held in London on May 3rd, with Colonel L. W. Harrison in the chair. A paper on

Vasostomy and its Place in the Treatment of Early Urethritis

was read by Mr. Frank Kidd, who said the operation had not yet been practised in this country, though it was projected in 1905. Until 1928 Mr. Kidd had reserved it for chronic cases of vesiculitis. He had been struck by letters to The Lancet (1928, i., 883 and 989) last year from Mr. Peart, who said he had employed vasotomy with satisfactory results. Criticisms on a priori grounds had followed in the correspondence columns, but they were by people who had not had experience of the procedure. Mr. Kidd had long noticed that many cases of early urethritis presented themselves in which the condition was confined to the anterior urethra. But after a week or two of irrigation, when all signs of discharge had disappeared and the urine was clear, it suddenly became hazy, with the supervention of acute prostatitis and vesiculitis, which required several months of treatment. In a number of cases he thought a quiet ascent of gonococci took place, the organisms lying dormant in the prostate or epididymis for some weeks before either manifesting their presence or dying out. In some cases, he suggested, if the patient indulged in alcohol or venereal excess, or had influenza, or treatment was too strong, though the anterior urethritis disappeared, the resistance of the deeper tissues broke down, bacteria came through, and the result was violent deep urethritis, prostatitis, vesiculitis, and even epididymitis. In these cases it seemed quite reasonable to cut down and fill each vesicle with colloid silver, or any other substance which would bring about complete and quick destruction of the organisms.

Though it was not easy to persuade patients who suffered from early gonococcal urethritis to submit to vasostomy, he had dealt in this way with five selected cases at St. Paul's Hospital, and observed the final results. Three were cases of early acute posterior gonococcal urethritis. The first had had his trouble a little over a fortnight, and had developed a deep posterior haze and a swollen, tender prostate. Mr. Kidd cut down on each vas, and washed out each vesicle with 5 c.cm. of a 5 per cent. solution of colloid silver. Daily posterior irrigation with weak permanganate was given for three days. He left the hospital and had no treatment of any kind since. He was followed up for three months and was found to be cured. Never before had the speaker seen acute posterior urethritis cured in three days by any method. The second patient had posterior urethritis, with swollen prostate, as a result of contact 13 days previously. Posterior daily irrigation was given for nine days after the operation, but Mr. Kidd was unable to follow up the case. At the ninth day gonococci could not be detected in the urethra, and there was no discharge. The third case was very dramatic. Acute gonorrhœa was contracted on June 4th, 1928, and on the 18th the patient was admitted into St. Paul's Hospital with profuse hæmaturia, strangury, and greatly increased frequency of micturition. Each attempt at irrigation brought on hæmaturia, therefore he was left in bed for a time. On July 11th, as no progress was being made, Mr. Kidd cut down on each vas and washed out each vesicle with colloid silver. Three hours after the operation pain, frequency, and hæmorrhage had vanished, and urethral discharge disappeared the next day. Sometimes in chronic cases, after washing out a vesicle, there was still some pus, and the vesicles were somewhat thickened, but no gonococci were found. The next patient had had gonorrhœa two months; he had had the disease twice in the past, each time with some arthritis. Mr. Kidd washed out the vesicles with 5 per cent. colloid silver, and afterwards gave posterior irrigation with permanganate once daily for eight days. The discharge disappeared but the patient still had fever, so 1 c.cm. of symmetrical urea products ("s.u.p. 36") was injected intramuscularly on three successive days. On the twelfth day the fever had wholly departed, there was no discharge, the urine was clear, and the joint trouble cleared up. He was kept under observation until the twentieth day, but without further treatment, and he went out with no discharge and the urine clear. Another case was that of a man aged 68 who contracted severe gonorrhœa. His doctor had failed to carry out irrigation properly; the only result of it was to project other germs into the urethra, including *B. coli*, and the discharge became severe. Mr. Kidd, under local anæsthesia, washed out each vesicle through the vas, and the patient was irrigated daily for a week. The discharge disappeared, but the urine remained hazy for some weeks, though no more gonococci or further discharge were to be seen.

Irrigation was discontinued, and hexamine was administered, and then the case cleared up.

Mr. Kidd submitted that, small as was the total number of cases brought forward by Mr. Peart and himself, the results justified further research and comparison of notes. Surgeons in the Services enjoyed good opportunities for carrying out this treatment, which produced such rapid results in suitable cases. Then the question of ensuring a continuance of treatment while on board ship or on foreign service would not arise. He did not advocate it for every early case, as many cases of anterior urethritis reacted quickly to irrigation, controlled by the urethroscope. There were also many posterior cases of urethritis which reacted in two or three months to prostatic massage and posterior irrigation. But he was sure that in a large number of cases this operation of vasostomy would be of distinct use. Certainly it would enable the medical man to tide over the acute embarrassment of a man returning from abroad with the disease who was expected quickly to rejoin his wife; also for the young who became infected shortly before marriage. He intended to use the operation more in joint cases, as it seemed to him the quickest way of clearing up the joint condition. When vasostomy was contemplated it was essential to put the patient to bed for at least three days; a week in bed was better. There was a temptation, especially in America, to do the operation in out-patient departments and under local anæsthesia, allowing the patients to walk. In Mr. Kidd's opinion that was a mistake. And during the days that the patient remained in hospital posterior irrigation should be carried out. Pyuria and haze in the urine should not cause discouragement; they might result either from chemical irritation or from secondary infections. The operation was more difficult under local than under general anæsthesia, at least at first. When he did it in 1923 he left the vas exposed, but he had discontinued that, as it was difficult to get a second or a third wash through.

The operation involved some risks, but they were not common. If the vas was not carefully stitched up a leakage of colloid silver would occur, and the consequent irritation might result in the formation of a stricture at the site of puncture. A real stricture, if occurring on both sides, might mean sterility. Out of his 50 cases complaint of sterility had been made in only one case, and Mr. Kidd felt convinced that the man was sterile before the operation was done; certainly he was not a father. Perhaps it was better to puncture the vas with a needle, and not to cut it at all.

Discussion.

Mr. J. F. **Peart** said he had done vasostomy only twice, the last time a year ago, and in both cases the results had been dramatically good. The first patient had had gonorrhœa only seven days, but even then epididymitis was evident. The condition cleared up completely three days after operation. A month later the patient gave himself a severe alcoholic test, but no further signs of the disease appeared. The second case was a more serious one, as the patient had been acutely ill with gonorrhœa for three or four weeks before he was seen. The temperature was 101° F., and he had very acute epididymitis. When Mr. Peart was called in, he evacuated the epididymitis and injected the silver only on the affected side. On the day following the rise of temperature the discharge and the pain had disappeared. When seen a month later there were no gonococci. But he used, for both his cases, a much stronger silver solution than Mr. Kidd employed—namely, 20 per cent.

Mr. F. **Fowler Ward** spoke of having done vasostomy many times for chronic gonorrhœa. He was convinced of the value of the operation.

Mr. **Hugh Lett** thought the form of silver used possessed considerable power of penetration, and remained for some time in contact with the vesicles. The danger, as with every new method, was lest it should be used indiscriminately for every kind of case of the disease. A further real danger was that when the operation was done on both sides a stricture might occur on both sides. That alone would deter him from doing it except in very severe cases. If limited to the suitable type of case he regarded the operation as a very distinct advance.

Mr. V. E. **Lloyd** spoke of his experiments in injecting methylene-blue in the cadaver, remarking that he was led by these to conclude that some of the cases which reacted so well to silver preparations during life were infections of the ampulla of the vas rather than of the vesicles themselves.

Mr. G. E. **Neligan** said he had done vasostomy in three cases of chronic gonococcal infection of vesicles and prostate which did not yield to other forms of treatment. He deprecated doing it on any but carefully selected cases. He discussed the modus operandi of the silver preparation, and expressed some doubt that the injection described could directly cure epididymal orchitis.

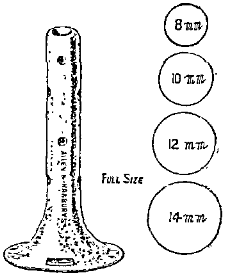
Mr. A. H. **Harkness** said that cases of acute posterior urethritis could usually be checked by giving local irrigations for 48 hours, followed by large doses of sandalwood oil.—Mr. **John Adams** asked how it was considered that cure of joint conditions was so quickly brought about by this treatment.—Dr. B. B. **Sharp** said he would hesitate to employ the operation except for chronic relapsing vesiculitis, which often caused despair.—Dr. E. G. **Ffrench** spoke of quick cures following vasostomy. Had this operation been known and practised during the war, many men could have been returned to the line weeks before they were sent.

Mr. **Kidd**, in his reply, said he was convinced that the arthritis in these cases was due to vesiculitis, and soon after the vesicles were empty the joint condition cleared up.

New Inventions.

DYSMENORRHŒA TUBES.

A dilatation of the cervix for dysmenorrhœa gives freedom from pain of the spasmodic type for only 12 to 14 months, as a rule. Stems have been used to ensure prolonged dilatation at the time of operation and are inserted for four to five days. Their use lengthens the time of freedom from recurrence of the pain. It was thought that the nest of stems, graduated to suit different sizes of uteri here illustrated, would be an improvement. They are silver electroplated on brass and of four sizes, 8, 10, 12, 14, corresponding to the sizes of Hegar's dilators. They are hollow, rounded at the upper end, and the wall of the tube is perforated with small holes. The base has two holes for the insertion of a withdrawal tape. They are long enough to occupy the uterine cavity and so straighten an acute antiflexion of the corpus uteri. The cervix and body of the uterus are dilated to the extent desired, and a stem the size smaller is inserted after steadying and exposing the cervical canal by vulsellæ on the anterior and posterior lips.



A nest of four of these is made and supplied by Messrs. Allen and Hanburys, Limited, Wigmore-street, London, W. 1.

Reviews and Notices of Books.

FRACTURES AND DISLOCATIONS.

Immediate Management, After-care and Convalescent Treatment, with Special Reference to the Conservation and Restoration of Function. Second edition, revised. By PHILIP D. WILSON, A.B., M.D., F.A.C.S., Instructor in Orthopædic Surgery, Harvard Medical School; and WILLIAM A. COCHRANE, M.B., Ch.B., F.R.C.S. Edin., University Tutor in Clinical Surgery, University of Edinburgh. London: J. B. Lippincott Company. 1928. Pp. 789. 45*s.*

THIS new edition of a work already well known has been brought thoroughly up to date by the inclusion of new methods and illustrations, and constitutes a worthy monument to the labours of the fracture service of the Massachusetts General Hospital. Containing, as it does, 1029 illustrations, all of them apt and admirably reproduced, it puts the subject of fractures and dislocations before the reader in a most attractive form. What a relief it is to find authors with the courage to discard illustrations and descriptions of time-honoured splints of bygone ages which still occupy space in our text-books, in our hospital splint stores, and even on our examiners' tables! Instead of these we are given admirable accounts of the use and application of methods of which the value has been proved by experiences of the war and the post-war period. The mechanism and anatomy of the various fractures are clearly described, and the appropriate means of reduction and fixation are detailed, but we feel that with the material on which the authors are able to draw more attention could with advantage be given to prognosis, a side of fracture work so important to the patient and so troublesome to the surgeon. The book is intended to meet the needs of the general practitioner, but we doubt whether many practitioners would be justified in attempting many of the methods described. The authors give to open operation in simple fractures rather grudging recognition. The advice that "when metal plates, screws or bands are used it is advisable in all such instances to remove them at a later period when union has been obtained" is surprising. The reason given—"that the presence of such foreign bodies in contact with bone is apt to be harmful in the long run, and may determine the development of a localised osteomyelitis or weaken the bone to such an extent as to result in fracture"—would place the technique of any less eminent surgeons than the authors under suspicion.

Minor defects such as these only serve to emphasise the excellence of the work as a whole; it is one which all who have to deal with fractures will find invaluable. It is difficult to know whether the publishers are to be more congratulated on the reproduction of the illustrations or the authors on their selection, but the result makes one of the most readable works on fractures with which we are acquainted.

IMPERATIVE TRAUMATIC SURGERY.

With Special Reference to After-care and Prognosis. By C. R. G. FORRESTER, M.D., F.A.C.S., Consultant, Teaching Staff, Illinois Post-Graduate School, Laboratory of Surgical Technique, Chicago. New York: Paul B. Hoeber, Inc. 1929. Pp. 464. $10.00.

THE author explains that he has chosen his title as being more descriptive than the previously contemplated one of "Industrial Surgery." We might have forgiven, while still regretting, his second thoughts, but when we find him referring throughout his work to "the traumatic surgeon" and "traumatic surgery," and using the expression "surgically compounding a fracture" in reference to the use of the Steinman pin the effect is definitely irritating. The book itself deals mainly with the treatment of fractures and nerve injuries, and embodies Dr. Forrester's experience of 26 years devoted to this branch of surgery. The advice given as to treatment is clearly expressed, and considerable attention is paid to the prognosis of the various injuries, a matter of great importance in industrial accidents. On the whole the author employs a longer period of immobilisation than is usual in this country, but this is probably due to the type of patient with whom he is dealing. He shows considerable ingenuity in the methods he employs, and his results, which are presented with admirable candour, do great credit to the thoroughness of his work. The book is well illustrated and printed, with the exception of the reproductions of the author's fracture cards. These, of which some 70 are given, are far too small to be read without considerable discomfort, and while no doubt excellent as case sheets, it seems doubtful whether they are necessary in the presentation of details of cases in a work of this kind. We hope that Dr. Forrester, encouraged by the results of his first essay in authorship, will continue to write on surgical subjects; but we trust he will in future refrain from referring to himself or any other as a "traumatic surgeon."

A GRAPHIC GUIDE TO ELEMENTARY SURGERY.

By Prof. Dr. TH. NAEGELI, Bonn. Translated by J. SNOWMAN, M.D., M.R.C.P., with an introduction by Dr. C. GARRÉ, Bonn. London: John Bale, Sons and Danielsson, Ltd. 1929. Pp. 205. 12*s.* 6*d.*

THE object of this book is to present an introduction to surgery in pictorial form, with simple illustrations as the main feature, and the text reduced to a minimum. With such an object every teacher must be in sympathy, but the present volume scarcely attains its end. Upon the title-page we are informed that the book contains 322 illustrations (mostly coloured), but the illustrations are diagrams (of the utility of some of which we have grave doubts), and the colour consists in a crude use of red, yellow, and blue to emphasise points in the diagrams. The text is more satisfactory than the illustrations and constitutes an introduction to elementary surgery on orthodox lines. The translation is performed with Dr. Snowman's usual facility, but we doubt whether this book is likely to find favour with students in this country.

ELEMENTARY MEDICINE.

Aids to Medicine. Fourth edition. By JAMES L. LIVINGSTONE, M.D., M.R.C.P. Lond., Junior Physician, King's College Hospital, London. London: Baillière, Tindall and Cox. 1929. Pp. 414. 5*s.*

DR. Livingstone has succeeded in enclosing a surprising number of the medical facts that the student requires for qualification within the space of 414 pages. To decide what to insert and what to omit and to lay due and proportionate stress on individual diseases in such a small volume must have been a difficult task, and on the whole it has been well accomplished. There are some points to criticise. The Schick reaction is not mentioned. If adherent pericardium deserves one page, coronary thrombosis deserves more than four lines. The subject of gastric ulcer is introduced as follows: "The simple perforating ulcer of the stomach or duodenum occurs most commonly in girls between the ages of 15 and 25. . . . Predisposing features are chlorosis, dyspepsia, and constipation." The ordinary chronic ulcer is surely commoner in men, while the acute ulcer is not here described. The leukæmias are divided into three groups, the one acute form being described as having a white blood count "from 2000–50,000 almost entirely of the mononuclear variety—probably of myeloblastic origin." Although the acute forms are rare, we cannot see any justification in grouping acute lymphatic and acute myeloid leukæmia as one disease. Spinal cord tumours occupy 12 lines. More space could well have been given here, for a correct diagnosis may mean much more to the patient than in such conditions as the muscular myopathies which are given fair prominence. A chapter is devoted to a synopsis of the more common skin diseases.

The book is clearly and concisely written, and the treatment of conditions such as diabetes, pernicious anæmia, and peptic ulcer are supplied in a just and up-to-date manner. To those students who are accustomed to occupy themselves with a small book a week or so before an examination this one can be recommended.

Practice of Medicine. A Manual for Students and Practitioners. Fifth revised edition. By HUGHES DAYTON, M.D., Consulting Physician to the United Hospital, Postilaster, New York. Philadelphia: Lea and Febiger. 1928. Pp. 340. $2.25.

THIS edition has been revised and brought up to date. Additions include an outline of the Dick test in scarlet fever with some remarks on the use of serum in prophylaxis and treatment and a brief account of the use of insulin in diabetes mellitus. Descriptions of the more common affections of the upper respiratory and digestive tracts, which had previously been omitted for lack of space, have now been added. The book contains much essential information required by the student revising for a qualifying examination, and has the additional advantage that it is small enough to fit easily in the pocket, while the print is large and clear.

Elementary Medicine in Terms of Physiology. An Introduction to Clinical Work. By D. W. CARMALT JONES, M.A., M.D. Oxf., F.R.C.P. Lond., Professor of Systematic Medicine, University of Otago, N.Z.; Physician, Dunedin Hospital; Consulting Physician, Westminster Hospital. London: H. K. Lewis and Co., Ltd. 1929. Pp. 364. 12*s.* 6*d.*

ONE of the most critical periods in the career of a medical student is the time when he first begins his clinical work. Up to that period his energies have been chiefly devoted to the study of anatomy and physiology, physics and chemistry, only too often under the tuition of those whose interests in the practical problems of medicine are slight. When he goes into the wards the position is abruptly reversed. He is suddenly confronted with the problems of disease, often by teachers whose physiological interest and knowledge has been largely submerged in the study of pathological processes and symptoms. Because of this unfortunate arrangement the continuity of the medical curriculum may be lost, and also much of the knowledge painfully acquired during the first two or three years of the curriculum. Dr. Carmalt Jones has recognised this chasm and has attempted to bridge it in this book by building up the principles of medicine for the student on a foundation of physiology. The scope of the work is limited to the recognition of organic disease, for, as the author points out, the practical questions of treatment and prognosis and the scientific one of ætiology belong to a later stage in the student's career.

The book opens with a brief outline of the causes of disease, and this is followed by a short account of the methods of examination of the various systems. The common disease syndromes are then dealt with according to systems. Throughout the book the effect of pathological changes on the normal physiological processes are made the basis of the teaching. Explanations are in simple language, while only such details of pathology and bacteriology as are necessary for understanding a disease are included, and there is no discussion of ultimate ætiology. Naturally this method has involved arbitrary limitations in many directions. There is, however, much in the book which should help the medical student to make his physiology the basis of his medicine rather than, as it so often is now, a prelude which appears to bear no relation to the theme which follows it.

THROMBOSIS AND PHLEBITIS.

Phlébites, Thromboses et Embolies, Post-opératoires. By Dr. J. DUCUING, Professeur Agrégé, Faculté de Médecine, Toulouse, France. Paris: Masson et Cie. 1929. Pp. 478. Fr.60.

THIS book is a comprehensive review of the whole subject of venous thrombosis and phlebitis, particular stress being laid on post-operative conditions. All types of thrombosis and phlebitis are dealt with from the pathological and clinical sides. There are chapters on the anatomy of the veins most commonly involved, the pathological changes underlying thrombosis, and the experiments performed by the author. Treatment, including prophylactic measures, is fully discussed. Dr. Ducuing has evidently studied his cases from the point of view of thrombosis more minutely than most surgeons, for he gives a much higher percentage incidence of clinically manifest thrombosis than any other author, and, moreover, believes that embolism frequently occurs where even the most meticulous examination can reveal no evidence of thrombosis. Dr. Ducuing sets out in detail the signs and symptoms on which his diagnoses are based, and gives case records to illustrate his points. Of particular interest are his investigations into the flow of blood by means of radiological observation of lipiodol injected into veins; on the basis of these investigations he attributes an important rôle in the production of thrombosis to venous spasm. His statistics are not always convincing. For instance, the total incidence of embolism occurring at various ages is stated, but as it is in no way related to the number of operations performed at these ages, an erroneous impression is given.

The book is not easy to read, for its continuity is much broken up with headings and subheadings, and the sequence of thought is not evenly maintained. The author has, however, summarised an exhaustive survey of the literature on all aspects of the question and has brought to his subject a wide clinical experience, a personal enthusiasm, and an impartial judgment. The presence of an extensive bibliography and a full index deserves record, since this feature is too often lacking in French monographs.

TRIAL OF JOHN DONALD MERRETT.

Edited by WILLIAM ROUGHEAD. Edinburgh and London: W. Hodge and Co. 1929. Pp. 326. 10*s.* 6*d.*

John Donald Merrett, a young man about 19 years old, educated at an English public school and afterwards at Edinburgh University, was tried in Edinburgh in 1927 on the two charges of having murdered his mother and of having uttered forged cheques upon her banking account. Mrs. Merrett had died of a revolver bullet wound received at a time when she was alone in the room with her son. He came out and called to the servant that his mother had shot herself. Mrs. Merrett was taken unconscious to the Royal Infirmary at Edinburgh, where her son explained her conduct as due to "money matters." In these circumstances she was treated as an attempted suicide; she lived for a fortnight, and until a few days before her death her mind was perfectly clear; but, as she was never told what was the matter with her, she was naturally at a loss to understand what had occurred. The bullet entered the right ear and lodged behind the nose. The late Prof. Harvey Littlejohn's post-mortem conclusion was that the position of the wound was consistent with suicide; "there is some difficulty in attributing it to accident, although such a view cannot be wholly excluded." Several months later the suspicion of murder began to gain ground, especially as it became clear that young Merrett had forged his mother's signature on some 29 cheques. Prof. Littlejohn then revised his former opinion in a second report, in which he described the accidental discharge of the pistol or the intentional self-infliction of the wound as equally inconceivable in view of the direction of the bullet, the position of the wound, and the absence of any blackening of the skin. At the trial much attention was given to the questions of the distance at which a pistol-shot would produce blackening, and whether the discoloration would be permanent or would be removed in washing the wound. In addition to firearms experts several medical witnesses dealt with these matters, Prof. Littlejohn and Prof. John Glaister as witnesses for the Crown, and Prof. G. M. Robertson and Sir Bernard Spilsbury on the other side. Merrett was found guilty of the forgery; on the murder charge there was a majority verdict of "not proven."

The case, which forms one of the Notable British Trials series, is edited with great competence and enthusiasm by Mr. William Roughead. As, however, he manages to convey a strong opinion upon the cause of Mrs. Merrett's death, the inclusion in that series of a trial which took place only two years ago seems open to criticism. A man who has been so recently acquitted of murder ought not so soon to be re-tried, either by journalists or historians.

COSMETICS.

Die Behandlung der kosmetischen Hautleiden. Second edition. By Prof. E. KROMAYER. Berlin: George Thieme. 1929. Pp. 124. R.M. 5·50.

THE art of cosmetics, by which is implied the correction of cutaneous stigmata, not serious in themselves but obnoxious to their victims, is almost ignored by the profession in this country. The dermatologist, whose knowledge of the fundamentals of his science would seem to mark him as the natural and legitimate practitioner in this field, is often too busy in the domain of disease to trouble himself with blemishes, and has no desire to run the risk of earning the opprobrious title of beauty specialist. The unfortunate patient is therefore frequently driven to seek the aid of the unqualified quack or the beauty-parlour, and is lucky if he escapes their clutches in a condition in statu quo ante, both physically and as regards the pocket. It is curious how difficult it is to erase a label. In Germany, the names of Max Joseph and Kromayer have been honoured as cosmetic specialists for nearly half a century, and both of them number among their clientèle many English patients, to whom it would never occur that in this country their benefactor would probably have succumbed long since in the slough of professional suspicion and contempt. It is high time that cosmetics should be placed on a reputable footing, and receive official recognition. She is, after all, the younger sister of dermatology, and no Cinderella at that, for success in this field demands at least as much medical knowledge, and even more manual dexterity, than is considered essential in the elder relation. To any beginner we can strongly recommend Kromayer's manual. He is one of the pioneers of actinotherapy, the water-cooled mercury-vapour lamp that is called by his name was invented no less than 22 years ago, and in its own sphere still has no competitors. If that had been his sole contribution to science his name would live, for the instrument can be used, as a brief perusal will show, in many unsuspected ways. Its well-known attributes are not unduly stressed by the author, but we cannot too strongly emphasise that it is superior to X rays in one most important particular—it is difficult, nay almost impossible, to do lasting damage—an issue that is not always remembered when repeated radiotherapy is undertaken.

A description of the uses and indications of the author's ring-knives and burrs (borrowed from dentistry) is followed by a brief but very useful essay on the principles underlying the treatment of dry and greasy skins; this section contains some excellent and easily memorised formulæ. In the next chapter on corns, and that succeeding on boils, the author describes the uses of ignipuncture, a rather neglected procedure in these days of radium, and there follows a detailed treatise on the ætiology and treatment of acne, than which none better could have been written. The treatment of rosacea and its associated nasal hyperæmia by means of compression application of the "blue-filtered" Kromayer light is worthy of study by every dermatologist, and in no other work that is known to us has a rational treatment of "large pores" been attempted. The remaining chapters are devoted to a study of such common stigmata as lichen pilaris, hyperidrosis—with the author's own method of using X rays (a dangerous expedient in unskilled hands for this affection)—seborrhœa, the various alopecias, and hypertrichosis. The methods advocated for the latter vary according to the size and inclination of the individual hairs. For those emerging at right angles to the surface and of coarse texture, the 0·8 mm. ring-knife is recommended. This is rotated evenly round shaft and root-sheath, thus dividing the epidermal connexions, and allowing easy withdrawal from the loosely connected fibres of the subcutaneous tissues. As the author writes: "The method does not seem to have gained many adherents" . . . it is nevertheless of good service in selected cases. Permanent epilation by X rays and some new claims by the younger generation of radiotherapists are critically examined, and rightly condemned. There is no safe X ray method for the permanent cure of hypertrichosis yet designed; and electrolysis is still the best and safest procedure when skilfully conducted. The two sections on this important subject will repay close study. It will be news to most experts that it was Kromayer who designed the now universally employed "insulated" needle.

Equally wise and valuable are the concluding chapters on the eradication of the almost inexhaustible varieties of nævi, vascular and otherwise, by alcohol injections, radium, CO_2 snow, ignipuncture, each according to its size and texture. And yet, including, as it does, a really vast amount of information, this little paper-covered volume consists only of 124 pages.

A general index, and one relating to the author's unique contributions to the subject, conclude an eminently readable and scientific treatise.

COMPARATIVE PATHOLOGY.

Lectures on Plant Pathology and Physiology in Relation to Man. By L. O. KUNKEL, H. C. COWLES, G. H. COONO, E. C. STAKMAN, H. H. WHETZEL, and W. J. V. OSTERHOUT. London and Philadelphia: W. B. Saunders Company, Ltd. 1928. Pp. 207. With 16 figures. 12*s*.

THESE lectures, given under the auspices of the Mayo Foundation, bring out very clearly the specialisation of racial susceptibility and resistance of plants to parasites and the corresponding variations in the aggressive qualities of fungi. Animal pathologists know of the phenomena but they appear much more plainly in plants, where constitution is evidently of paramount importance. It is also interesting to note that students of parasitic fungi are getting much help in classifying their species and varieties from serological methods.

PHYSIOLOGY.

Homoiothermism: the Origin of Warm-blooded Vertebrates. By A. S. PEARSE and F. G. HALL. New York: John Wiley and Sons. 1928. Pp. 119. 10*s*.

THE development of warm-bloodedness is a very interesting chapter in evolutionary physiology. The authors of this book have lost a good opportunity and give us only a superficial and disappointing discussion of the subject, singularly deficient in data. The bibliography, which occupies more than a dozen pages, contains no reference to H. M. Vernon's essay in *Science Progress* for 1898 (vol. vii., p. 378) which the authors would do well to read.

THE LANCET.

LONDON: SATURDAY, MAY 25, 1929.

LESSONS OF THE CLEVELAND DISASTER.

THE terrible catastrophe on Wednesday of last week at the Cleveland Clinic Hospital, Ohio, when a hundred or more persons, including members of the medical and nursing staff, lost their lives, has illustrated the potential danger of storage of X ray films on a large scale. This hospital was founded in 1891 by a group of Cleveland physicians at their own cost in order to investigate more fully the clinical problems with which they were faced. It was therefore natural that the basement should contain a larger collection of X ray films than would be found in a less well-equipped hospital, and there is a further suggestion that an equally well-equipped laboratory added fuel and noxious products to the flames once these had got out of control. Dr. JOHN PHILLIPS, one of the three founders, himself perished in the fire from which his chief, Dr. G. W. CRILE, escaped only with difficulty. No authoritative account of the disaster has yet reached us, but it seems that after an explosion in the basement of the hospital the products of combustion invaded the rest of the building with results reminiscent of a gas attack in warfare. Although the actual origin of the explosion or fire remains to be cleared up, and may, in fact, be difficult accurately to ascertain since none of those present is alive to tell the story, it is assumed by experts here that, however originated, the lethal agency was the partial combustion of celluloid film. Various gaseous poisons have been mentioned, but chemists here will agree with the Washington Chemical Warfare Service in believing that the deadly brown gas evolved was nitrogen dioxide rather than bromine. The latter, however, cannot be ruled out where quantities of silver bromide were present in what became to all intents a reducing furnace, nor is the suggestion of hydrocyanic gas untenable in the same conditions. But apart from these possibilities more than sufficient is unhappily already known of the higher oxides of nitrogen in giving rise to a rapidly fatal pulmonary œdema, which occurs the more readily in that they are actually less irrespirable than the halogen gases.

The danger from the inflammability of celluloid has proved a serious drawback to the employment of this substance ever since it was discovered in 1869 by the Brothers HYATT, of Newark, U.S.A. The fact that it is a product of gelatin, nitrocellulose, and camphor is itself a sufficient indication of danger, but in practice celluloid, while highly inflammable, is non-explosive under any conditions to which it may be subjected in the work of cutting, turning, or moulding, or indeed under any normal conditions. Ever since the London disaster of 1912 in Moor-lane, when nine girls lost their lives in the flames of a fire started by celluloid, and a Departmental Committee was appointed to inquire and report into the precautions necessary in its handling and storage, research has never flagged into the possibility of obtaining a less inflammable material with equally useful properties. Some success has been achieved, although the addition of extraneous material proved futile by diminishing the homogeneity of the product so essential for photographic purposes. For the preparation of plastic splints, a safe form of celluloid has long been in use, the acetate of cellulose with which these splints are covered, in conjunction with plasticisers, rendering the material practically non-inflammable. But while the dangers of the use of celluloid in the photographic and cinematographic industries have been constantly before the public mind and have resulted in strict official regulations, it is a fact that the X ray film has in no single instance proved to be a source of accident in this country. During the last 25 years the most serious hospital fire was that which occurred in 1923 at the Highbury Pensions Hospital, Birmingham, with the loss of two lives. This outbreak caused the management of King Edward's *Hospital Fund to issue a* revised memorandum of precautions against fire, but although many possible sources of danger are mentioned the X ray film is not one of them. Seven years ago a Protection Committee was formed, as the result of coöperative action between the British Institute of Radiology and other interested bodies, in order to diminish the risks of the X ray room, but, at that time and since, these risks have been primarily those of sudden danger to life from high-tension current and of slow biological risk from prolonged exposure of tissues to rays of short wave-length.

The modern X ray room itself contains little or nothing of an inflammable nature. The insulating oil used in the transformers, switches, and circuit-breakers has a flash-point of 170° C., and oil of this safe kind has practically replaced the use of coal gas as a dielectric. There is no accumulation of unexposed celluloid film in the X ray room, for it obviously cannot be left about except in a thickly leaded container. As to the inflammability of the films in common use, it is true that they will burn fiercely when actually set alight, but it requires flame to do so, and a mere glowing cigarette-end will not start the combustion. The filing cabinets where the films are stored are remote from the rooms in which current is generated or used, and where films are stored on a large scale arrangements are made for the fireproofing of the room itself. This at all events is the practice in institutions where the risk has been most carefully envisaged and provided against; should there have been a certain added element of happy chance in the almost universal immunity from accident, no doubt the Cleveland disaster will lead to a screwing up of precautions to the level of the best.

◆

THE RIGHT POLICY IN LEPROSY.

THE British Empire Leprosy Relief Association states boldly that its object is to rid the Empire of leprosy. That such an end should be regarded as feasible is a measure of the success attending the therapy introduced by Sir LEONARD ROGERS as a result of his leprosy work in Calcutta over a decade ago. In the latest issue of the Association's quarterly journal[1] the Editor discusses this new and confident outlook which has developed during the last ten years. We know well what happened to the leper of old: "without the camp shall his habitation be." In policy this meant: get rid of the leper; segregate him strictly, and keep him close until he dies. In consequence most cases were hidden, and isolation, when it came at all, too often came too late to prevent him spreading his disease. The new injunction—get rid of leprosy—is altogether different. It works out, and successfully, in the provision of clinic centres where expert medical officers may give lepers the modern treatment which, it has been amply demonstrated, will render contagious cases non-contagious, and prevent the early non-contagious case from becoming a danger to the community. Wherever these treatment centres are established, their success is quickly proved and advertised by the large numbers of hitherto hidden lepers who eagerly seek treatment. The treatment has indeed brought in the era when the leper declares himself a leper.

---

[1] Leprosy Notes. No. 5. April, 1929. The British Empire Leprosy Relief Association, 24, Cavendish-square, London, W. 1.

This success depends on accurate treatment after accurate diagnosis—and the importance of the latter can be understood when we realise how potential as a focus of infection is the very early case, not yet become contagious, comparatively difficult to recognise, and yet easiest of all to treat successfully. The medical officers staffing these clinics must therefore be specially trained in their work, and the Association has made financial grants to medical men, so that they shall receive this training, notably at the Leprosy Clinic under Dr. Ernest Muir at the Calcutta School of Tropical Medicine. Sir Leonard Rogers records that by 1927 over a hundred medical men, mostly from India, but some from Africa, Greece, and the West Indies, had received instruction in leprosy work in Calcutta and, since that time, a great many more have had this advantage. There is now a second teaching centre at the leprosy clinic at Dichpali in Southern India. Numbers of men trained at these places are already at work in clinics in other parts of India, new centres for the treatment of leprosy and the dissemination of accurate knowledge having thus budded off from the parent institutions. The leper settlements of Trinidad and of British Guiana are clearly centres ready at hand for the training of leprosy workers for the West Indies; and the leper colony at Kuala Lumpur for those for Malaya. Whole-time experts are now at work in Nigeria, the Gold Coast, and Uganda; they have the material for training needed additional workers in those areas, and many lepers are now voluntarily coming forward for treatment in these African colonies. Their demand must be adequately met. And apart from the expert medical officer at the leprosy clinic, the general medical practitioner can render valuable aid by the recognition of early cases and by treating leprosy where there is no special treatment centre. Doubtless, with the multiplication of leprosy clinics in the tropics, he will increase his knowledge and competency in leprosy by attending the work of a clinic in his province.

Dr. Andrew Balfour points out that the bacteriology and morbid anatomy of leprosy are taught to undergraduates in the medical schools in this country, and especially to post-graduates at the schools of tropical medicine. Furthermore, in London, at the Wellcome Museum of Medical Science, there is a fine graphic exposition of the disease, and a leprosy section is being prepared for the new museum of the London School of Hygiene and Tropical Medicine which will thoroughly illustrate every aspect of the leprosy problem. But even at the schools of tropical medicine opportunities for the clinical study of leprosy are rare in England. No use for teaching purpose is made, or can be made, of the lepers—few in number—in the Homes of St. Giles, in Essex. It would be well, therefore, in view of the great importance of this among tropical diseases, that in any hospital in this country devoted to tropical diseases there should be a special ward for the study and treatment of lepers, and for instruction of post-graduates in the clinical aspects of the disease. At present the rare clinical material in this country is wasted, but such a treatment ward might well attract cases which would otherwise go undetected.

DRUNK IN THE ABSTRACT.

The standardisation of drunkenness is an ancient difficulty. A medical witness stated lately at Marylebone police-court that the defendant was drunk and unfit to be in charge of a motor-car. The magistrate, Mr. Hay Halkett, thereupon invited the witness to disregard the defendant's relation to the motor-car. "You have nothing to do with the car," said Mr. Halkett, "all you have to say is to answer whether he was drunk." If a witness let his mind dwell on the motor-car, continued the magistrate, he was apt to slide into the dangerous theory that, because a car was involved, therefore it was an offence for a man half drunk to be in charge of it; the man must be so drunk as to be justifiably arrested in the street for disorderly conduct. Medical witnesses, therefore, must simply ask themselves the usual questions by which drunkenness is tested. Could the accused coördinate his faculties? Could he speak properly? Was there anything he could not do which he could do ordinarily? These remarks were the more significant because the law is inclined to ignore drunkenness unless the accused is also riotous or disorderly or is engaged at the moment in some particular employment. Thus it is an offence to be drunk while acting as a pilot or as the master of a ship, or as a railway employee, or a postal official, or while in charge of cattle, or of a child in a highway or public place, or while in possession of loaded firearms. Earlier enactments make it also an offence to be drunk in charge of a steam engine and of various carriages, and now, under Section 40 of the Criminal Justice Act of 1925, it is an offence to be drunk while in charge on any highway or other public place of any mechanically propelled vehicle.

In spite of the learned magistrate's direction it is, we think, a little hard for a medical witness to concentrate upon the presence or absence of a kind of abstract drunkenness without taking into account the defendant's relation to his environment. A man may be judged drunk by the way he behaves with his car. Another element in the situation is a certain discrepancy between the medical estimate of drunkenness and the police estimate. A man may be drunk, but if his condition is not too provocative—if, in fact, he is not *very* drunk—he may well find his unsteady way homeward without arrest. We seem to be no nearer to a simple universal standard of drunkenness which witnesses can easily apply and magistrates can accept. It would probably be easier for the police-surgeon if his task were merely to say whether or no the motorist had indulged in alcohol to such an extent as to unfit him for driving. This is what the law has enacted for the pilots and crews of aircraft. The Air Navigation Order penalises them if they place themselves under the influence of any narcotic sedative or stimulant drug so as to become unfit for their duties in respect of the aircraft. Perhaps some day the law will enact a similar penalty for the motorist who, without being fully drunk, is under the influence of alcohol. If proof of such influence is easier than proof of drunkenness, the magistrates may welcome such a change in the law. Even under the present system, out of a total 120,629 motoring offences, 926 persons were found "drunk in charge" of a car during the latter half of last year. It is understood that the metropolitan stipendiary magistrates have recently voted in favour of retaining the speed limit partly on the ground that excessive speed, though not necessarily a cause of accidents, is a fact more easily proved than mere dangerous driving. At any moment public opinion may be aroused by the appalling loss of life due to traffic accidents. The latest statistics show that something like 6000 people are killed on our roads in a year. The only redeeming feature of this holocaust is the fact, which the figures seem to support, that injuries to children are diminishing. Is the youngest generation evolving a protective caution or nimbleness in traffic which the older pedestrians cannot acquire ?

Annotations.

"Ne quid nimis."

THE ROYAL SOCIETY CONVERSAZIONE.

A CONVERSAZIONE is, in the terms of the lexicographer, *a soirée given by a learned society*. In the case of the Royal Society it is this and something more—namely, a cross-section for public view of the current of modern scientific thought. The conversazione of May 15th was memorable for the cinematograph demonstration of tissue cultures by Dr. R. G. Canti. The film has been exhibited before, but it gains by repetition. The growth of periosteum, choroid, and nervous tissue of chick embryos is shown by photographs taken at regular intervals and accelerated as much as 900 times. The result ranks among the most ingenious and successful attempts to depict the processes of reproduction and of growth. From a purely technical point of view the film is nearly perfect, and to medical men it gives a sense of contact with the familiar, yet elusive, phenomena of repair and new growth which is awe-inspiring. Fibroblasts are seen to grow, as it were, with deliberation from a tiny point of tissue, and around them there hover, like bees among flowers, an ever-increasing colony of wandering cells. With a higher power of magnification, nuclei are seen to divide into chromosomes, the dividing cell struggles for a few moments, then splits in twain, each cell wandering quite definitely away from its sister. Scarcely for a moment is any cell at rest; the sensation of impermanence is oppressive. This aspect is exaggerated under darkground illumination; the mitochondria within the cell are in even more incessant movement, themselves dividing and threading their way through the cell-substance like silver wires. The wandering cells phagocytose dead and dying tissue, leaping on their components like spiders on flies, and their appetite seems infinite, though their size remains the same. To the uninitiated, malignant tissue appears to behave much in the same way as the normal. If the medical student's education were to include the demonstration of such films as these the dry bones of pathology would spring into new and prolific life.

Tissue culture was conspicuous among the exhibits, since the action of radium on mitosis, the delayed lethal dose of radium, and the nature of microglia may all be studied by this means. The exhibit staged by the Strangeways Research Laboratory (Cambridge) indicated that the effect of low temperatures, and of radium on cell division, are very similar, allowing for the considerable lag in the effect of radium. Clinicians are familiar with this phenomenon in the treatment of myeloid leukæmia. Microglia was shown, from its behaviour in repair, and its power of vital staining, to belong to the reticulo-endothelial system. The Rothamsted study of insecticides was of great interest. Pyrethrum is the foundation of most commercial articles for domestic use. Its active principle, which has been isolated and analysed, is of simple structure, but it varies greatly in its effect on different species of insects. For many kinds of agricultural pests, however, its toxicity is many times as great as nicotine, which is taken as the standard. Efforts are being made to grow pyrethrum on a commercial scale in this country. The same institution showed many tropical plants used for the extraction of poisons for fishing. The powdered wood is thrown into the river, and the dead fish collected. It is of interest to note that, in places so far apart as British Guiana and the South Seas, the active principle of the wood is the same. Dr. H. Ettringham presented a beautiful series of models and sections of the scent-producing organs of insects. These are chiefly found in the male insect, and are used to excite or attract the female Cadder-flies, whose heads are less than one-fiftieth of an inch across, they have the most complex organs, sometimes shaped like miniature shaving-brushes, and covered by caps when not in use. The smell is usually imperceptible to man, and the nature of the organs is surmised from analogy. Dr. R. J. Ludford showed the relation of nerve-fibres to normal and malignant epithelium. In the latter there is a great proliferation of nerves, interpreted as an attempt at repair. The actual penetration of epithelium by nerve-endings is a point of great interest. Miss D. M. Cayley, of the John Innes Horticultural Institution, gave the answer to a problem which in the days of exorbitant prices for rare tulips was much discussed. Uniformly coloured tulips are apt to "break"—that is, to give rise to striped forms. The habit is now assumed to be due to a virus, transmissible by aphis bites, and to bear some analogy to the mosaic disease of tobacco plants. The graphic illustration of a sensory nerve impulse was shown by Mr. Bryan Matthews, now a Fellow of King's College, Cambridge. The potential change is one of 20 microvolts only, and lasts for 2/1000 of a second. Valve amplification is used to demonstrate it, the record being made with an oscillograph of a natural frequency of 6000 per second. Sensory impulses have been much studied by Prof. E. Adrian, whose influence is to be seen in this beautiful piece of work.

Other demonstrations in this remarkable collection included a method of tracing the direction and source of atmospherics in wireless telephony, fossils of considerable evolutionary interest, and a collection of insects, widely separated both geographically and phylogenetically, yet with markedly similar morphological details. The last-named exhibit was very suggestive in its indication that similar environments and functional demands create analogous and even monstrous forms wherever they operate. The general impression left by these demonstrations is that the biological sciences in England are in a healthy state. The application of the newest knowledge and most elaborate techniques to biological problems is flattering to the breadth of the biologist's horizon. Life, when its intricacies are too slow in their manifestations to be synthesised, are speeded up by the cinematograph; when too fast to be analysed, they are slowed down by the oscillograph. By means of radium the metamorphoses of nuclei are inhibited; the most beautiful optical devices and the most refined products of the dye-works are at the service of the histologist. The outcome of all this is a sensation that we have controlled life—to some extent; we have at least compelled it to run at our speed. Perhaps we can now take breath, and find out what it is all about. The Royal Society Conversazione is even more impressive in retrospect than in experience. The reach of man still exceeds his grasp; but his weapons of apprehension are to-day a matter of justifiable pride. The universe is too great and too small, it moves too fast and too slow, its voice is too loud and too small for our five senses; but we are beginning to translate it into their language.

THE AMENITIES OF ZÜRICH.

THE annual congress of the Royal Institute of Public Health was held at Zürich from May 15th to 20th under the presidency of Lord Meston, Chancellor of the University of Aberdeen. The visitors were given ample opportunity to see the sanitary arrangements of the city, of which certain peculiar features created considerable interest. The water-supply is derived from two sources, the lake, and springs in the Sihl and the Firzetal, about 30 kilometres from the city. The daily average consumption by about 220,000 inhabitants is approximately 65,000 cub. met., the maximum 95,000, about 30,000 of which are obtained from the springs. The spring water is not treated; it supplies two of the four zones of distribution. The intake of water from the lake is at a point 375 metres from the shore and 29 metres below the surface; at this spot the lake is 50 metres deep. Pollution of the lake in the vicinity of the intake is avoided by connecting up the drains of neighbouring villages with the city sewers. The effluent from the city sewage works goes into the river which flows away from the lake. The water passes through a roughing filter put down in 1914; this takes out the algæ and reduces the organisms to 40–70 per c.cm. After passage through a slow sand filter (covered to prevent the growth of algæ) the maximum number of organisms in a cubic centimetre is 10. The water over the filter never freezes; in the coldest weather the mean temperature of the lake water is always several degrees above the freezing-point. It is not found necessary either to store or sterilise the water.

For a number of years the covered dustcart used at Zürich has been held up as worthy of wide imitation. Recently this has been improved, reduction having been made in the loading level; the height of the side is now only 148 cm., and thus the time and energy expended during the emptying of the bin into the cart has been considerably lessened. Economy is also effected by requiring the driver to help in the loading of the vehicle. Householders have been gradually persuaded to buy a dustbin of uniform pattern, sold in three sizes containing 22, 35, and 50 litres respectively; a subvention of about 3 francs was paid towards the cost by the city. Saving of time in loading has resulted from the use of the uniform bin, 120 being collected in the same time as 100 bins of irregular sizes. For economical reasons collection is not confined to the morning but takes place throughout the day. Horse transport is used in the older flat part of the city with its narrow streets and motor traction in the hilly outskirts. The refuse is burnt in a Heenan and Froude's destructor erected in duplicate, after separation of any iron materials, the emission of black smoke being diminished by the use of an electric device. The heat evolved is used to raise steam which produces electricity. Household refuse from nine adjacent villages is also consumed by the destructor. The streets of the city were noticeably clean and free from litter. Cremation is making considerable strides in Zürich; since 1925 there have been more cremations than burials. An excellent municipal swimming bath is provided along the lake side. Swimmers in Zürich are thus able to avoid all the disadvantages attached to artificial baths in the absence of adequate change or purification of the water. Altogether full use is made of the city's great natural advantages.

LIVER EXTRACT IN DERMATOLOGY.

THE discovery of an efficient antidote to the occasional toxic manifestations of salvarsan and bismuth is overdue, for evidently sodium thiosulphate is not of much value in the later stages. It is well known that in the large majority of cases the liver is the organ which chiefly suffers, and when the patient succumbs cloudy swelling or so-called acute atrophy are the usual post-mortem findings. Dr. B. Spiethoff[1] of Jena raises the important question of the protective rôle of liver extracts in diseases attributed to hepatic dysfunction, and informs us that his anticipations of their antidotal effect in salvarsan poisoning were not disappointed. In several cases (number unstated) of the severe forms of salvarsan dermatitis with high fever, and the much-dreaded complication of cutaneous abscesses, a rapid and noteworthy improvement seems to have set in within a few hours of administering liver. Spiethoff recommends intramuscular injections of a sterile aqueous extract (5 c.cm. = 5 g. liver) up to three weekly doses of 5-10 c.cm. being given for all acute and subacute cases, and for such as are unable for some reason to assimilate liver preparations by the mouth. He never observed intolerance to intramuscular extracts; thus two women with psoriasis developed urticaria when the extract was given by the mouth, although it was well tolerated by injection. He found the liver treatment useful, furthermore, in preventing or aborting a commencing salvarsan or bismuth dermatitis in children with the idiosyncrasy, and it enabled him to carry on the specific treatment pari passu. Since the number of organisms in cases of *Bacillus coli* bacilluria was scarcely influenced by the injections of liver extract, although there was simultaneous improvement of the general health, Spiethoff deduces tentatively that the action of the liver is antitoxic rather than bactericidal. In experiments on psoriasis during the last two years, he found that as long as liver extract is being given there is a definite inhibition of fresh lesions, although no influence on the established eruption is apparent. He suggests that there may be a hepatic factor or association in the production of psoriasis, for relapses and recrudescences are seen as soon as administration of the extract is discontinued.

CENTENARY OF THOMAS YOUNG.

THIS month sees the centenary of the death of Thomas Young, of whom the late Dr. Howship Dickinson truly said that he was "the most comprehensive genius and greatest man of science who ever held the office of physician to St. George's, or indeed any other hospital." Young was born at Milverton, in Somerset, the eldest of ten children, of Quaker parentage, in the year 1773, and was thus in his fifty-sixth year when he died. As a child he was precocious, being able to read with considerable fluency by the time he was 2 years old. He started the study of Latin at the age of 6, and at 7 was sent to a boarding school near Bristol, and began, as he says himself, to be his own teacher. From 1782–86 he was at a school kept by a Mr. Thompson at Compton in Dorset, where, in addition to the ordinary classical curriculum, he read books on natural philosophy and some of Newton's works, with Martin's optics. He also learnt to draw, to turn on a lathe, and to use a quadrant in measuring altitudes. In 1792 he began the study of medicine at the Hunterian school in Great Windmill-street, and in the following year entered as a pupil at St. Bartholomew's Hospital. In that year, when only 20 years of age, his celebrated paper on the mechanism of the eye was read before the Royal Society, and for this paper he was elected F.R.S. in 1794. In 1802 he was elected Foreign Secretary of the Society, and in 1827 he was chosen one of the eight foreign associates of the Academy of Sciences at Paris, succeeding Volta.

Young had greater advantages than usually fall to the lot of an embryo medical man, for his uncle was the well-known Dr. Brocklesby, who left house, books, and a considerable sum of money to his nephew; but he also had a far more catholic education than most of his contemporaries, for he studied at Edinburgh, Göttingen, and Cambridge Universities, before beginning practice in Welbeck-street. It is not easy to summarise his scientific activities briefly. We may recall his work on the undulatory theory of light and the ingenious experiments on his own eyes which proved the presence of a considerable degree of lenticular astigmatism in his own person; and, of course, his investigation of colour vision. His work for the "Nautical Almanack" and the Board of Longitude, and that in connexion with life assurance, must be mentioned, whilst to the lay mind his research on Egyptian hieroglyphics, which was done independently of, and rather earlier than, that of Champollion, is even more interesting. His "Practical Nosology and Pharmacology," which appeared in 1813, is an extremely learned work which will repay perusal by the curious to-day. The students at St. George's are reputed to have said of Young that he was a great philosopher but a bad physician. He was regarded by his medical contemporaries as a feeble practitioner, but the Apothecary (the "super house physician" of the day) is credited with the observation that a greater proportion of Dr. Young's patients were discharged "cured" than of those subjected to the more heroic treatment of his colleagues. The beautiful copy of his portrait by Sir Thomas Lawrence is one of the chief glories of the board room of St. George's Hospital.

---

[1] Münch. Med. Woch., April 5th, p. 577.

Young was buried at Farnborough, in Kent, and a medallion with a tablet to his memory is in Westminster Abbey. From the inscription, which was composed by Hudson Gurney, we may quote the sentence, that he was "a man alike eminent in almost every department of human learning."

CONGENITAL VALVULAR OBSTRUCTION OF THE POSTERIOR URETHRA.

IN the April number of *Surgery, Gynecology, and Obstetrics* Dr. Hugh Young and Dr. Robert McKay, of Johns Hopkins Hospital, write on that comparatively rare condition, congenital valvular obstruction of the prostatic urethra. Although valvular obstruction of this kind was recognised 135 years ago, it received little attention until recently, partly because it was only discovered at autopsy or accidentally during the course of an operation. Probably the first time it was observed through a cystoscope was in 1912, and the first successful operation is said to be that recorded by Young himself in 1913. Since then more notice has been taken of the condition in urological literature. In their present paper Young and McKay have collected reports of 21 cases of congenital valvular obstruction of the posterior urethra seen at the Brady Urological Institute, and besides these have collected from the literature 41 additional cases, of which 12 were treated by operation. The symptoms attributable to valves in the posterior urethra may be grouped under two headings—namely: (1) those brought about by obstruction to urination, and (2) those resulting from so-called back-pressure upon the kidneys, producing renal damage and insufficiency, and finally uræmia. The patient is always a child, and the symptoms of the first category may be difficult to elicit. On careful questioning, however, a history of difficult micturition since birth, with delay in starting the act and a tendency towards dribbling at the end, is usually obtained. Not infrequently there is incontinence both by day and night, this being of the paradoxical type, due to overflow from a distended bladder which is never quite emptied. The symptoms of the second category are those of chronic uræmia and may simulate chronic diffuse nephritis or polycystic kidneys. The diagnosis rests on posterior urethroscopy, cystoscopy, and radiography after distension of the renal pelvis, ureter, and bladder with sodium iodide. A cystogram will always show dilatation of the vesical orifice and a continuation of the opaque medium down the posterior urethra to the site of the valves, producing a typical tunnel-shaped end to the cystogram. Careful urethroscopic examination of the posterior urethra will reveal three types of congenital valves in the neighbourhood of the verumontanum—a double bifurcating valve springing from the distal portion of the verumontanum, a bifurcated valve extending from its proximal portion, or an iris-shaped valve lying above the verumontanum. It may be recalled that a case corresponding to the first type was described not long ago in our own columns.[1] Once the condition has been recognised operative treatment is usually a simple matter, according to Young and McKay, who have had satisfactory results from the use of a small-sized punch of the type associated with Young's name. Unfortunately, in the vast majority of cases, the diagnosis has not been made until extensive damage has occurred to the renal tissue, so that the patient, although temporarily relieved of obstruction, ultimately dies of uræmia. In handling these cases the same precautions must be taken as are required in the treatment of long-standing prostatic obstruction. The distended bladder must be slowly emptied through an in-dwelling catheter, and for this purpose a small ureteral catheter will be found useful. Once the urinary tract has been emptied and equilibrium is established cystoscopy and radiography may be carried out in safety. No operation should be undertaken until renal efficiency tests show that a maximum of recovery has been obtained. As for its nature, nothing more than a per-urethral operation is ever required; it may take the form of punching out the valves or of fulguration through a suitable posterior urethroscope. The prognosis naturally depends on the amount of renal damage done before the obstruction was discovered. The points specially emphasised by Young and McKay are the need for early diagnosis, the importance of methods of decompression, and the good results obtainable from a simple punch operation.

ETHER IN THE TROPICS.

THE medical profession in India has been curiously conservative in its allegiance to chloroform. From time to time articles have appeared in the *Indian Medical Gazette* advocating the use of ether, but they have generally attracted little notice, and the result, so far as any extended change from one anæsthetic to the other is concerned, has been almost nil. Quite recently Major J. B. Hance,[1] I.M.S., and Dr. Joti Pershad have made out a good case for the superiority of ether to chloroform, or chloroform mixtures, for anæsthesia in India. They contend that the position of ether is unchallenged in temperate climates and that the same arguments are equally applicable in India, and they ask very pertinently why an anæsthetic which has the advantage of being a cardiac and respiratory stimulant instead of a depressant, and which has none of the dangers associated with delayed poisoning, is not more popular with surgeons practising in that country. Various explanations have been put forward for this attitude, the chief being that chloroform is safer in warm climates than in cold, and that the rapid evaporation of ether, when administered by the ordinary open method, renders its general employment too expensive. As regards the first of these considerations, deaths on the operation table in most Indian hospitals are not subject to any scrutiny comparable to that of the British coroners' courts, which may have something to do with the idea that chloroform is safer in warm climates; it is, however, true that the vapour is not so likely to hang about in undue density as at a lower temperature. With regard to expense, the cost of pure anæsthetic ether may well have been a serious factor in the past, but the position has been simplified by a recent modification of the excise regulations. The method of administration has an important bearing on the question of expense. In a hot country, if the drug is poured direct on to a mask, there is great wastage, but other means of administration are available. Major Hance recommends Shipway's apparatus, which needs no description here. Another apparatus which is not so familiar, but which has certain advantages of its own, is Pinson's "ether bomb"[2]; this has already been used by several surgeons of repute in India. The apparatus consists essentially of a strong steel-container, with a needle valve to control the supply of vapour, which travels through a small-bore rubber tube, and is delivered under an ordinary open mask, by means of a metal nozzle inserted through the covering of the mask. When in use the container is placed in a large bowl of boiling water, which is renewed from time to time according to the instructions. The apparatus seems particularly suitable for up-country use. It may be recalled that chloroform long held its own in Edinburgh. Even now the simplicity of administration remains a great advantage, and one may still occasionally hear a devout aspiration, from an overworked general practitioner, for a Scotsman with a bottle of chloroform and a piece of lint. But, except in India, considerations of this kind are not allowed to outweigh the superior safety of ether. The latter has been used regularly in the Philippine Islands under tropical conditions, and surgeons in many lands have demonstrated the fact that a warm climate does not contraindicate its use. Any inconvenience which may arise from the employment of special apparatus, or the slight delay in the induction of anæsthesia, is more than compensated by the feeling of confidence.

THE CONTROL OF MEASLES.

THE old proverb about taking the horse to the water seems to be borne out by the state of affairs which, according to the local press, exists in St. Helens. We learn that the medical officer of health of that county borough at a recent meeting of the public health committee was moved to express his disappointment with the response made to various administrative measures intended to meet the needs of the population during the measles epidemic which presently prevails. These arrangements are what have now come to be regarded as standard practice by public health workers and consist of arrangements for the visitation of patients in their homes by trained nurses, and the setting aside of hospital accommodation for cases requiring it. How far these praiseworthy efforts have justified their provision may be calculated from the fact that in 1927 among 2892 cases of measles, assistance in home nursing was sought in only 59, and of 78 cases admitted to hospital 60 proved fatal. In 1928, of 1336 cases, home nursing was sought on behalf of 14 and hospitalisation for 21. In January and February of this year, although 572 cases have occurred, 10 only have had home nursing, and in two four-weekly periods of the present epidemic 35 deaths have occurred. From this evidence Dr. Frank Hauxwell's complaint seems to be well founded. The reluctance to take advantage of the services provided is ascribed to great apathy of the citizens and lack of support on the part of the general practitioner. Possibly, however, the good offices of the latter, like those of the medical officer himself, are themselves reduced to naught by the inertia of the parents. The negative attitude of the public about measles is nothing new and may be due to the fact that during epidemics, while few escape who are unprotected, the great mass of those attacked, and especially older children, come off comparatively lightly, so that the majority of parents are not impressed with the danger. In the past the serious results of scarlet fever and diphtheria were well established in the popular memory and the dread of these diseases is still a factor to be reckoned with. Now that their mortality has fallen, measles is left prominent among the causes of death in childhood, but this fact has not apparently got home to the community at large. The only way in which the public can be brought to realise the dangerous nature of measles is by propaganda, and of all the forms that can be directed on this particular problem there is little doubt that the tactful influence of the nurse in home visiting is the most effective. We think that Dr. Hauxwell is right in giving this measure a prominent place in his anti-measles campaign, but like other forms of propaganda, it must find its own way to the persons whom it is necessary to stimulate. We do not know what has been the custom of St. Helens, but many authorities have found it advantageous not to wait for applications from parents, but to seek out cases which have come to their knowledge through absence from school, infant welfare centres, and other places. Visits to affected homes often supply information about cases in other houses, and experience has shown that the district nurse, to whose ministrations the people are accustomed in other types of illness, is well suited for this class of work. Furthermore, these nurses are already in daily contact with practitioners in respect of ordinary routine cases, their visits are seldom regarded as intrusions, and often they will urge the calling in of a medical man at a stage in the illness when he can usefully intervene. It should be realised that during measles epidemics the resources of a health department may be greatly taxed and energies may have to be diverted temporarily from other less urgent activities and concentrated on the problems of the moment. There is another way of attacking an epidemic of measles which has been proved effective but is not sufficiently exploited in this country—the prophylactic injection of serum from convalescents. Clinics and laboratories for the collection, preparation, and distribution of measles serum have been established for several years now in Paris, Berlin, Munich, New York, Vienna, and many other towns, and the reports from each centre are favourable. In Paris alone during the last four years nearly 4000 children have been injected with convalescent serum with marked success, and the organisation is rapidly progressing. In London the Metropolitan Asylums Board prepares just enough serum for its own use. The collaboration of Dr. Richard Massingham, medical officer in charge of the London Fever Hospital, has enabled the Hospital for Sick Children, Great Ormond-street, to obtain serum for use in threatened epidemics. In an emergency the Middlesex Hospital has been supplied from this source, and also a few private practitioners. But in the provinces, as far as we know, there has been no attempt to bottle convalescent serum for use outside the institution in which the patients are being treated. It is to be hoped that the article by Dr. Nabarro and Dr. Signy, published on p. 1106, will arouse interest in this method of prophylaxis, and that practitioners will demand at least such facilities as are available in other countries for the supply of serum. Although there is no striking national epidemic, many deaths are occurring weekly from measles. Experience has proved that many of these deaths could be avoided if good use were made of the proved willingness on the part of adult convalescents in fever hospitals throughout the country to act as donors. It may be that in the future a more convenient source of serum will be found, but at present, according to Gunn, the animal serums supplied have not proved effective, and human serum remains the only certain method of controlling the disease.

THE INITIAL LESION OF SLEEPING SICKNESS.

ON Sept. 16th a European on a plantation in Cameroon noted a smarting pimple on his face; next day he had fever and slight shivering, and that night he was greatly worse. On the 18th Dr. Graf, at Buea, was told that the patient had a boil, and as it sounded not unlike malignant pustule, he went to see for himself. He found [1] a round inflamed area, about an inch across, on the left side of the face just below the ear; there was a red spot in the centre, around that a pale ring, looking like blisters run together, and outside this another red ring. The neighbouring tissue was swollen, and the central "boil" was hard and painful; the temperature was 102° F., and the pulse-rate 100. A bystander said the boil reminded him of a tsetse sting another friend on the same plantation had had two years before. A drop of blood was taken from the inner edge of the white ring, and in the stained film many trypanosomes were seen. Next day the patient was taken to Victoria to have the diagnosis confirmed. On Sept. 20th, which was the fourth day of the illness, trypanosomes were found in the finger blood. Germanin 1·0 g. was given intravenously on the 20th, 22nd, and 24th. Parasites were not seen on the 23rd or later, and after that day there was only a trace of albumin in the urine and the boil healed. In his report Dr. Graf said that he was keeping the patient under observation and would repeat the course of germanin in two or three weeks, and test the blood by inoculation if no trypanosomes were seen. He thought that a cure might already have been effected.

---

[1] Arch. f. Schiffs- u. Tropen-Hygiene, April, 1929, p. 219.

One case leads to another. A second patient from the same plantation, having heard of the earlier case, came to Dr. Graf on Sept. 23rd. He believed that he had been bitten on the right temple by a tsetse-fly eight days before; he had at least seen the fly make its escape. The development of the lesion had been similar but less acute; it had decreased after the third day, and had disappeared by the fifth. Always well before, the patient had since suffered from headaches and had lost his appetite. Trypanosomes were found on immediate examination of blood from the finger, and he had his first injection about Sept. 20th. The temperature went up and no trypanosomes could be discovered, though there were parasites of subtertian malaria. The patient took germanin and quinine at the same time without inconvenience.

THE ACTION OF THALLIUM

Buschke has done more than any one else to establish the therapeutic value of thallium, and his views deserve careful study. A recent paper,[1] in which he collaborates, classifies the effects of the drug into specific and non-specific. Those noted in the chronic poisoning of animals—especially young rats which appear to be more susceptible than rabbits or guinea-pigs—are as follows: (1) alopecia, specifically limited to the hairs enervated by the sympathetic; (2) disturbances of bony growth, resembling those of rickets and osteomalacia, together with a tendency to cataract and iritis; (3) cessation of the normal sexual periods, which can be restored by administration of ovarian and pituitary extracts; and (4) eosinophilia, hypochlorhydria, alkalosis, and convulsions. (5) Gastric tumours somewhat resembling those produced by Fibiger but not of the same malignancy, may also be observed, and lastly (6) there is an antihidrotic action, on which the whole fabric of thallium therapy was originally based, almost certainly depending on an endocrine-sympathetic action. As applied to man, however, the chronic effects of thallium acetate do not concern us. The drug is administered for the epilation treatment of tinea tonsurans in a single dose of an average strength of 8 mg. per kg. body-weight, and, according to most observers, must on no account be repeated within a period of at least three months. Young children tolerate it much better than those who have passed the age of puberty, a fact which is held to support the theory that it acts partly on or through the endocrines. The specific effects of thallium are shared in lesser degree by other metals in the same "heavy" series. Thus lead may produce slight epilation and an inhibition of breeding proclivities, whilst gold and arsenic, and incidentally salvarsan, are sympathetico-tropic in their toxic effects. The pains in the knee so often observed in children treated with thallium may be traceable either to some intramedullary influence on the bones, or to a mild peripheral neuritis. The non-specific effects of thallium are the same as those encountered in the toxicology of all the heavy metals. They include damage to the axis-cylinders of nerves and to the central nervous system itself, optic atrophy, various cutaneous eruptions, and above all, damage to the renal epithelium. For this last, especially, a careful watch should always be kept, although a slight degree of albuminuria is common and need cause no alarm.

LORD ROSEBERY.

THE death of the Earl of Rosebery on Tuesday last, shortly after his eighty-second birthday, recalls the sympathetic comprehension with which he regarded the medical profession at a time when its public reputation was in some measure in jeopardy. On the eve of the coming into force of the National Insurance Act of 1912 Lord Rosebery, as Chancellor of the University of London, addressed the students of the London Hospital on what he described as the noblest secular profession in the world. He set out in eloquent words the many directions in which medicine was necessarily a forlorn hope; first, in that it never despaired and was always seeking new inspiration and new strength for the battle which could only have one termination, and again because disease when surmounted and conquered was sure to spring up in some new form. He went on to speak of a life spent in the complete conquest of obstacles as a rare one in any profession, and his words can hardly have failed to inspire courage and determination in the hearts of a number of his hearers who were just entering upon the profession of medicine at one of its most critical periods.

THE Interstate Post-graduate Assembly of North America will meet in London next week, when a series of lectures will be delivered at the House of the Royal Society of Medicine. The first session will be opened at 10.15 A.M. on May 27th by Sir John Bland-Sutton, after which short discourses will be delivered by Dr. James Collier, Mr. Victor Bonney, and Dr. Henry Semon. On the next day Sir John Broadbent will preside; Mr. J. E. H. Roberts and Sir William Willcox will give addresses; and Dr. R. G. Canti will give a cinematograph demonstration of tissue cells growing in vitro. On May 29th Sir W. Arbuthnot Lane, Dr. Donald Hunter, and Mr. Donald Armour will speak. In the afternoon special programmes have been arranged at ten general and special hospitals. At 8.30 P.M. on May 28th and 29th receptions will be held respectively at the Wellcome Historical Medical Museum and at the Royal Society of Medicine.

THE St. Cyres Lecture of the National Hospital for Diseases of the Heart will this year be given at the hospital at 5 P.M. on Thursday, June 6th, by Dr. R. O. Moon. His title will be Some Observations on Diseases of the Myocardium.

TWO large anonymous gifts to hospitals, intended as thankofferings for the King's recovery, have been announced within the past few days. Money to the amount of £10,000, together with freehold properties worth about £48,000, have been given to endow the proposed new hospital at Southend-on-Sea, whilst the Royal Portsmouth Hospital has been offered a pound for every pound raised by the end of the year, up to £40,000. The income from the properties made over to the Southend Hospital will not become available for ten years unless the donor should die within this period.

ALEXANDRA DAY.—Wednesday, June 12th, has been fixed as the date of Alexandra Day. Since 1912, when it was begun, about £1,500,000 has been collected.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCIII.—THE PROPHYLACTIC TREATMENT OF MEASLES.

IT is opportune, in the face of the recent rather severe epidemic of measles in some Midland cities, to bring up anew the subject of prophylaxis of this disease. In this outbreak there have been many hundreds of cases reported with a considerable number of deaths. In our opinion these numbers could have been very greatly reduced had the use of convalescent measles serum been more generally adopted and contacts more vigorously treated. Moreover, the family doctor is often faced with the demand for advice as to how to protect a younger or more delicate child from infection when measles has been diagnosed in one member of the family who is being nursed at home. Isolation is sometimes impracticable under modern housing conditions and, in any case, the infection may have been passed on before the sick child was separated from its brothers. There might at present be some difficulty in obtaining convalescent serum for a case seen in private, since young children cannot safely be used as donors, but if the demand became insistent doubtless adult volunteers could be secured by arrangement with the medical officer in charge of local fever hospitals. Even where this is not possible, the alternative method, described below, of giving whole blood could be used, and for this purpose sufficient blood could be taken from all but very young children.

Our experience has been chiefly with institutional cases, and it is from this point of view that the following notes have been compiled. When for any reason there is particular anxiety to avoid the infection of a particular child, the practitioner should find it possible to procure the material necessary to ensure prophylaxis or at least a very mild attack.

Convalescent measles serum was used in prophylaxis and treatment of measles many years ago on the Continent, but fell into general disfavour owing to faulty technique in its preparation. Cases are reported of death following grossly contaminated sera and also of a tuberculous lesion of the skin at the site of inoculation. In recent years many attempts have been made by various workers to isolate a streptococcus from cases of measles and to produce on a large scale an antitoxic serum. R. Tunnicliff, N. S. Ferry and L. W. Fisher, and R. Degkwitz, amongst others, have all produced sera which have had extensive clinical trials and have, so far, all been found to be inferior to convalescent measles serum in their power to prevent or modify an attack of measles. Gunn, working at the Metropolitan Asylums Board (THE LANCET, 1928, ii., 691), compared the three sera mentioned with convalescent serum and found that whereas Tunnicliff's serum protected 43 per cent. of contacts, Ferry and Fisher's serum protected none, Degkwitz's protected 40 per cent., and convalescent measles serum protected 95·7 per cent. These figures show a marked superiority in the protective powers of the convalescent serum, and this is supported by the fact that the non-protected cases were markedly attentuated.

Preparation of Serum.

This presents one or two difficulties, the most important being that the majority of cases of measles occur in children, and it is difficult, and often inadvisable, to take much blood during their convalescence. We have been particularly fortunate in the collaboration of Dr. R. Massingham, superintendent of the London Fever Hospital, who has collected a large amount of blood for our combined uses from the numbers of adult measles cases which are admitted to his hospital. Many adult volunteers gave 200–300 c.cm. of blood, and suffered no ill-effects. Care is taken to ascertain that there is no tuberculous or syphilitic taint in the family history, that the case was not a complicated one, and that the patient is not incubating another disease. The blood is taken on the seventh–tenth day after defervescence, collected aseptically into sterile tubes, and allowed to clot. The serum is pipetted off when separated, and the remaining clot loosened and centrifuged. By this means we have been able to obtain as serum at least 50 per cent. of the blood collected. Each batch is tested for sterility, the Wassermann test is done, and 0·5 per cent. phenol is added. If these tests are satisfactory, the batch is pooled with several others to make a serum of fairly uniform potency. Before final bottling, the serum is filtered and another sterility test is done. Some workers advocate heating the serum on two successive days at 56° C. for one hour. Prof. R. Kraus, of Vienna, inoculates a sample of each batch of serum into a guinea-pig to make certain of the absence of tuberculous infection. In no case hitherto has tuberculosis developed in the guinea-pigs, and this should be sufficient proof of safety.

Indications for Use.

1. *The protection of young children* in whom an attack of measles might have a fatal or very severe effect. This applies particularly to sick children, such as those who have recently been operated upon and then been exposed to infection, or those suffering from other acute diseases.

2. *The prevention of the spread of infection.* All contacts in hospitals and institutions should be inoculated within six days of exposure. This protects the contact in about 90 per cent. of all cases and efficiently prevents the spread of the disease. It also saves a great deal of expense and worry to those responsible for the institutions, and is particularly useful in fever hospitals to prevent cross infection from spreading.

3. *The attenuation of an attack.* This is achieved by injecting the serum from the sixth to the ninth day after exposure. In most cases so treated the incubation period is prolonged and the attack is greatly modified, there being a greater interval between the initial coryza and the appearance of the rash (six days in one case) and the absence of Koplik's spots. This method has a great advantage when used apart from institutions, because it confers a permanent active immunity against the disease, whereas inoculation in the early incubation period gives a passive immunity lasting approximately three weeks.

4. *In the diagnosis of measles.* If the serum is injected on the tenth day, the course of the disease will be unaffected, but the so-called Debré phenomenon will be observed—an area of blanching of the measles rash around the site of an intradermic injection of the convalescent serum. The potency of the serum can be gauged by the Debré phenomenon. Intradermic injection of serum into a well-developed measles rash has not produced blanching in any of the cases in which we have tried it—cf., the Schultz-Charlton reaction in scarlet fever.

Convalescent serum has been used therapeutically in the treatment of severe cases of measles, but although large doses of the serum have been injected, no improvement that could be attributed to the serum has been noted.

Dosage.

Sutherland and Anderson, when attacking an outbreak at the Monsall Hospital, Manchester, used 10 c.cm. given subcutaneously, irrespective of age, condition, or length of exposure. This is a very large dose, but it is advocated when it is essential to wipe out a local epidemic. Debré, at the Paris Clinic, uses 3 c.cm. for children under 1 year, and this is increased by 0·5 c.cm. for every additional six months.

We have used 3 c.cm. for children up to 3 years of age and 5 c.cm. for children over 3. These amounts, however, were not strictly adhered to, an extra c.cm. being added if the children were well-developed for their ages. All our injections were made intramuscularly, and in no case was any untoward effect of the serum noted, there being no serum sickness or rash.

Gunn's dosage was much like our own, but he prefers to give the injections intramuscularly on the second or third day of incubation. He finds a greater percentage protected than with first day injections.

Injections of Whole Blood.

W. S. C. Copeman, who has recently written a good résumé of this subject (Proceedings of the Royal Society of Medicine, May, 1927), states that in cases of emergency citrated whole blood may be used in place of serum. Such a procedure might be of value where one child in a family was convalescing from measles, and it was thought desirable by the practitioner to protect one or more of the patient's brothers and sisters. As the blood would be injected subcutaneously or intramuscularly, there would be no need to do a blood-grouping, but the dose of blood injected would have to be about double the amount of serum which would have been given. One c.cm. of 10 per cent. solution of sodium citrate taken up into a 10 c.cm. syringe would prevent the coagulation of that amount (10 c.cm.) of blood.

Results.

Debré reports 80 per cent. complete protection over a very large number of treated children. Gunn reports 95·7 per cent. of complete protection. Of the five cases which developed measles three had been injected on the first day and two on the eighth day. Those injected on the first day could hardly be diagnosed as measles. The control cases of Gunn and of Sutherland and Anderson show a very high percentage of infection.

In our own series 55 children housed in wards which had had cases of measles were injected usually on the second day of exposure. Some of these cases, however, were children who were newly admitted into a measles-infected ward without any further precaution. This procedure was justified inasmuch as none of the children developed measles. The ages of the children varied from six months to twelve years. Fifty-one cases were completely protected—i.e., 92·7 per cent. Of the remaining four, one developed an apparently normal attack 16 days after the injection, two others had very mild attacks (19 and 21 days), and one had a doubtful attack (21 days). In view of the epidemic, however, it was thought advisable to send these mild cases to the fever hospital. Certain wards, where the use of serum was not allowed, served as controls, although not scientifically exact ones. The incidence of infection in these wards became high and eventually they had to be closed completely, or open only to children who had definitely had measles previously, and whose parents were willing to risk the infection.

Conclusion.

We agree with Gunn that until an animal serum more efficacious than those at present available is put upon the market, human convalescent serum is the only certain method of controlling measles. Even if it were possible by this means to stamp out the disease, it is doubtful if, on epidemiological grounds, such a policy would be a wise one. It should be our aim, however, to protect *every* child under 3 years of age, as well as older children who are in feeble health, from contracting measles. The method is already being applied to a limited extent in institutions in this country, but it should be used in suitable cases in private practice, either for prevention—i.e., production of passive immunity—or preferably and where possible for attenuation—i.e., production of active immunity. As has been pointed out, no ill-effects are noted where the serum has been carefully prepared, and as the serum is of human origin there is no fear of anaphylaxis following upon its injection.

D. N. NABARRO, M.D., F.R.C.P. Lond.,
Director of the Pathological Department, The Hospital for Sick Children, Great Ormond-street.

A. SIGNY, M.R.C.S. Eng.,
Assistant Pathologist to the Hospital.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. P. F. Woodruff-Minett is placed on the Retd. List with rank of Surg. Capt.

C. J. Farr to be Surg. Lt.

The following appointments are notified: Surg. Lts. J. W. Simpson to *Excellent;* R. C. Webster to *Dolphin*, temp.; and H. J. McCann to *Mackay* (on recommg).

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Lt. J. D. Simpson to be Surg. Lt.

Proby. Surg. Sub-Lieut. D. MacK. Craig to be Surg. Sub-Lieut.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. J. S. Harvey, having attained the age for compulsory retirement, is placed on retd. pay.

Lt.-Col. F. J. Garland retires on retd. pay.

Maj. G. S. McConkey relinquishes the appt. of Dep. Surg., R. Hosp., Chelsea.

Maj. F. M. Lipscomb to be Dep. Surg., R. Hosp., Chelsea.

The undermentioned Majs. to be Lt.-Cols.: C. E. W. S. Fawcett and A. M. Rose.

Lt. (on prob.) W. F. L. Hannay, from the secd. list, is restd. to the estabt.

TERRITORIAL FORCE.

Capt. H. C. Sands to be Maj.

Capt. A. C. Ballance resigns his commn.

Lt. A. Roberts (late R.A.M.C., Supp. Res. of Off.) to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt. F. R. Daniel, from Active List, to be Lt.

ROYAL AIR FORCE.

Flying Officer R. E. Alderson ceases to be seconded to the Royal Victoria Infirmary, Newcastle-upon-Tyne.

Surg. Lt.-Comdr. T. N. D'Arcy, having obtained the highest aggregate marks at the examination held in 1929 for promotion to the rank of Surgeon Commander, has been awarded the Sir Gilbert Blane gold medal.

ENLARGEMENT OF CHELMSFORD HOSPITAL.—It is intended to enlarge the Chelmsford and Essex Hospital by the addition of men's and children's wards, out-patient, and casualty and other accommodation.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—Lieut.-Colonel G. S. Parkinson, D.S.O., R.A.M.C. (ret.), has been appointed part-time assistant director of hygiene at this school.

During the late war Colonel Parkinson was Deputy Assistant Director of Hygiene with the First Army, and later Assistant Director of Medical Services. After the armistice he served for five years D.A.D.H. at Gibraltar, where he undertook the duties of Medical Officer of Health for the civilian population and the administration of a complete health department responsible for sanitation, school medical work, tuberculosis, venereal diseases, maternity and child welfare, and poor-law medical service. On his return from Gibraltar, he was appointed Assistant Professor of Hygiene at the Royal Army Medical College, Millbank, and held the senior post for several months during the absence of the Professor on leave. After his retirement in July, 1927, Colonel Parkinson held several temporary posts in the public health service before becoming assistant to the Executive Secretary of the Society of Medical Officers of Health. For the past six years he has been hon. secretary of the Naval Military and Air Force Hygiene Group of this Society.

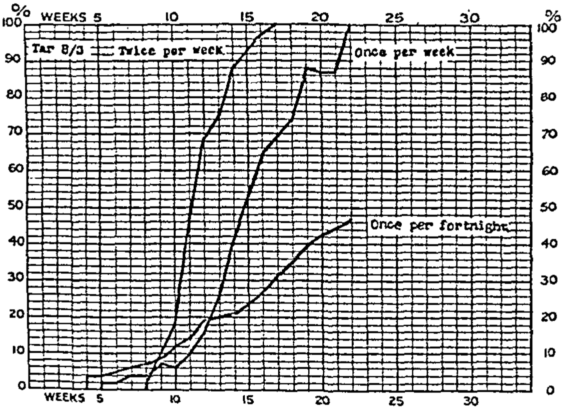
SOME FACTORS INFLUENCING THE DEVELOPMENT OF EXPERIMENTAL OIL AND TAR TUMOURS IN MICE.

BY C. C. TWORT, M.D. ABERD.,
AND
J. M. TWORT, B.SC. LOND.,
PATHOLOGIST AND ZOOLOGIST TO THE MANCHESTER COMMITTEE ON CANCER.

ALMOST all our early experiments with carcinogenic agents consisted in the application of the tar or oil to the backs of 100 mice twice weekly. This procedure constituted our standard experiment. For several reasons we imagined that when using a strong agent, such as a synthetic tar, the intervals between the paintings was not long enough to enable the epithelium to give a maximum response, while with a weak agent, such as an American petroleum oil, the interval between the paintings was probably too long. In the former case it is possible that the epithelium is so damaged that it is unable to perform the healthy functions of an active tissue, while in the latter case a certain degree of tolerance or immunity to the agent applied may supervene, with the result that tumour development is delayed. There seem to be four chief aspects of the problem of tolerance and immunity. A tolerance may be developed simply from a thickening of the epithelium, or there may be an acquired local or general immunity of the cells of the host to the agent applied. The tolerance or immunity may be developed to the specific carcinogenic substances or to the tissue-destructive substances so frequently associated with oils and tars. It does not appear that in either oils or tars the carcinogenic substances and tissue-destructive substances are necessarily identical.

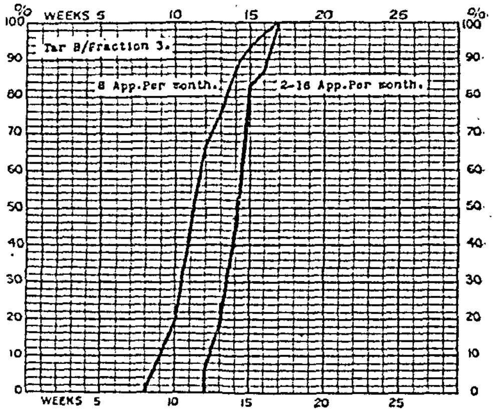
FIG. 1.



Stages in Development of the Method Employed.

These considerations led us to deviate in both directions from the frequency of application in our standard experiment. Our synthetic tars were applied to the skins of animals only once a week or once a fortnight, while mineral oils were applied daily, five times a week. Two experiments with a pinene synthetic tar have been discussed previously,[1] so that here it will be sufficient to give a graph of the final results (Graph I.).* The feature of interest in these experiments is the early development of the first tumour in the skins which were allowed long intervals of rest from contact with the carcinogenic agent, and the subsequent falling-off in the number of tumours developing as the skins acquired a tolerance for the agent. The control animals of the standard experiment were unable to react to the too powerful agent until a tolerance had developed, when the tar was what may be considered 100 per cent. active, or—what comes to the same thing—when the skins were 100 per cent. responsive to this particular agent.

FIG. 2.



From these results it seemed obvious that to obtain the steepest graph with a very powerful agent it would be necessary to commence the experiment with applications at long intervals and gradually to increase the frequency of the applications to keep pace with the skin tolerance developed.

We conducted an experiment wherein the 44 applications of an experiment lasting 22 weeks were not equally distributed over the whole course of the experiment. Two applications were given during the first month, 4 during the second month, 12 during the next six weeks, 18 during the following six weeks, and 8 during the last two weeks. In Graph II. will be found the results of painting the animals 2–16 times per month compared with those of the standard experiment, wherein the animals were painted 8 times per month.

The experiment was very unsatisfactory owing to a poor batch of animals. For this reason there were no early tumours—i.e., the occasional very susceptible animal usually found among each batch was absent. The general development of tumours was later than that among the controls until the seventeenth week, when in both experiments all animals remaining alive were bearing tumours. At this stage of the experiment the controls had received 34 applications, while the batch painted 2–16 times per month had only received 27 applications. In this respect the experimental results were in conformity with our anticipations, but we are not satisfied that they are reliable, and the experiment is being repeated.

Our first oil experiment consisted in the daily application of shale oil to the backs of 100 mice five times per week. The refined sample of shale oil used had a moderate degree of carcinogenic activity, being somewhat less powerful than the average gas tar but very much more active than any American petroleum oil we have tested. The results of this experiment were in accordance with our expectations. The first tumour appeared during the ninth week after the commencement of the experiment, and at the twenty-third week the few animals remaining alive all bore tumours. The first tumour appeared among the animals of the control standard experiment also in the ninth week, but at the twenty-third week only 41 per cent. of the animals living bore tumours. Malignancy supervened six weeks earlier in the animals painted five times per week than in the controls, and Graph III. shows that the general development of tumours among the more frequently painted animals reached a high level much more quickly than among the controls.

---

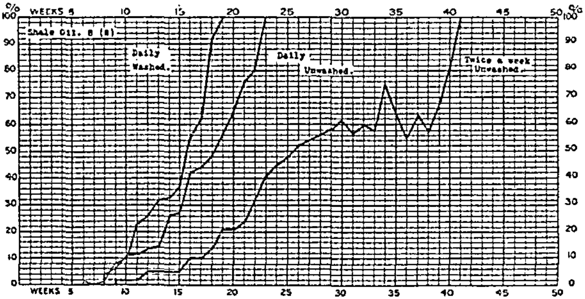
[1] Jour. Hyg., 1928, xxviii., 219.

* The graphs are compiled from the percentage of living animals which bore or had borne tumours at the end of each week since the commencement of the experiment. As 100 animals were used for each experiment and the duration of the experiments was not long, in order to make the graphs clearer the death-rates have not been included.

The effect of the frequent application of the American petroleum oils was then tested, and it was found that tumours developed earlier than when the oils were applied only twice a week.

Oil No. 3, a highly refined Pennsylvanian oil, applied twice a week to two groups of 100 animals, gave rise to the first tumour in the thirty-fifth and the thirty-eighth week respectively, while among the animals painted five times a week the first tumour appeared as early as the eighth week, and it had become malignant by the twelfth week. Malignancy did not occur among the control animals until the fifty-ninth week. Similarly, oil No. 9, a refined Californian oil, which in two standard experiments induced a tumour in the nineteenth and the fourteenth week, when applied five times a week induced a tumour in the remarkably short time of two weeks. By the tenth week 10 per cent. of the animals remaining alive bore tumours, while among the control animals painted twice a week no tumours had arisen at this stage.

FIG. 3.



Three further samples of refined lubricating oils are being applied to animals frequently, but it is too early to draw definite conclusions from the experiments, although the hyperplastic response of the epithelium can already be seen to be excessive as compared with that found in the standard experiments. Meanwhile we have been unsuccessful in inducing tumour formation by the daily application of two oils, No. 4, a liquid paraffin, and No. 12, a sperm oil, which had given us negative results in our standard experiments over 85 and 70 weeks respectively.

When we began our investigations on the carcinogenicity of lubricating oils we endeavoured to obtain a reliable method of concentrating the active principle to enable us to make a more rapid diagnosis of a particular sample than was possible when using the whole oil. It appears from our results with the daily applications that we have here a reliable and even quicker method than that of the bi-weekly application of the concentrated oils. Whether daily application of the latter will still further shorten the period necessary for diagnosis is doubtful, although we are proceeding to test this possibility.

The Protection Offered by Animal Fats.

It has been shown that, if the superfluous tar which may remain on the back of the animal from a previous painting is removed by petroleum ether before the next application, tumours develop more rapidly than in control animals where the tar is not removed. It was imagined that these results were due to the removal of the hard cake of tar, thereby permitting an easier penetration of the active substances which were contained in the fresh tar. A more likely explanation seems that the petroleum ether removed the natural skin fats so that the tar could penetrate more easily than when applied to untreated skin.

We have found that tumour development is very much delayed if, during the intervals of painting of animals with a potent carcinogenic agent, an emollient oil, such as anhydrous lanolin, is smeared over the skin to soften it and to protect it from the air.

In our first lanolin experiment 100 mice were painted twice a week with a very potent synthetic tar, and on two days between each application lanolin was smeared over the painted area. It was at once noticed that the hair was much less inclined to fall than among the control animals painted only with tar, but nevertheless the few first tumours appeared very early, possibly for the same reason as that given when discussing the early tumours in animals painted with tar at infrequent intervals. Subsequently tumour development among the lanolin-treated animals fell behind that of the control animals, while the tendency for malignancy to supervene was remarkably low.

Graph IV. gives a good idea of the protective action of lanolin; during the middle of the experiment, when conditions may be considered relatively stable, the lanolin delayed the advent of tumours by about 3–4 weeks.

A further confirmatory experiment consisted in the utilisation of shale oil instead of the synthetic tar, when the protection offered by the lanolin was even more clearly shown. The experiment has been in progress for 30 weeks without the advent of a single tumour, while among the control animals untreated with the lanolin at this stage of the experiment 61 per cent. of the animals remaining alive were bearing tumours and 21 per cent. malignant tumours. Not even one or two very early tumours developed in the treated animals, which fact accords with our experience that the shale oil is only a moderately powerful agent. As by this procedure we were unable to demonstrate any carcinogenic activity of the shale oil we performed a more severe test on the protective action of the lanolin. Animals are being painted daily with the shale oil and later in the day a small amount of lanolin is being smeared over the painted area. Also we are investigating the effect of adding a small percentage of lanolin to the shale oil and subsequently applying the mixture daily. It has to be remembered that animal fats are sometimes utilised for the blending of mineral lubricating oils, which may be an important factor in the number of tumours arising in certain groups of spinners. Also, if it is true that wool-spinners do not suffer from epithelioma to the same extent as cotton-spinners, the explanation may lie in the fact that a small quantity of animal fat is intermixed with the oil in the wool-spinning rooms, while no animal or vegetable oil contaminates the mineral oils in the cotton-spinning rooms. Incidentally, our results with the lanolin and our results from washing experiments, about to be described, lend support to the thesis that ichthyotic and xerodermatous skins are more liable to be the seat of epitheliomata than are normal skins.[2]

Removal of the Natural Fats.

The protection offered to carcinogenic agents by the application of a small quantity of an animal fat led us to conduct experiments in the opposite direction—i.e., to remove the natural fat of the skin when in contact with and before the application of the carcinogenic agent.

The first experiment consisted in daily application of

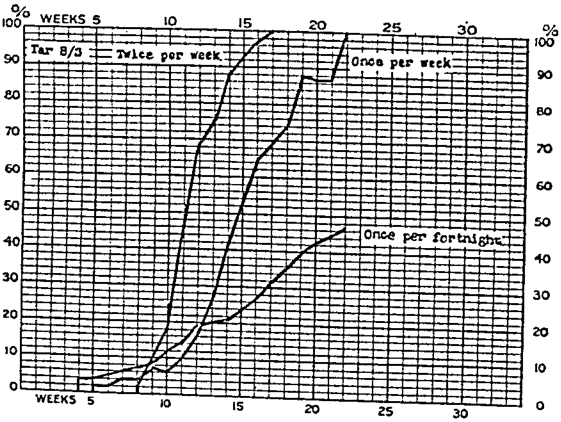
SOME FACTORS INFLUENCING THE DEVELOPMENT OF EXPERIMENTAL OIL AND TAR TUMOURS IN MICE.

BY C. C. TWORT, M.D. ABERD.,
AND
J. M. TWORT, B.SC. LOND.,
PATHOLOGIST AND ZOOLOGIST TO THE MANCHESTER COMMITTEE ON CANCER.

ALMOST all our early experiments with carcinogenic agents consisted in the application of the tar or oil to the backs of 100 mice twice weekly. This procedure constituted our standard experiment. For several reasons we imagined that when using a strong agent, such as a synthetic tar, the intervals between the paintings was not long enough to enable the epithelium to give a maximum response, while with a weak agent, such as an American petroleum oil, the interval between the paintings was probably too long. In the former case it is possible that the epithelium is so damaged that it is unable to perform the healthy functions of an active tissue, while in the latter case a certain degree of tolerance or immunity to the agent applied may supervene, with the result that tumour development is delayed. There seem to be four chief aspects of the problem of tolerance and immunity. A tolerance may be developed simply from a thickening of the epithelium, or there may be an acquired local or general immunity of the cells of the host to the agent applied. The tolerance or immunity may be developed to the specific carcinogenic substances or to the tissue-destructive substances so frequently associated with oils and tars. It does not appear that in either oils or tars the carcinogenic substances and tissue-destructive substances are necessarily identical.

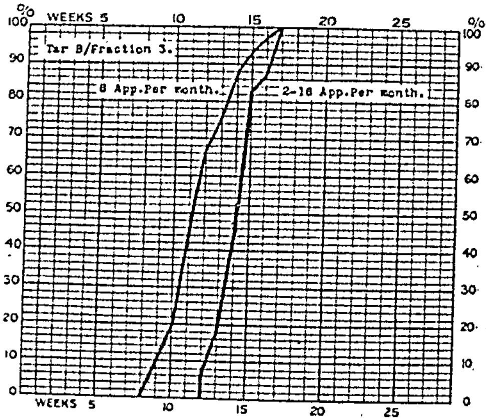
FIG. 1.



Stages in Development of the Method Employed.

These considerations led us to deviate in both directions from the frequency of application in our standard experiment. Our synthetic tars were applied to the skins of animals only once a week or once a fortnight, while mineral oils were applied daily, five times a week. Two experiments with a pinene synthetic tar have been discussed previously,[1] so that here it will be sufficient to give a graph of the final results (Graph I.).* The feature of interest in these experiments is the early development of the first tumour in the skins which were allowed long intervals of rest from contact with the carcinogenic agent, and the subsequent falling-off in the number of tumours developing as the skins acquired a tolerance for the agent. The control animals of the standard experiment were unable to react to the too powerful agent until a tolerance had developed, when the tar was what may be considered 100 per cent. active, or—what comes to the same thing—when the skins were 100 per cent. responsive to this particular agent.

FIG. 2.



From these results it seemed obvious that to obtain the steepest graph with a very powerful agent it would be necessary to commence the experiment with applications at long intervals and gradually to increase the frequency of the applications to keep pace with the skin tolerance developed.

We conducted an experiment wherein the 44 applications of an experiment lasting 22 weeks were not equally distributed over the whole course of the experiment. Two applications were given during the first month, 4 during the second month, 12 during the next six weeks, 18 during the following six weeks, and 8 during the last two weeks. In Graph II. will be found the results of painting the animals 2–16 times per month compared with those of the standard experiment, wherein the animals were painted 8 times per month.

The experiment was very unsatisfactory owing to a poor batch of animals. For this reason there were no early tumours—i.e., the occasional very susceptible animal usually found among each batch was absent. The general development of tumours was later than that among the controls until the seventeenth week, when in both experiments all animals remaining alive were bearing tumours. At this stage of the experiment the controls had received 34 applications, while the batch painted 2–16 times per month had only received 27 applications. In this respect the experimental results were in conformity with our anticipations, but we are not satisfied that they are reliable, and the experiment is being repeated.

Our first oil experiment consisted in the daily application of shale oil to the backs of 100 mice five times per week. The refined sample of shale oil used had a moderate degree of carcinogenic activity, being somewhat less powerful than the average gas tar but very much more active than any American petroleum oil we have tested. The results of this experiment were in accordance with our expectations. The first tumour appeared during the ninth week after the commencement of the experiment, and at the twenty-third week the few animals remaining alive all bore tumours. The first tumour appeared among the animals of the control standard experiment also in the ninth week, but at the twenty-third week only 41 per cent. of the animals living bore tumours. Malignancy supervened six weeks earlier in the animals painted five times per week than in the controls, and Graph III. shows that the general development of tumours among the more frequently painted animals reached a high level much more quickly than among the controls.

---

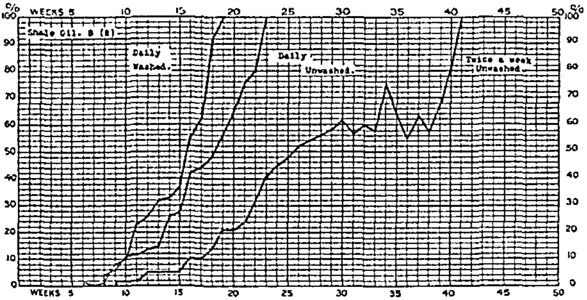
[1] Jour. Hyg., 1928, xxviii., 219.

* The graphs are compiled from the percentage of living animals which bore or had borne tumours at the end of each week since the commencement of the experiment. As 100 animals were used for each experiment and the duration of the experiments was not long, in order to make the graphs clearer the death-rates have not been included.

The effect of the frequent application of the American petroleum oils was then tested, and it was found that tumours developed earlier than when the oils were applied only twice a week.

Oil No. 3, a highly refined Pennsylvanian oil, applied twice a week to two groups of 100 animals, gave rise to the first tumour in the thirty-fifth and the thirty-eighth week respectively, while among the animals painted five times a week the first tumour appeared as early as the eighth week, and it had become malignant by the twelfth week. Malignancy did not occur among the control animals until the fifty-ninth week. Similarly, oil No. 9, a refined Californian oil, which in two standard experiments induced a tumour in the nineteenth and the fourteenth week, when applied five times a week induced a tumour in the remarkably short time of two weeks. By the tenth week 10 per cent. of the animals remaining alive bore tumours, while among the control animals painted twice a week no tumours had arisen at this stage.

FIG. 3.



Three further samples of refined lubricating oils are being applied to animals frequently, but it is too early to draw definite conclusions from the experiments, although the hyperplastic response of the epithelium can already be seen to be excessive as compared with that found in the standard experiments. Meanwhile we have been unsuccessful in inducing tumour formation by the daily application of two oils, No. 4, a liquid paraffin, and No. 12, a sperm oil, which had given us negative results in our standard experiments over 85 and 70 weeks respectively.

When we began our investigations on the carcinogenicity of lubricating oils we endeavoured to obtain a reliable method of concentrating the active principle to enable us to make a more rapid diagnosis of a particular sample than was possible when using the whole oil. It appears from our results with the daily applications that we have here a reliable and even quicker method than that of the bi-weekly application of the concentrated oils. Whether daily application of the latter will still further shorten the period necessary for diagnosis is doubtful, although we are proceeding to test this possibility.

The Protection Offered by Animal Fats.

It has been shown that, if the superfluous tar which may remain on the back of the animal from a previous painting is removed by petroleum ether before the next application, tumours develop more rapidly than in control animals where the tar is not removed. It was imagined that these results were due to the removal of the hard cake of tar, thereby permitting an easier penetration of the active substances which were contained in the fresh tar. A more likely explanation seems that the petroleum ether removed the natural skin fats so that the tar could penetrate more easily than when applied to untreated skin.

We have found that tumour development is very much delayed if, during the intervals of painting of animals with a potent carcinogenic agent, an emollient oil, such as anhydrous lanolin, is smeared over the skin to soften it and to protect it from the air.

In our first lanolin experiment 100 mice were painted twice a week with a very potent synthetic tar, and on two days between each application lanolin was smeared over the painted area. It was at once noticed that the hair was much less inclined to fall than among the control animals painted only with tar, but nevertheless the few first tumours appeared very early, possibly for the same reason as that given when discussing the early tumours in animals painted with tar at infrequent intervals. Subsequently tumour development among the lanolin-treated animals fell behind that of the control animals, while the tendency for malignancy to supervene was remarkably low.

Graph IV. gives a good idea of the protective action of lanolin; during the middle of the experiment, when conditions may be considered relatively stable, the lanolin delayed the advent of tumours by about 3–4 weeks.

A further confirmatory experiment consisted in the utilisation of shale oil instead of the synthetic tar, when the protection offered by the lanolin was even more clearly shown. The experiment has been in progress for 30 weeks without the advent of a single tumour, while among the control animals untreated with the lanolin at this stage of the experiment 61 per cent. of the animals remaining alive were bearing tumours and 21 per cent. malignant tumours. Not even one or two very early tumours developed in the treated animals, which fact accords with our experience that the shale oil is only a moderately powerful agent. As by this procedure we were unable to demonstrate any carcinogenic activity of the shale oil we performed a more severe test on the protective action of the lanolin. Animals are being painted daily with the shale oil and later in the day a small amount of lanolin is being smeared over the painted area. Also we are investigating the effect of adding a small percentage of lanolin to the shale oil and subsequently applying the mixture daily. It has to be remembered that animal fats are sometimes utilised for the blending of mineral lubricating oils, which may be an important factor in the number of tumours arising in certain groups of spinners. Also, if it is true that wool-spinners do not suffer from epithelioma to the same extent as cotton-spinners, the explanation may lie in the fact that a small quantity of animal fat is intermixed with the oil in the wool-spinning rooms, while no animal or vegetable oil contaminates the mineral oils in the cotton-spinning rooms. Incidentally, our results with the lanolin and our results from washing experiments, about to be described, lend support to the thesis that ichthyotic and xerodermatous skins are more liable to be the seat of epitheliomata than are normal skins.[2]

Removal of the Natural Fats.

The protection offered to carcinogenic agents by the application of a small quantity of an animal fat led us to conduct experiments in the opposite direction—i.e., to remove the natural fat of the skin when in contact with and before the application of the carcinogenic agent.

The first experiment consisted in daily application of shale oil to mice five times a week, and the subsequent daily removal of the oil with ordinary soap and water. Each day 200 animals were painted with the oil in the early morning, and about six hours later the oil was removed from the painted area of 100 animals by soap and water, the skins being rinsed with pure water and dried with cotton-wool to remove excess of soap. The manipulations being made with care, the animals tolerated the treatment extremely well, and it was found that the death-rate compared favourably with that of the controls.

---

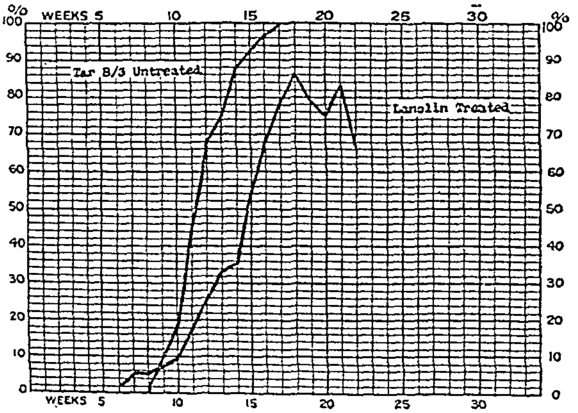
[2] Savatard, L.: Proc. Roy. Soc. Med., May 19th, 1927, p. 1589

Graph III. shows that tumour formation was not delayed by the washing; in reality it was somewhat hastened, despite the fact that the epithelium of the washed animals had only been in contact with a superfluity of the oil one quarter the time of the control epithelia.

Our results were different when dealing with less active agents such as American petroleum oils. Two similar washing experiments were performed with oils Nos. 3 and 9, the Pennsylvanian and the Californian oils. With oil No. 3 the first tumour among the washed animals appeared one week after the first tumour among the unwashed animals, the tumours appearing in the ninth and eighth weeks respectively. With the Californian oil the first tumour in both groups of animals was observed as early as the second week. However, as the experiments proceed, it is found that tumours are not arising so frequently among the washed animals as among the controls, so that it appears that partial removal of the oil with soap and water does offer some protection to the noxious action of these weak oils.

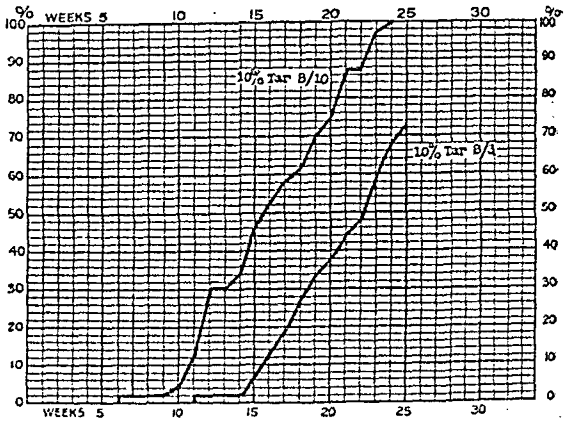
In view of these results we thought it advisable to lessen still further the duration of contact of shale oil with the skin, when we imagined that we should arrive at a contact time in which tumour formation among the animals would fall behind that of the controls. Accordingly 100 animals were painted five times a week with shale oil No. 8, and each day the animals were washed with soap and water one hour after the oil had been applied. In this group of animals the first tumour appeared in the fourth week, an exceedingly early date for the development of a shale oil tumour. We have so far had no more tumours, but the death-rate among the animals has been very high and the experiment will presumably have to be repeated. As a result of this experiment a further 100 animals are being painted with shale oil which, as far as possible, is being removed immediately with soap and water, in order to get an idea of the minimum time it is necessary for the oil to be in contact with the skin for a tumour to supervene.

FIG. 4.



We nave used soap and water to remove the superfluous oil because of its use in ordinary life. We have, of course, appreciated the fact that only the surface mineral oil and some of the natural skin fats are removed by this mechanical means. Presumably minute quantities of the mineral oil would not be removed but would be rubbed into the pores of the animal's skin, and this residual oil might be sufficient to give rise to new growth formation. On the other hand, a carcinogenic agent may exert practically all its toxic action immediately on being applied. In consideration of these possibilities we have initiated a further experiment wherein the oil is removed by a solvent instead of soap. Shale oil is being applied to 100 mice, and six hours later it is being removed by petroleum ether. In another experiment we are removing the natural fats with the same solvent immediately before the daily application of shale oil. In the former experiment the first tumour was observed in the fifth week, while in the latter the first tumour made its appearance in the third week.

FIG. 5.



The Effect of Dilution of the Carcinogenic Agent.

Closely related to the question of the frequency of application of a carcinogenic agent is that of the degree of its activity and consequently of its dilution. In order to obtain a true criterion of the relative potency of any given agent it is necessary to vary one's experimental procedure according to the presumed strength of the agent. Thus when dealing with a strong agent, such as our pinene synthetic tar, we have found that dilution of the fractions extracted was an easy means of getting at the difference of potency of two or more fractions which in the pure state had given almost identical results. When dealing with very weak agents, concentration gives the greatest amount of information.

For example, two Pennsylvanian oils Nos. 1 and 3, when applied as the whole oils, gave results similar to two other Pennsylvanian oils Nos. 7 and 11 which were obtained from a different business source, and there was little to indicate the presence of very active carcinogenic substances among their constituents. Distillation experiments showed, however, that in oils Nos. 1 and 3 there was a small quantity of very active substances; concentration of oil No. 3 by means of methyl sulphite confirmed the distillation results. On the other hand, distillation of oils Nos. 7 and 11 gave no fractions more toxic than the whole oils, and methyl sulphite extraction failed to concentrate to the same extent as in oil No. 3.

We have, as a rule, used ordinary medicinal liquid paraffin as an inert diluent, although this substance may exert a slight protective action on the skin epithelium. Graph V. is compiled from the results obtained by the application of two fractions of a synthetic tar, diluted ten times with liquid paraffin which in the pure state gave results so closely resembling one another that it was impossible to say which was the stronger. When both the fractions were diluted the difference in the carcinogenic activity was at once evident. As the concentration of the active principle in our tar fractions is becoming higher and higher we are diluting still further, and at present we are utilising dilutions as great as 1 in 100.

We have performed several dilution experiments with shale oil, as this is important from the practical point of view. A 10 per cent. and a 20 per cent. solution of shale oil in liquid paraffin have so far failed to induce the development of a single tumour among 200 mice when applied twice a week, in one case for a year and in the other for a lesser time. However, in practice shale oil is not blended for lubricating purposes with liquid paraffin but with a natural petroleum oil, and it is interesting to note that the activity of a weak American petroleum oil is increased by the addition of a small quantity of shale oil. Thus the addition of 5 or 10 per cent. of shale oil to our Pennsylvanian oil No. 11 gave a blend which, when applied to mice twice a week, induced a tumour as early as the fourteenth and the tenth week respectively, while in the control experiment with the pure oil No. 11 the only tumour observed in an experiment lasting 60 weeks did not make its appearance until the *forty-ninth* week. Also this tumour remained benign, while the first tumour which developed when using the 10 per cent. shale mixture had become malignant by the twentieth week. It may be mentioned that 200 animals painted with blends of shale oil and oleic acid responded like those treated with blends of shale oil and liquid paraffin. These results indicate that the autolysed scrotal excreta and desquamated epithelium may not play such an important part in the genesis of mule-spinners' cancer as has been imagined by some workers.

In order to get an idea of the actual amount of carcinogenic agent it was necessary to apply to the skin for tumour development to supervene, dilution methods were of little use. The beneficial or harmful action of the diluent itself rendered the interpretation of the results difficult. Also the application of definite minute quantities of the pure oil is impracticable. To overcome these difficulties we used a weak solution of oil in a volatile solvent, so that only a trace of the pure oil would be left on the back of the animal after the evaporation of the diluent. A 1 per cent. solution of shale oil in petroleum ether was applied daily in our first experiment; up to the present time we have obtained several tumours, but the experiment has not been in progress very long.

Conclusions.

1. The early development of tumours is not facilitated and may even be delayed by the too frequent *application of a potent carcinogenic agent.* With a weaker agent the more frequent the applications the earlier do tumours appear to develop.

2. Similarly, the dilution of a potent agent does not materially affect the time of arrival of the early tumours, while the dilution of a weak agent may render it apparently inert.

3. The carcinogenic activity of a very weak American petroleum oil appeared to be increased considerably by the addition of a small percentage of shale oil. On the other hand, we failed to induce tumours with a blend of a small quantity of shale oil with medicinal liquid paraffin.

4. If the skin of animals which have been painted with shale oil are washed with ordinary soap and water *a few hours later the incidence of tumour* development is not lessened but may even be increased. The removal of the natural skin fats is presumably harmful. With weaker agents, such as American petroleum oils, the washing seems to offer a certain amount of protection.

5. If lanolin is applied to the skin in the intervals between synthetic tar applications the development of tumours is substantially delayed. In the case of a less potent agent, such as shale oil, the lanolin has, in our experiments, given absolute protection, and no tumours have so far developed in the lanolin-shale oil treated animals.

THE DEATHS OF MERCHANT SEAMEN IN 1927.

BY FLEET-SURGEON W. E. HOME.

THE Board of Trade Return,[1] which includes the deaths on vessels registered in the United Kingdom in 1927, tells us that the "first crews" of ships in that year included 161,800 British, 19,000 foreign, and 55,100 Lascar seamen, among whom 1223 deaths were reported. No suggestion is made of a death-rate for any of these groups, but in 1926 a census was taken of the seamen employed, and the number found on board on the census day was for British seamen 80 per cent. of "first crews," and for Lascars 90 per cent. So, to get a nearer idea of the population at risk, of the ration strength from day to day, it will be better to take these proportions of the first crews as stated—namely, for the British 131,000, for the Lascars 50,000, and with these figures to calculate the death-rates, as the nearest approximation possible.

The total British deaths were 853 (6·48 per 1000), of which 408 (3·10) are attributed to disease, 22 (0·16) to alcohol (a reduction), 40 (0·30) to suicide, and 362 (2·82) to accidents. The total Lascar deaths were 240 (4·98), the corresponding figures being disease 182 (3·64), alcohol 1 (0·02), suicide 13 (0·26), and accidents 47 (1·00). Rather more than half the total deaths were thus due to disease. The chief named causes of death from disease were, for British seamen, tubercle 48 (0·37), pneumonia 42 (0·32), malaria 17 (0·13), enteric fever 16 (0·12), and for Lascars, tubercle 37 (0·74), pneumonia 33 (0·66) beri-beri 14 (0·28), malaria 12 (0·24). It will be *noticed that the death-rates from tubercle and* pneumonia for Lascars (0·74 and 0·66), who need only have 72 cubic feet of space in their ships, are roughly double those (0·37 and 0·32) of the British seamen, who must have each 120 cubic feet. During the last four years (1024–7) deaths from tubercle of lung and tubercle "other" have been separated in the return, and if they are assembled and the death-rates on *"first crews" are calculated, we get the* figures, for pneumonia, British 0·3, Lascar 0·6; and for lung tubercle, British 0·17, Lascar 0·6 per 1000, the British having a half-rate for pneumonia, and for phthisis a quarter-rate of that of the Lascars.

By the help of the census figures and those of deaths for 1926, given in the return for 1927, it is possible to make a very approximate estimate of the occurrence of deaths among seamen in sail, steam, and motor-ships, from which it appears that 1634 men were employed in sail, with deaths 4·3 per 1000 from disease, and 11·0 from accidents; 187,536 men, in steam, with deaths 3·8 from disease and 3·1 from accident; and 7338 men in motor ships, with deaths 3·0 from disease and 2·3 from accident. It will be noted, however, that the number in sail was very small, the total deaths being, sail 25, motor-ships 39, steam 1289 in the year 1926.

MEDICINE AND THE LAW.

Prosecution of Unregistered Practitioner.

Lieut.-Colonel J. W. Kynaston, late R.A.M.C., appeared at Marlborough-street police-court on May 15th on two summonses, alleging that he had falsely pretended to be a doctor of medicine and had wilfully and unlawfully used the title of "M.R.C.S. Eng." contrary to the Medical Acts. It was stated for the prosecution that he had been placed upon the *Medical Register in 1885, and it was explained that the* Medical Act of 1886 created a different and additional qualification for registration. The defendant had become duly qualified as a Member of the Royal College of Surgeons of England and a Licentiate of the Royal College of Physicians of London. Seven years ago his name was removed from the Register for what was described as, and found to be, "infamous conduct in a professional respect." That did not imply criminal conduct; the explanation was that Colonel Kynaston was convicted of advertising. The Royal College of Surgeons thereupon withdrew its diploma and the Royal College of Physicians expunged his name from the list of licentiates, but recorded that an application for restoration of his licence might be considered after two years. Mr. G. D. Roberts, who prosecuted, said that the defendant was practising at Langham-place and was doing two things which he was not entitled to do; he called himself "doctor" and put this word in front of his name on his brass plate and in advertisements; he was also using the description "M.R.C.S." This, said Mr. Roberts, implied that he was registered under the Medical Act. Counsel seems to have stated the position with fairness. He disclaimed any idea that the defendant was a quack; Colonel Kynaston had the skill to maintain his qualifications. A man not on the Medical Register was entitled to practise in the same way as a medical practitioner, but he must not pretend that he was on the Register or lead the public to believe that he was a registered practitioner. The Register was the hall-mark of professional skill and professional honour. Evidence was given by Mr. G. F. S. Cowell, secretary of the Royal College of Surgeons. In cross-examination, he agreed that he had not asked the defendant to return his diploma after being struck off the Register; the diploma was, it seems, still in Colonel Kynaston's physical possession. Other evidence was given of the draft of an advertisement sent by the defendant for insertion in the *Radio Times*. Colonel Kynaston went into the witness-box and described the circumstances of his removal from the Register: "I did not appeal against the decision of the General Medical Council which I held, and have always held, to be ultra vires, but I admit de facto that my name is not on the General Medical Register; my complaint is, that I have been illegally removed from it." "You never thought it right," remarked the magistrate, "to test it in the High Court." The defendant rejoined that he could not afford the expense; but, if he were to be prosecuted and brought before a criminal court, he proposed at the earliest opportunity to ask the Court of Chancery to say whether or no the General Medical Council had acted within its jurisdiction. "With regard to the title of doctor," he added, "I have been addressed as 'doctor' for 20 years; in the ordinary acceptance of that term I am a doctor; I have never pretended to be a doctor of medicine, it is no false pretence to say I am "M.R.C.S." or "L.R.C.P.," because I have the diplomas in my possession." Mr. Cancellor, the magistrate, adjourned the case sine die, as there was no time to finish it; the parties would have notice of the resumed hearing.

---

[1] Return of Shipping Casualties, &c., for 1927. H.M. Stationery Office, 1928. Pp. 8 2s.

The further proceedings will be awaited with interest. On the general question of the jurisdiction of the Medical Council it is well settled that there can be an appeal to the High Court, but that the High Court leaves the Council to judge in matters affecting the medical profession and refuses to intervene unless some principle of natural justice is violated—e.g., if a defendant has not been informed of the charge against him, or has not had adequate chance to reply thereto, or if the tribunal has acted with bias. The question whether in the circumstances of the present proceedings Colonel Kynaston has been guilty of a false pretence is presumably a question of fact for the magistrate or (on commitment for trial) for a jury. The issue whether it is correct to say, "once a 'M.R.C.S.,' always a 'M.R.C.S.'" is a part of the question of fact. Similar circumstances existed, it may be recalled, when Colonel Kynaston was prosecuted at the Central Criminal Court in November, 1926, on a charge of aiding and abetting the obtaining of a dangerous drug while not a registered medical practitioner. His conviction on that occasion was upset by the Court of Criminal Appeal on the technical ground that the prosecution had in part based the proceedings on the Dangerous Drugs Act of 1925, which at that time had not yet come into operation. It will not be satisfactory to either party unless a definite decision can be reached upon the merits of the case.

The Proceedings against Mr. Raphael Roche.

We are informed that "the officers of the Society of Apothecaries of London, having had the opportunity of investigating the alleged matters of complaint against Mr. Raphael Roche, have satisfied themselves that he had not contravened the provisions of the Apothecaries Act, 1815; and, having obtained from him the subjoined undertaking, the Society are glad to be able to announce that there is now no reason for invoking the powers vested in them under the aforesaid Act." The undertaking signed by Mr. Roche includes the statement that: "I hereby undertake that I will not, in the course of my work, act in such a manner as to contravene the provisions of the Apothecaries Act, 1815, relating to acting and practising as an apothecary."

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Content of a General Practice.

A PRACTITIONER, in a city of 15,000 people in a populous Eastern State, has analysed his diagnosis file containing some 6200 diagnoses entered during the last eight years. He admits that some of the commoner complaints among his patients have doubtless been omitted from the file. In spite of this, and of the natural uncertainty about the rigid classification of certain cases, the results are of considerable interest in showing approximately what are the demands upon a general practitioner in this country. Medical cases number 2499, or 40 per cent. of the total, and surgical cases 1497 (24 per cent.); whilst the following numbers are attributed to the other branches of practice: obstetrics 471, pædiatrics 345, dermatology 322, neurology 274, laryngology 254, gynæcology 156, genito-urinary diseases 140, otolaryngology 100, orthopædics 81, and ophthalmology 73. Among the medical cases colds (281), bronchitis (285), and influenza (290) were the most common, while the inclusion of one case each of Banti's disease, aortitis, tapeworm, and pulmonary embolus shows how long the practitioner may have to wait to use a large part of the knowledge acquired in the schools. The importance of minor surgery in this practice is rather striking; there were 683 cases of trauma and 348 of infection. The pædiatric cases are mostly contagious diseases, to which must be added a number of the diseases of early infancy which would naturally be associated with the obstetric work. Only two cases of rickets are recorded, three of enuresis, and five of malnutrition. In obstetrics placenta prævia was encountered once, eclampsia four times. Of the diseases of eye, ear, nose and throat, the commonest were tonsillitis (333), laryngitis (96), otitis media (64), conjunctivitis (24), foreign body in eye (30), and sinus infection (24). Among the conditions occurring once only are iritis, ectropion, retropharyngeal abscess, and—pyorrhœa! This practitioner's conclusion that more time should be devoted to minor ailments in the medical schools may be justified, but not many will agree with him in wanting the time of education to be allotted in proportion to the frequency of diseases encountered.

Death of Haley Fiske.

The death of the president of the Metropolitan Life Insurance Company removes from our midst a pioneer in preventive and industrial medicine. His belief that it is a main function of the business of life insurance to promote health has exercised a remarkable influence on the lives of the 25,000,000 citizens of this country and of Canada who are served by the organisation, of which he was president. It was in 1908 that the decision was reached to make a health campaign amongst the policy-holders. Since then more than 535 million health pamphlets have been circulated, and an important nursing service has grown up. It is calculated that, as a direct result of this campaign, more than 350,000 lives have been saved at an economy in death claims to the company of $70,000,000. Less than half this sum has been expended on the health campaign work.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Aviation in the Service of Medicine.

THE First International Congress of Sanitary Aviation has been a great success, 40 nations or dominions sending delegations. Great Britain was represented by Air Vice-Marshal David Munro and Group-Captain Martin Flack; Australia by Dr. Parks and the Rev. Mr. Flynn; Canada by Captain Williams, head of the Canadian Sanitary Service; and India by Air Vice-Marshal Munro.

Colonel Schickelé (France) and Captain Chochup (Japan), who reported on the use of sanitary aviation in war, consider that the speed of medical aircraft should be 175 kilometres per hour with a range of 500 km. Aeroplanes for the medical services should be gathered together at the beginning of a war out of the available commercial material. It was pointed out that the campaign in Morocco has shown what may be expected of air evacuation, 4500 wounded being brought rapidly to hospital from the front. Colonel Sprich said that before aeroplanes were used there were no "severely injured" in the Morocco hospitals, because they never got there alive.

Among the other topics discussed was the immunity of medical aircraft in warfare and medical aviation at sea. Dr. Garsaux and Dr. Behague discussed the effect of air transport on the patients themselves; for instance, they asked, should men wounded in the brain be carried by air? To this question they thought no positive answer could as yet be given. The use of aircraft in peace-time was the subject of reports by Dr. Tilmant (France) and Dr. Krzys-Koroski (Poland), who urged the need for preparing landing-grounds in great number. A very interesting film was shown to illustrate transportation to hospitals in Sweden, where sick and wounded are carried south from the snowy plains of Lapland to hospitals 300 or 400 kilometres distant. The aeroplanes are equipped with skis or floats for snow or water, according to the place of landing.

At the end of its meeting the Congress passed resolutions to the following effect: (1) That the nations represented should make every possible effort to extend and develop sanitary aviation. (2) That everything should be done in peace-time to make travel easier for medical aircraft, especially by giving them a permanent priority on landing-grounds, and by granting them free crossing of frontiers. (3) That landing-grounds should be as many as possible, especially in countries lacking ordinary means of communication. (4) That encouragement should be given for the conversion of commercial aircraft to medical uses either in peace or war by easy and prompt modification of equipment. (5) That manufacturers should be given moral and material encouragement in their attempts to improve the study and building of medical air material. (6) That international agreement should be reached as soon as possible on the status of medical aeroplanes granting them neutrality in warfare.

The next Congress will study: the equipment, staffing, and security of medical aircraft, and the medical and surgical contra-indications of transportation of wounded by air. A permanent committee will have its offices at the Aero Club of France, 25 rue François Ier, Paris. The president is Prof. Richet (Paris), the vice-presidents being General Bauer (Sweden), General Rouppert (Poland), and Prof. Di Nola (Italy).

Mr. R. Charlet, the secretary, is a dental surgeon. He is president of the Paris University Air Club, and is the man who first conceived the idea of the Congress. Having organised it from beginning to end, he deserves congratulations for the remarkable success achieved by a year's very heavy work.

Midwives and Social Insurance.

The new law on social insurance should come into force in April, 1930, and those implicated are studying the effect it is likely to have on their work. Midwives, whose service will now be almost wholly paid for under the insurance scheme, are only now beginning to organise themselves, and it was not until last week that they set up their "syndicate" for Paris and suburbs, under the presidency of Mlle. Mossé. They are now trying to form a single national confederation with the other syndicates, some of which are already associated in local groups. In negotiating with the Government a national body has many and obvious advantages.

Cocktails.

That alcoholism is now commoner among the smart set than among the working classes was the assertion of Dr. Guillain, professor of clinical neurology, in a recent lecture before the Academy of Medicine. The noxious habit of taking cocktails before meals, now acquired by young women of the "best world" accounts, he said, for their developing disorders that before the war were the prerogative of the hospital classes. One must now go to the houses of the wealthy to find alcoholic polyneuritis, since only rich people can afford the price of highly toxic drinks. Prof. Guillain gave his colleagues some receipts for making the best-known cocktails, and the Academy concluded its deliberations by passing a resolution intended to draw the attention of the upper classes to the dangers of absorbing these poisonous substances. This and similar warnings lose much of their effect, however, through the non-participation of most of the newspapers, as they do not care to get into trouble with the "alcoholocracy" in this country, which is neither more nor less powerful than it is in the rest of the world.

The Last Influenza Epidemic.

The Société Médicale des Hôpitaux has had a special discussion on the forms of influenza observed during the recent outbreak in Paris. The pulmonary symptoms seem to have been much the same as in 1918–19, though less severe. Toxæmia was the real cause of death in many cases, in which the lesions found post mortem did not seem sufficient to explain the rapid termination of the illness. Dr. Hallé gave an interesting account of a family whose members reacted to influenzal infection by various different nervous symptoms, such as nystagmus, sialorrhœa, headaches, and mental confusion.

In the course of the discussion Prof. Netter expressed his view that influenza and encephalitis are separate diseases with their own viruses. He thinks that everything pleads for their separation though, of course, there is as yet no absolute proof of this.

Prof. César Roux, the celebrated surgeon of Lausanne, has been awarded the title of "Doctor Honoris Causa" of the University of Paris.

Dr. Lesné, of the medical staff of Paris hospitals, specialist in pædiatrics, and General Rouvillois, professor at the military medical school of the Val-de-Grâce, have been elected members of the Academy of Medicine.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Health of County Galway.

THE Department of Local Government and Public Health has drawn the attention of the Galway County Board of Health to the advisability of recommending the county council to appoint a county medical officer of health, and has stated that the Board of Health would be incurring a grave responsibility if further postponement were permitted. It was further pointed out that the incidences of infectious disease was far too high in the county. During the past two years 70 cases of enteric fever and 184 cases of diphtheria had been reported from the County of Galway. These figures, which pointed to extensive disregard of proper sanitary precautions, were much in excess of other counties in the Irish Free State, and indicated the necessity for a centralised county control of infectious diseases. The money spent in maintaining institutions for the treatment and isolation of preventable disease would cover the cost of beneficial schemes for prevention of disease. In Connemara there was a chronic smouldering infection of typhus fever, with periodic outbreaks which exacted a heavy cost both in human life and in money. Modern sanitary methods would eradicate this disease, as had been done in other countries. During the year 1926 a widespread outbreak of encephalitis lethargica occurred in County Galway, about 100 persons being affected. Those cases were not reported to the Minister, and as there were no local facilities for coördinated supervision, a valuable opportunity for studying the disease and, perhaps, preventing further outbreaks, was missed. There was great need for the establishment of a system of medical inspection of school-children in County Galway, and the care of expectant and nursing mothers was awaiting attention. It was added that as the port of Galway was becoming an important centre for immigration and emigration, it was prudent that it should be under the supervision of an expert medical officer of health. After discussion the Board of Health referred the letter of the Department to the county council without making any recommendation.

Medical Certification of the Insured.

The National Health Insurance Commission has addressed a letter to the several medical certifiers, drawing their attention to an alleged laxity and irregularity in the issue of certificates of incapacity for work. It is stated that although in the year 1928 the number of insured persons in the Irish Free State was less by 26,000 than in 1925, the number of certificates issued rose from 831,000 in 1925 to 1,145,000 in 1928. At the same time less expenditure on sickness and disablement benefits rose from £410,000 to £562,000. The Commission states its opinion that, in the absence of any evidence other than the certificates to show a corresponding increase in sickness, the growth of expenditure is due largely to laxity in certification. In support of this view it is pointed out that of 20,000 cases referred for second opinions under the District Medical Referees Scheme in 1928, less than 40 per cent. were found on examination to be incapable of work. The Commission declared its intention of exercising a closer control over the work of the medical certifiers. An analysis is being recorded in regard to each certifier showing (*a*) the result of the testing of his certification by the medical referee, and (*b*) the result of a scrutiny of the blocks of the certificates issued by him quarter by quarter. These records will be borne in mind in deciding on the action to be taken when complaints are made against individual certifiers. It is added that, unless a substantial improvement is made in the standard of certification, the Commission will take the step of terminating the agreements with certifiers who refuse or neglect to comply with the terms of their contracts. Moreover, in any case in which a medical certifier may be found, after investigation, to have made a false or misleading statement in connexion with the issue of a medical certificate, the Commission will not hesitate to report the case to the Medical Registration Council.

It has, unfortunately, to be admitted that there is a certain amount of lax certification by medical certifiers. This is made the most of by certain officials of the approved societies who are anxious to obtain for the societies the right to provide certifiers under their own control, and, therefore, miss no opportunity of finding fault with the present system. The letter of the Commission appears to take an altogether exaggerated view of an admitted evil.

National University of Ireland.

Dr. Denis J. Coffey, President of University College, Dublin, and Vice-Chancellor of the National University, has been reappointed to represent that University on the General Council of Medical Education and Registration.

Registration of Dentists in the Irish Free State.

The Register of dentists set up by the Dentists Act, 1928, came into existence in the Irish Free State last week, and it is now illegal for anyone to practise dentistry in the area of the State unless his name is on the Register. The conditions of admission to the Register are similar to those for admission to the British Register.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Care of the Feeble-minded.

THE Edinburgh District Board of Control some years ago purchased Gogarburn House and Estate, with 58 acres of land, and later added the adjoining estate of Kellerstain, with 361 acres. In 1923, when these transactions were carried through, financial stress hindered the immediate development of these estates as homes and colonies for the feeble-minded; but in March, 1927, the first sod of the service roads was cut. The institution will ultimately contain blocks of dormitories, laundry, stores, hospital, and additional staff quarters. Two dormitories, each with 50 beds, are completed and two more will be built. When the present scheme is brought to a close, there will be accommodation for 500 feeble-minded persons, and the plans permit of extension to 1000. The institution is meant to serve not Edinburgh alone, but all south-eastern Scotland. It is to provide for the detention of adult defectives and for educable children under 16 years of age, the usual occupations being provided. The entire scheme is expected to cost more than £400,000, about half of which will be borne by the Treasury.

An associated institution, on the same grounds, is in contemplation for the treatment of incipient insanity, but this is a separate scheme. The Glasgow District Board of Control has a large home and colony for feeble-minded at Stoneyetts, near Glasgow. The powers of the 1913 Mental Deficiency Act will now be more effectively applied. The reform in local government will no doubt affect the Gogarburn Institution for the better; but the present District Board of Control are to be congratulated on the measures they have taken in the last few years. The conception of a segregation colony has, thanks to the recent agitation by the Scottish Women Citizens, taken full possession of the official mind. The colony at the Royal Larbert Institution is being rapidly developed. All our institutions will obviously be needed, now that we are learning more exactly the numbers of the feeble-minded. The familiar deliverances of several judges that they cannot deal with the feeble-minded because there are no institutions to send them to will soon be a thing of the past.

The New Principal of Edinburgh University.

The Principalship of Edinburgh University, rendered vacant by the retirement of Sir Alfred Ewing, which takes effect at the close of the present session, has been accepted by Sir Thomas Henry Holland, K.C.S.I., Rector of the Imperial College of Science and Technology, London. Sir Thomas is President-elect of the British Association, which is meeting this year in South Africa, and he is not expected to arrive in Edinburgh until about the middle of October. He is in his sixty-first year. Joining the Indian Civil Service in 1890, he held many important appointments in India before returning to this country in *1909 to become professor of geology and mineralogy* in the University of Manchester, a post which he held until 1918. In 1915 he became President of the Institute of Mining Engineers; in 1920 he was appointed a member of the Governor-General's Council of India; and from 1924–25 he was Vice-President of the Royal Society.

Addressing the Summer School of Social Study at Rothesay, Dr. J. Parlane Kinloch, Chief Medical Officer of the Department of Health for Scotland, said he had reached the conclusion that the present arrangement whereby health visitors are required to devote their whole time to health visiting from the central offices of a health department, and are largely divorced from actual nursing, is essentially bad. If the public health nurse and health visitor is to fulfil her function she must have clinical association and actual participation in nursing work, for unless doctors and nurses continually receive fresh inspiration by actual contact with medical and nursing work they are bound to become stale. Dr. Kinloch urged united action by the authorities of all the nurses' training schools to establish in each of the principal regions of Scotland a complete training school for health visitors and nurses.

At the annual general meeting of the Scottish Branch of the Smoke Abatement League on May 3rd Colonel P. S. Lelean, Professor of Public Health in the University of Edinburgh, mentioned an experiment carried through in the Warrender Park district of Edinburgh. In that area 4800 windows of flats occupied by an educated and good class of citizen had been kept under observation. It was found that in the summer only 1 in 12 windows was wide open, and only 5 in 12 were open at all. These were appalling figures, and showed the lack of education in public health matters.

In the thirty-eighth annual report of the Glasgow Royal Cancer Hospital it is stated that the ordinary income was £7668 and the ordinary expenditure £9527. Extraordinary income, &c., amounted to £7143. The report refers to the recent gift of £10,000 by Lady Burrell for the purchase of radium. In order to obtain the best results, the directors have decided to form a radium institute, and with that object have purchased a property adjoining the hospital. The institute will be under the supervision of a full-time medical officer, and will be available for the treatment of patients in Glasgow and the West of Scotland, whilst it is also hoped to be able to lend radium to other hospitals in the neighbourhood.

Dr. W. M. McAlister, deputy physician-superintendent of the Royal Edinburgh Hospital for Mental Diseases, lately spoke to the Edinburgh Soroptimist Club on the Modern Treatment of Mental Disorder. He pointed out that in every mental hospital about 70 per cent. of the population is a chronic population, which is a deplorable state of affairs. It is out of the apparently trivial disorders outside the asylums that such cases develop, and the remedy is not a simple one. Hitherto people have been content to see things growing, and then to step in and try to alleviate the damage. The real beginning of treatment lies in the formative years of the child's life. The treatment is not of an individual, but of a situation, and the aim is prevention before definite symptoms have arisen. To achieve this aim requires the coördinated help of social worker, health visitor, teacher, psychologist, and alienist.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Barnstaple Rural District.

We have received from Dr. J. R. Harper the first health report for the year 1928. The estimated population of his district was 19,180; the birth-rate was 12·9, and the death-rate 12·5. The 240 deaths included 122 male and 118 female. Twice as many females as males died from cancer and tuberculosis, the rates from these causes for both sexes combined being 1·56 and 0·78 per 1000 of the population respectively. On the other hand, there were 28 male deaths and 20 female from heart disease and 12 deaths of male infants to 2 deaths of female infants. The total rate for heart disease was 2·4 and the infant mortality-rate was 56·9 per 1000 births. Influenza was not so prevalent as in 1927 and only caused 2 deaths as compared with 17, the death-rate from respiratory diseases and influenza being only 0·8 per 1000 of the population. Schools in eight parishes were closed on account of measles in the early part of the year; one school was closed for 12 days for disinfection on account of scarlet fever; and one for eight days on account of chicken-pox. A maternal death-rate of over 8 per 1000 births was occasioned by two deaths, one of them from sepsis.

Dr. Harper refers to the need for the replacement of unsatisfactory cottages. The Housing (Rural Workers) Act is being utilised. The reconditioning of 13 houses was begun during 1928, and the work was completed in the case of three during the year. The County Council has approved two further schemes under this Act. Twelve new "subsidy" houses were completed during the year. The unsatisfactory water-supply at Combe Martin is being dealt with, and it is expected that the new water supply will be available for the village in 1929. The sewage outfall at Combe Martin is to be extended in order to prevent the deposit of sewage on the beach near low-water mark. Samples of milk are examined bacteriologically and the results communicated to the producers concerned. Grade A (T.T.) milk is produced on two farms in the district.

PORT SANITARY AUTHORITIES.

Hull and Goole.

Dr. W. Allen Daley, in his report for 1928, observes that the medical staffs of the city and port have this year been conveniently made interchangeable. In all, 7096 ships arrived and were inspected; also 1157 canal boats and 4431 fishing vessels. These latter, if on long-distance cruises to Iceland or the White Sea had generally better accommodation than had most ships for their crews. Of the ships, 888 had defects; these are separated into three groups: (*a*) defects of original construction, the most notable being no water service to the w.c., 33; (*b*) defects due to wear and tear, leaky ports, 169; leaky decks, 88; (*c*) dirt, vermin, &c., dirty forecastles, 547; verminous berths, 103; insanitary w.c.'s, 77. There were no cases of plague, cholera, yellow fever, small-pox, or typhus on any ship arriving. Opportunity for vaccination was offered to crews, but no application for it was received. Sanitary administration of the port cost £4511, of which £2152 was refunded by the Government. The water-supply of the port is from deep wells and is very pure; the tanks of 95 ships were ordered to be cleansed; in no case was there a written record on the ship of the origin of the water on board. Rats, 7522, were killed on board ships, 1150 ashore—a gratifying reduction of 35 per cent. in eight years. Ships are searched for evidence of recent rat-infestation (photographs are given); if there is no evidence, a "deratisation exemption certificate" is given; if less than 10 rats are suspected on board, a "deratisation by trapping certificate" is given, but if over 10, the ship is fumigated; in default of search, the ship must be fumigated every six months. Over 270 tons of food (imported) were condemned at Hull, but all received at Goole was sound. Aliens arriving were 7401; among the transmigrants 90 were certificated for trachoma, favus, and similar conditions.

Port of London.

In his report for 1927, Dr. W. M. Willoughby mentions that in all 23,233 ships were examined. The latrines of the port have been increased by some 260; a new infectious pavilion was added to the Denton Hospital at Gravesend. The Ministry of Health suggested it might be well to inoculate seamen on the way to the Persian Gulf against cholera, and 137 were so immunised. Schick-testing and immunisation is thought to have freed one training ship from diphtheria, and another, it is hoped, will follow suit. No case of human plague was seen, but 35 dead rats were reported on board a grain ship from South America; of these five were found plague-infected, two brown, three black. The ship was twice fumigated with hydrocyanic acid—once when half-discharged 291 rats killed, and a second time with the holds empty, five found. Small-pox was brought on board a ship at Calcutta on Dec. 7th by a man who developed the disease on the 14th, and died on the 24th. The ship's crew, all but one man who was overlooked, were vaccinated at Suez; no one else but this one missed man took small-pox; he became ill on Jan. 8th, 14 days after the death of the first case. On ships 12,897 rats were destroyed, ashore in the port 11,395; only the five mentioned were plague-infected. There appears to be most confidence in hydrocyanic acid fumigation which kills fleas even quicker than rats. Of unsound food 1813 tons were destroyed or specially dealt with; of 60,659 beef tongues particularly examined, 2 per cent. were found affected with actinomycosis. The chief nuisances detected on ships were: dirty quarters, 1218; leaks in quarters, 102; defects in lighting, 94; in ventilation, 81; in heating, 62; in sanitary conveniences, 47; and 50 crew spaces were verminous. Of venereal disease 133 cases were reported among crews on arrival. It is noted that the total number of cases of infectious disease reported is decreasing, a possible result of greater attention paid in foreign ports.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 11TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 277 (last week 356); scarlet fever, 2166; diphtheria, 966; enteric fever, 37; pneumonia, 1407; puerperal fever, 49; puerperal pyrexia, 126; cerebro-spinal fever, 25; acute poliomyelitis, 2; encephalitis lethargica, 25; continued fever, 1; dysentery, 9; ophthalmia neonatorum, 101. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on May 14th-15th was as follows:—Small-pox, 292 under treatment, 15 under observation (last week 338 and 12 respectively); scarlet fever, 1501; diphtheria, 1636; enteric fever, 11; measles, 117; whooping-cough, 943; puerperal fever, 24 (plus 12 babies); encephalitis lethargica, 109; poliomyelitis, 4; "other diseases," 61. At St. Margaret's Hospital there were 15 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 4 (0) from enteric fever, 57 (1) from measles, 6 (1) from scarlet fever, 83 (28) from whooping-cough, 24 (3) from diphtheria, 48 (9) from diarrhœa and enteritis under two years, and 79 (7) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to West Ham C.B. A second death provisionally assigned to Rochdale C.B. was omitted from last week's return. No great town reported more than 3 deaths from influenza except Manchester with 7 and Bradford with 4. Liverpool reported 15 deaths from measles, Birmingham 7, and Sunderland 6. The mortality from whooping-cough is now diminishing, although Liverpool reports 5 deaths, West Ham, Birmingham, and Manchester 4 each. No great town reports more than 3 deaths from diarrhœa.

The number of stillbirths reported during the week was 327 (corresponding to a rate of 47 per 1000 births), including 65 in London.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, MAY 8TH.

WAR PENSIONS ADMINISTRATION.

On the report of a vote of £32,723,500 for the salaries and expenses of the Ministry of Pensions,

Major TRYON, Minister of Pensions, said that the vote of the Ministry was still nearly the largest single vote of all the civil estimates. The Ministry's work affected the weekly budget of nearly a million families and the actual beneficiaries of the Ministry numbered a million and a half—a larger number than had been reached under any pensions system in this country. At the end of the current year they would have spent since the beginning of the war—i.e., during the past 15 years—no less than £913,000,000 on war pensions. By comparison with that sum France would have spent not more than about £500,000,000, and Germany but little more than about £400,000,000. Our expenditure on war pensions had therefore been roughly equal to the expenditure of both France and Germany together. The reason was that our scales of pension were considerably better than those of France and Germany. For example, a disabled man with a 50 per cent. pension—about the average pension rate—drew under the British pension system £52 a year for himself, and a 50 per cent. pension would be never less than £52. In France the same man would draw £23 a year, including a variable bonus. In Germany he would draw £18 a year, including a bonus. This country was prompt to adjust pension scales to meet enhanced prices so that, whoever suffered, the pensioner should not. Other countries did not take this course, and the pensioner suffered; and it was only since those countries had given up the policy of inflation of prices and had attained a stable currency that they had begun to adjust the scales of pension to the altered cost of living. In strict financial theory this country should have been bringing our pension rates down as other countries were just beginning to increase theirs, because our cost of living had gone down steadily since 1919, but the Government decided that pensioners should not suffer a reduction of the scale of pension to which they had become accustomed for years and they decided to stabilise the existing scales of pension.

The estimated expenditure of £53,000,000 represents a decrease of nearly 3½ millions on the estimate of the preceding year. This at the present stage is a normal decrease. It would not last because the principal factors of that decrease were gradually ceasing to operate. The expenditure would, in fact, very shortly show no more than a fall of little more than 1 per cent. a year, and he estimated that over the next ten years the mean expenditure would be about 45 millions a year. But, taking the course of expenditure for the last five years, including the year in which the Labour Party were in office, there had been an annual decrease in the expenditure amounting on an average to round about 3 millions. Indeed, the actual (not the estimated) expenditure of last year showed exactly the same decrease, namely, about 2¾ millions as occurred in his predecessor's year of office. The decreased expenditure was the result of a decline in practically every item of the Bill—administration, medical services, pensions, and allowances. The administrative machinery of pensions would cost this year £1,231,000. There was still a decline in this item of our expenditure. Though naturally enough it was tending to stabilise, there would still be the substantial decrease of 6½ per cent. on the previous year's figure. They were still spending on administration no more than 5½*d.* to every £ of expenditure on benefits to pensioners, as compared with 1*s.* 3*d.* in 1920, the first year of his association with the Ministry. The staff showed a decline in numbers corresponding with the diminution in the volume of work. At March 31st last the staff numbered 6608, a decrease of 800 on the previous year. Roughly one-third of the number consisted of female staff, of whom a large number were employed as nurses in Ministry hospitals; 4100 were men, of whom 96 per cent. were ex-Service men. In pensions and allowances, which accounted for 94 per cent. of the Ministry's expenditure, they would spend this year £50,798,000 for a pension list of, roughly, 950,000 adult pensioners and their dependents. Of the total £27,300,000 went in pensions and cash benefits of all kinds to disabled officers and men; and £23,400,000 to the widows and dependents of officers and men who had lost their lives in consequence of war service. There were, of course, still factors operating in the direction of increased expenditure, but on the whole the net result was a declining expenditure.

Medical Services.

There were two sides of the medical service attached to the Ministry, first, the medical examination for pension purposes, and, secondly, the work of medical and surgical treatment. The medical examination, or boarding, of pensioners for the assessment of their pensions was rapidly diminishing. The bulk of the work was now directed to the making of final settlements or final awards in all suitable cases. He was continually pressed to settle pensions finally both by the men themselves, at meetings in the country, and by Members of that House. The security which these final awards brought was being appreciated as they knew it would be. There were only about 100,000 cases still drawing pensions that were temporary and subject to further review. Their present lines of working were calculated to complete in a few months time practically the medical boarding of all these cases, so far as they were likely to be found suitable, for final award. For many of the men it would probably be found impossible and unfair in their own interests to give final awards, at any rate yet if at all, because they were cases that were actively deteriorating. But for the bulk of cases he hoped that finality might be reached before the present year ended. The other side of the Ministry's medical work consisted of the medical and surgical treatment of cases. The demand for treatment of all kinds continued to show the same decline year by year as had occurred for the last seven or eight years and the hospital accommodation of the Ministry had, of course, been reduced proportionately. The Ministry was still maintaining 17 hospitals of its own with approximately 3000 beds, and had a call on 25 other hospitals under the control of voluntary bodies which reserved their entire accommodation, or the bulk of it, for the Ministry. These provided accommodation for a further 2000 cases. In addition the Ministry made use of civil hospitals to a substantial extent. The number of patients in the Ministry and civil hospitals on March 31st was 5106.

He had taken every possible step to ascertain that the pension system was working justly and adequately, and he had abundant testimony to the fact that the system, as a whole, was working soundly. The time limit was a remarkable example of the unanimity of the three political parties when in office on the subject of war pensions. It was imposed on medical advice in 1921 under a Liberal Prime Minister and a Liberal Minister of Pensions. It received the unanimous approval of that House in the 1921 Act. It was upheld by the Government of Mr. Bonar Law. The Labour Party had promised to remove it, but when in office they not only proposed no change in this House, but maintained it in individual cases which were already arising. The principle was again carefully considered by the present Government, who decided that it should be maintained. In imposing a time limit they had done what every other country had done which enrolled its men in the late war by universal service on British lines. Every country had imposed restrictions of one kind or another on the meeting of claims for disablement by war service as a right for an indefinite period. At the same time they had done what every other country had done in applying this limit. They had qualified the rigid time limit by a procedure for the admission of exceptional cases which could prove that they were genuine cases of war disablement. This qualification had been the work of the present Government. In the small number of exceptional cases of genuine war disablement arising after the time limit he had made special arrangements for examination and if necessary hospital treatment. Between 300 and 400 cases that had arisen beyond the seven years' limit had been pensioned. If the time limit was thrown down it could only throw discredit upon the whole pension system. The system of final awards —the principle of a final settlement of the compensation due for every officer's or man's disablement, wherever that could fairly be arrived at—as it had been worked during the eight years by Ministers of Pensions of all political parties would by the end of this year have brought complete security of their pensions to nearly 500,000 officers and men. The Ministry had adopted the system of correction of error, by which any officer or man who had received a final award, but who subsequently was found to need hospital treatment and who, at the end of his course of treatment was found to be in a condition of disablement which was seriously at variance with the degree of disablement which had been assumed for the purposes of final settlement, could be, and was given further pension. In taking the basis of treatment as both the channel for the discovery of error and the test of its existence, he was satisfied that both his predecessor and he had acted wisely, because medical observation and treatment gave, as they alone could give, a basis of ascertained fact to the existence of error. It had been suggested that, notwithstanding that he had a right of appeal to an independent appeal tribunal within a full 12 months of his award, every man who had had a final award should be given a further right to appeal at any time and an indefinite number of times. Any such proposal must make an end of final awards.

Village Centres.

Mr. F. O. **Roberts** said that a great deal had been done by those charged with the responsibility of dealing with tuberculous men, but he would like to know whether the Ministry had given any consideration to the widening of the scope of operations of village centres which could meet the typical cases of ex-Service men which arose from time to time. The British Legion had a very definite policy on the matter, and from the results which had followed the treatment of cases which had come within their hands and the investigations they had made there seemed now some justification for the conclusion that the proper way of dealing with tubercular ex-Service men was to find a means of giving them some useful work under the most congenial and comfortable circumstances. The neurasthenics were probably the most difficult of all the cases with which the Ministry was called upon to deal, but it was a difficulty which ought to encourage those responsible for administration to even greater efforts in the future with the object of overcoming the difficulties. He urged the need for setting up greater and wider occupational opportunities for dealing with this particular type of patient. Certain avenues had been traversed in this direction, but the best opinion had now come to the conclusion that it was only by finding congenial occupations for these patients that they could hope to do anything to bring them either to a complete recovery or to that partial state which would enable them to lead a happier life. On the general question of treatment Mr. Roberts said that he understood that it took from three to six days before a man who had applied for treatment received a visit from the Ministry's medical officer. He urged that some arrangement should be made to avoid the delay and difficulty which must constantly arise. The men might be attended by local doctors on the production of the award showing that the disability had been accepted by the Ministry of Pensions. He appealed for a continuance of the human touch with pensioners without which none of the exceptional cases were likely to be adequately met.

Post-war Diseases.

Dr. **Vernon Davies** said the House was to be congratulated upon being able to deal with the subject of pensions purely from the non-party point of view. The medical profession was intimately concerned with the question whether justice was being meted out to ex-Service men. When all was said and done it depended upon the skill and accuracy of diagnosis and assessment of the medical profession as to whether any ex-Service man could make a case or not. The doctors had to hold the scales of justice with an equal poise, remembering on the one hand the taxpayer and on the other the pensioner. But they were all agreed that in any case of doubt the pensioner should receive the benefit of it. It was easy, however, to make a mistake, and he would explain to the House, roughly, what he meant. There was a certain class of case which everybody—layman as well as medical man—would recognise as simply due to war injury, such as the loss of an eye, the loss of a limb, or a gunshot or shrapnel wound. There was a second class of case which they were quite convinced was not due to war injuries. Because a man had been in the war it did not necessarily follow that every illness and injury he got was the result of his war service. Such cases as these, therefore, cases which were genuine from their knowledge and cases which were not genuine from their knowledge should not arise. Medical men with a certain amount of experience were equally as certain in other classes of case whether they were due to war injury or not. Members had letters from ex-Service men, apparently very sad cases and perhaps cases of paralysis. A man would say that he was perfectly all right when he went to the war and after five or six years he developed a certain form of paralysis and thought that it must be a case of injury or shock or nervous stress due to the war, but medical men knew that that paralysis was definitely the result of venereal disease. Nothing could cause that paralysis but venereal disease, and therefore they said that it was not due to the war. The medical man by his knowledge was able to give an accurate diagnosis but the layman or the laywoman did not recognise this and thought that injustice had been done. There was a third class of case, the doubtful case even from the point of view of the medical man. Medicine was not an exact science. They were not yet masters of all disease; they did not always know the cause of disease or the prognosis of disease. They had, therefore, a neutral ground where there was room for difference of opinion. What was the proper and right thing to do in that debatable ground? It was to see that they had the highest, the best, and the most competent medical advice before confirming an opinion because they could only depend upon medical advice when they had to decide on the question of entitlement and assessment. People had wondered sometimes whether the Ministry had acted quite as leniently as they might have done, and whether they had been as humane as they might be. He paid, however, a tribute to the kindness and humanity of the Minister who had offered him the opportunity of interviewing any of his medical staff and had arranged a meeting with the Director-General of Medical Services in the Ministry and his deputy. The medical department of the Ministry had three main duties. First of all, they dealt with the boards and the assessment and entitlement of a man's award from the medical point of view. Secondly, they dealt with certification and the necessity of treatment or treatment allowances. Thirdly, there was a non-medical branch which dealt with the supply of hospital apparatus, artificial limbs, &c. Dr. Davies proceeded to describe in detail the procedure followed by the medical boards and officers of the Ministry, and he said that he had satisfied himself that the greatest skill and medical attention was given to cases under review by expert medical men. The medical men attached to the Ministry were absolutely fair and unbiased and anxious to do the best for the ex-Service men. He had come away from a very long interview with the Director-General of Medical Services and his deputy perfectly convinced that the medical department of the Ministry were more than fair to the ex-Service man. Speaking as a medical man, he (Dr. Davies) would not have passed some of the cases which they had passed. He would give an example of a man who had syphilis before the war, and after the war developed symptoms of general paralysis of the insane which came on perhaps a little sooner than might have been expected. The Ministry accepted that as a case in which there had been aggravation due to war service, but he (Dr. Davies) would not have accepted the case. They might have the case of a man who went through the war at somewhere round about 50 years of age, and since then with the advance of years had developed, say, arteriosclerosis. That man had a stroke and got paralysis. Some people would say that such a case should be accepted as due to war service and the man be pensioned accordingly. He was glad to find in that particular case that the Ministry did not regard it as one where the disease had been aggravated. If they could get the idea to prevail throughout the country that the medical profession were a body of honourable men anxious to do all they could for the ex-Service men it would create a better spirit and a better atmosphere and reduce the amount of suspicion. It was not uncommon at the present time to hear it said, "But it is quite easy to get a doctor on one side to say one thing and another doctor on the other to say exactly the opposite." Members of that House must recognise that in surgery and medicine they had not reached the confines of knowledge and one man might with perfect honesty interpret a symptom in a certain way and the next man might with equal honesty interpret that same system in a different way. Very often they did not know which man was right until there was an operation or a post-mortem examination. When it was said that cases have been referred to the Ministry accompanied by certificates from doctors that did not necessarily mean that those medical men gave a false certificate. They gave a certificate according to the best of their ability on the symptoms they had observed, but when they had the opinions of experts—experts on tuberculosis, or neurasthenia, or insanity, or wounds—it was only fair to regard the experience of such an expert with all his experience as of more value than that of the ordinary practitioner. He was always prepared to take the view of an expert whether he agreed with him or not because he felt he had more knowledge.

Mr. KELLY said that while he was prepared to accept the statement of Dr. Davies that the main body of doctors were honourable men, he suggested that mistakes might be made even by experts and specialists. He was not at all sure that they could rely, or must rely, in pension matters upon the certificates handed out by medical men. They had experience of cases under the Workmen's Compensation Act where medical opinion had been accepted by the Court as sufficient to determine whether a man was capable of doing his work. He did not think that it was the function of a doctor to say whether a man was capable of doing his work, and judging by many cases their opinion was not worth a great deal.

Decline in Surgical and Medical Cases.

Lieut.-Colonel FREMANTLE said that with regard to the medical side of pensions administrations he would draw attention to the fact that while a very extensive amount of work in connexion with surgical and medical cases had been done in the Ministry's institutions, there was a very definite decline in the provision made and in the necessity for it, and he wished to know the direction in which this was leading. The number of general surgical cases dealt with by the Ministry had gone down from 2500 at the beginning of 1925 to something like half that number. In a period of just over four years the total number of surgical cases treated had been 64,000, and of medical cases 60,000, while there had been 26,000 neurological cases. Outside the Ministry of Pensions very few people realised the tremendous experience of neurological treatment that had been thus gained. It had been a source of information of immense value to medical science generally and for treatment in civil life hereafter. Now, however, naturally enough, there were fewer cases demanding fewer institutions and smaller staffs. The number of institutions had been reduced from 250 in 1921 to 28, the number of hospitals had been reduced from 75 to 20, the medical staff from 600 to 150, and the nursing staff from 1300 to 360. He would like to know what steps were to be taken to see that all this wonderful equipment and experience was going to be made proper use of. The difficulty of a service of this kind was that, as it dwindled more and more so the resources became more limited and it became difficult to give the same proper and suitable treatment to those patients who remained and to give the same kind of outlook in the service for those who were employed in it, while at the same time valuable equipment, institutions, and services were being lost which might otherwise be used for the general good of the community. He entirely agreed with Dr. Vernon Davies that undoubtedly the medical men who were doing the very difficult work of assessment were *sans peur et sans reproche;* but he had not the same absolute and unremitting faith as his hon. friend apparently had on the results of the judgments of the medical profession. They were all of them liable to make mistakes, even when there might be two or three of them together, and his own experience was that when cases were brought before the Minister in which there appeared to have been any error of judgment even in the higher courts they found themselves satisfied with the action that was taken. Obviously there must be protection for the public; there must be a limit. He believed that as much latitude as possible was given in individual cases, and he supposed they must recognise that while there were cases among their constituents with which they naturally felt sympathy, nevertheless it was a fact that the line must be drawn somewhere.

Reply to the Debate.

Major TRYON, replying to the debate, said that he greatly appreciated the references to the medical service of the Ministry made by Dr. Vernon Davies. He (Major Tryon) admired and respected the works of the medical staff himself and he resented attacks—not in that House—against the doctors of the Ministry of Pensions. An enormous proportion of the medical staff had been in the Army and had served overseas. Very often the man who was applying had not been overseas and the doctor who was examining him had. He thanked Colonel Fremantle for the very interesting points he developed. There were, however, a certain number of subjects on which the House was handicapped because they concerned a number of departments. That applied to the very interesting points which Colonel Fremantle had dealt with.

The Report of the Vote was agreed to.

DONATIONS AND BEQUESTS.—Sir William John Lancaster, of Putney Hill, S.W., in addition to other charitable bequests, left £500 each to the West Norfolk and Lynn Hospital, King's Lynn, the Bolingbroke Hospital, Wandsworth Common, and the Putney Hospital; £100 each to the Royal Hospital for Incurables, Putney, and the Hunstanton Convalescent Home.—Mr. James Stewart Williamson, of Auld Girth, Victoria Park, Manchester, left, among other bequests, £1000 each to the Manchester Royal Infirmary and St. Mary's Hospital, Manchester; and £500 to the Christie Hospital for Cancer, Chorlton-on-Medlock.—Mrs. Fanny Hester Wright, of Crescent House, Southsea, Hants, left £1000 to the Hospital for Sick Children, Great Ormond-street, W., for a cot to be called "The Mickle's Bed."

Correspondence.

"Audi alteram partem."

BLOOD STANDARDS.

To the Editor of THE LANCET.

SIR,—Difficulties with regard to blood standards and with regard to the accuracy of the methods employed must have been felt by everyone who examines blood. Fortunately in the practical application of blood examination for diagnosis, experience shows that the variations in many diseases are in general greater than the sum of all the experimental errors; thus the diagnosis of an inflammatory reaction, as in the presence of pus, will be made by different observers using different methods, and perhaps on counts showing considerable differences. Again, in watching the progress of a case—for example, pernicious anæmia—the fact that successive counts will often be made by the same person using the same method eliminates many experimental variations.

Difficulties must always arise whenever an arithmetical figure is fixed as standard for a varying human characteristic. Consider such simple measurements as those of stature or weight in which there need be no experimental error to be considered. We should not ask what is the "normal height" of, say, adult male human beings, but either what is the "average height" or what are the "normal limits of height," and any figures given for the latter, however elastic they might be, would still be difficult to defend against cross-examination in a witness-box. What we want to know with regard to blood standards for practical or even scientific purposes are not hard-and-fast fixed figures, but rather the various normal limits in order that we may judge what is abnormal. Unfortunately the problems of blood are further complicated by the experimental variations and errors of different instruments and methods of calculation.

With regard to the *total red cell count*, it is surprising that the figure of 5,000,000 per c.mm. can have endured so long in this country. But I remember discussing this point with Pappenheim before the war, and remarking on the higher counts constantly found in Great Britain. To my surprise he defended the figure strongly and stated that 5,000,000 was a correct average for healthy young males in Germany. In this country for a moderately selected group of healthy adult males I would put the figure at 5·5 to 7 million, usually between 6 and 6·5 million; for a group without selection, but no special ill-health, about 0·5 million less throughout.

The *hæmoglobin standards* are even more difficult owing to variations in the instruments. There is a further serious difficulty in that all measurements of hæmoglobin involve matching tints, in which the male sex is notoriously inefficient. This factor may be the explanation of the great differences obtained with the Haldane hæmoglobinometer by Dr. Goodhart and Dr. Jenkins respectively; it is also noteworthy that Dr. Jenkins gets higher readings with the Tallqvist scale than with the Haldane, although the latter is set to the lower standard. Different methods may suit different visions. Personally I always use the Dare instrument. I prefer the principle to Haldane's as several readings can be taken on the same specimen. In a recent test I made the hæmoglobin of a healthy male 92 per cent. on the Haldane instrument and 101 per cent. on the Dare as the mean of several closely similar readings. My standards had just been passed as accurate by a well-known firm which sells these instruments, and both the Dare and Haldane instruments are set to the same standard of hæmoglobin per 100 c.cm. of blood. I find that an inexperienced observer with the Dare instrument usually starts with a reading about 10 per cent. too low and corrects it after a few tests. Clearly it would be an advantage to have all hæmoglobinometers set to a common standard. Even this would leave those variations which are due to differences of vision, and also, no doubt, to differences in various instruments.

Dr. Dyke has mentioned the "hæmoglobin coefficient" of Osgood. According to this "Hæmoglobin is expressed as the number of grammes per 100 c.cm. of blood calculated to a red cell count of 5,000,000." Investigation shows that this "hæmoglobin coefficient" is given by multiplying by the colour-index the number of grammes of hæmoglobin accepted as the standard. Thus on a Haldane instrument, which is calculated to a standard of 13·8 grammes of hæmoglobin per 100 c.cm. of blood, any blood with a colour-index of 1 will give a hæmoglobin coefficient of 13·8. Obviously the "hæmoglobin coefficient" is only a more complex statement of the colour-index and gives no measure of the percentage of hæmoglobin. Osgood may have overlooked this simple resultant of a complicated calculation.

Normal White Count.—In reading Dr. Dykes's article I was especially interested on coming to a section headed Normal White Count, and was disappointed on turning the page to find that the article finished in a few brief lines. The difficulties are very great in arriving at any normal limits, for apart from true variations we must recognise the large experimental variations and errors of our methods. Suppose a blood actually contains 6,000,000 red cells and 8000 white per c.mm., how near are we likely to get in the count, and how far will a series of counts agree with each other? No doubt we would like our students to believe that we could get within 100,000 of the red and 100 of the white. Probably a more correct statement of the range is 10 per cent. of the total count, and not less than ± 100,000 for reds and ± 100 for whites, excluding extreme counts. Thus for 6,000,000 reds the range would be from 5,700,000 to 6,300,000, and for 1,000,000 reds from 900,000 to 1,100,000.

But the difficulty is far greater with the *differential count* of leucocytes. It is well known how erratically the various cells are distributed on a slide. There are wide differences between the distribution at the edges and the centres and at the ends. Some years ago a team of experienced laboratory workers attempted to investigate this question systematically. The differences which they obtained between different methods and between each other may be judged from the title of the article in which they recorded their results: "Have Differential Leucocyte Counts any Value?" Considering differential counts, I believe that for a series of counts of 500 cells on the same blood the range of variation for a cell is about the square root of its percentage. If the percentage of polymorphs is 64 various counts will lie between 60 and 68. For counts of 200 cells the range is about half as much again. Supposing a blood has correctly for polymorphs, lymphocytes, large hyalines (large mononuclears), and eosinophils, percentages of 64, 25, 9, and 2 respectively, the range of a series of counts of 500 cells will lie approximately without fractions, between 60, 27, 10, 3, and 68, 23, 8, 1, and for a series of counts of 200 cells between 58, 28, 11, 3, and 70, 22, 7, 1. No count ever reaches the accuracy of a decimal point, though perhaps for convenience 0·5 may be admitted for mast cells and eosinophils.

In spite of all difficulties some standard of normal limits for the differential count must be set before students and kept before ourself for comparison. I would suggest the following: Polymorphonuclear neutrophils 60 to 75, eosinophils 2 to 4, mast cells 0 to 1, large hyalines (mononuclears) 4 to 8, lymphocytes 15 to 35. The great difficulty is the limits of the neutrophils. Many good authorities would put the lower limit at 50. During the war counts between 50 and 60 per cent. were extremely common, but possibly these were not entirely normal. Of course the total count of leucocytes must always be taken into consideration together with the differential count when questions of abnormalities arise. For this reason the students at St. Bartholomew's are taught from the outset to calculate the total number of each cell and compare them with the normal total numbers. This is quite rational, but used as a routine must involve much unnecessary calculation.

Coagulation Time.—The standard of this has not been referred to in the discussion, but it is greatly in need of consideration. Recent work, especially that of Christie in Edinburgh, has shown how greatly and constantly the coagulation time varies in the first few drops. After the third drop a normal coagulation time at 37° C. is under a minute and may be under half a minute. At 25° C. the time is sufficiently lengthened to be a nuisance. Possibly a temperature of 30° C. would give a coagulation time long enough to be accurately estimated in various circumstances without being tediously prolonged.

I am, Sir, yours faithfully,

London, W., May 10th, 1929. H. LETHEBY TIDY.

THE NEW IMPORTANCE OF RADIUM.

To the Editor of THE LANCET.

SIR,—In reply to Dr. Douglas Webster, I should not like to be misunderstood. I have not forgotten the valuable pioneer work done by Prof. Lazarus Barlow, Prof. Sidney Russ, and Dr. Webster at the Middlesex Hospital with radium en masse, but when I referred in my letter to distant "bomb" therapy I had in mind something rather different from half gramme surface application.

I am, Sir, yours faithfully,

London, W., May 17th, 1929. C. GORDON-WATSON.

Dr. A. E. Barclay writes to express regret for the omission in his letter which appeared last week of any allusion to the exceedingly good work in the radiation treatment of cancer done at St. Bartholomew's Hospital.

PATHOLOGICAL POSTURES.

To the Editor of THE LANCET.

SIR,—The questions raised by Dr. Brain indicate that in criticising certain forms of appeal to phylogenesis I have not made my position quite clear, and I am glad of the opportunity of stating the case more precisely. Dr. Brain's proposition that "there is nothing inconsistent between a physiological and a biological explanation" is surely a truism, since the former is necessarily the latter. My complaint is against a biology that is not biological; in short, against the clothing of what is, in fact, pure allegory in the language of biology. The comparison of the mobile spasm of athetosis with the hypothetical tree-climbing antics of our ape-like ancestors is neither more nor less than this. There is not even the degree of superficial resemblance between the movements of athetosis and those of a monkey climbing a tree necessary to lend an air of plausibility to this fantastic analogy. Further, in the observed behaviour of the decerebrate sloth we have an indication that Dr. Brain's interpretation of the flexed arm of hemiplegia is in all probability a figment of a like order. Therefore, what was spoken of as "the appeal to phylogenesis" in the lecture criticised by Dr. Brain might more accurately have been styled "the allegorical method in neurology."

On the other hand, the conclusion that certain tonic reflexes seen in the human subject with spastic hemiplegia are physiologically identical with postural reactions observed and described by Magnus and de Kleijn, rests upon no such insubstantial basis of speculation. It is not an explanation of a present, of which we know something, in terms of a past of which we know nothing, but it is the fruit of a careful correlation by numerous observers of facts of experimental and clinical observation.

Having accepted the physiological relationship of two groups of phenomena upon a sound observational basis, we may—if we will—proceed to consider the possible phylogenetic significance of our findings. To such a rational sequence of steps in investigation there cannot be, nor have I raised, any objection. But I cannot accept Dr. Brain's suggestion that conclusions so reached constitute "a phylogenetic explanation" of the same order as are the allegorical examples I have cited. The fact is that, although using the same terminology, we are not speaking the same language.

Reduced to its simplest terms, the position that I was endeavouring to maintain in my lecture, and that Dr. Brain is in effect disputing, is one expressed by Bacon in the proposition: Non fingendum, aut excogitandum, sed inveniendum, quid Natura faciat aut ferat.—I am, Sir, yours faithfully,

London, W., May 18th, 1929. F. M. R. WALSHE.

THE FREQUENCY OF RED HAIR.

To the Editor of THE LANCET.

SIR,—Some years ago (THE LANCET, 1922, i., 1270) you were good enough to print the casual fact that in 1921 nine of the 750 (1·2 per cent.) graduands of the University of London were red-headed; in 1922 there were 16 in 961 (1·7 per cent.). To my surprise I learned the other day that someone had found a use for these numbers. It is therefore perhaps worth recording that the tedious splendour of degree-day this year revealed six in 1157 or 0·5 per cent., a doubtfully significant decline from the older figures.

I am, Sir, yours faithfully,

Radlett, Herts, May 21st, 1929. A. E. BOYCOTT.

THE EYE AS A DANGER SIGNAL OF DENTAL SEPSIS.

To the Editor of THE LANCET.

SIR,—I shall be obliged if you will make a correction in your report of the paper read by me at the International Congress of Military Medicine on Friday, May 10th. I said that in an unexpected number of persons between the ages of 20 and 40 years slight opacities of the lenses are found, and that in a large proportion of these I attributed the cause to the marked dental sepsis which was present. Also I said that I found that in a consecutive series of 100 patients who came for refraction, and who attained full visual acuity with glasses, 22 showed radiographic evidence of the presence of apical abscesses.

I am, Sir, yours faithfully,

A. F. MACCALLAN.

Welbeck-street, London, W., May 20th, 1929.

MILLER GENERAL HOSPITAL, GREENWICH.—On May 14th the new extensions to this hospital were opened by the Duchess of York—three new wards, two complete operation theatre units, new kitchens, and a nurses' home. The total cost of the extensions is in all about £118,000, of which £29,000 is still lacking. The President of the hospital, Lord Queenborough, welcomed the Duchess, and drew attention to the wide area served by the hospital. Dr. Harold Pritchard, the senior physician, detailed the 16 specialised departments of the hospital, and singled out for special praise the work of the Lady Almoner's department in befriending the patients and ensuring after-care.

RADIUM IN LIVERPOOL.—At a meeting held in Liverpool Town Hall on May 14th, presided over by the Lord Mayor and addressed by Lord Derby, it was resolved to make an appeal for funds to purchase radium for the treatment of cancer and to establish a radium institute in Liverpool. The sum aimed at is £120,000. The Radium Committee is said to be representative of all the big hospitals in the city and has worked out details of the scheme. The amount of radium in Liverpool is at present very small and many patients have to be sent to Manchester, where is often a long waiting list. Lord Derby suggested that the Radium Fund should be Liverpool's thankoffering for the King's recovery, and this suggestion has been adopted.

Obituary.

ARTHUR HENRY CHEATLE, C.B.E. F.R.C.S. ENG.,

AURAL SURGEON TO KING'S COLLEGE HOSPITAL.

As we have already announced, the death of Mr. Arthur Henry Cheatle, aural surgeon to King's College Hospital, occurred in London on Saturday, May 11th, in the sixty-third year of his age.

Arthur Cheatle was the son of the late George Cheatle and younger brother of Sir Lenthal Cheatle. He was educated at Merchant Taylors' School, and joined the medical school of King's College, whence he took the double diploma of the English Colleges in 1888, and the F.R.C.S. Eng. four years later. He was elected assistant surgeon to the hospital, and from that time forward had charge of the aural department, lecturing on aural surgery, and later being definitely appointed aural surgeon to the institution. He rapidly proved himself to be a pioneer along the pathological and operative lines which his duties placed before him, for it must be remembered that not till the beginning of the present century had the modern surgery of the ear been either reasonably planned or indeed devised. The results of a spread of infection from the middle ear to structures where absence of surgical relief meant a fatality, but where, at the same time, operative interference was perilous, became recognised about the period when Cheatle took up his practical duties, and from that time forward his name was associated with many fine developments in theory and technique. He showed how the clinical features and progress of infection of the middle-ear tract were influenced by the anatomical type, so that chronic suppurative middle-ear disease had its origin, though indirectly, in a normal anatomical structure. When the mastoid operation was introduced, many surgeons were without precise knowledge of the anatomy of the cavities as they are influenced by the individual development of the subject, by age, and even by sex. In the Royal College of Surgeons of England there is housed a collection made by Cheatle, over a period of 30 years, consisting of a series of some 700 preparations displaying the structure of the mastoid region in its varieties, and demonstrating the influence manifested by the factors of individuality, sex, and age. In this collection, the most complete that has ever been made to illustrate the surgical anatomy of the middle ear and the accessory air sinuses, every specimen was obtained from a subject of known age and sex, and the descriptive catalogue, prepared by the collector himself, is now published by the College for the use of those who come to study the work from all parts of the world. Under Cheatle's supervision about 200 of these specimens were photographed and a series of lantern slides prepared to meet the needs of teachers. Such work alone entitles Cheatle to the grateful memory of his profession and of the public.

The following has been received from D.M., and shows the position which Cheatle occupied in the minds of his co-workers. D.M. writes:—

"Arthur Cheatle's death has removed from the small and rather select band of the scientific otologists of Britain a mind that can ill be spared. Not that his life's work was incomplete, for he was granted time to finish what he had originally set his hand to; but in a branch of medicine in which, for several reasons, the practitioner is exposed to a daily temptation to forsake at times the narrow path of unpleasant truth, Cheatle knew no deviation, no hesitation even. And in the wider world, when easy roads to distinction in a popular sense were indicated to him, he would smile and take his own way, picking his steps and walking clean.

"Selecting for his particular attention as an investigator the structure of the temporal bone, in which lies the organ of hearing, and particularly that part of the bone known as the mastoid process, he emulated Browning's Grammarian in devoting a lifetime to this one small corner, and was rewarded by a discovery that revolutionised ideas regarding septic infection of the ear and its neighbourhood. Largely as a consequence of his teaching, modern operations on the mastoid, of which everyone has heard nowadays, rest upon a firm basis of anatomical fact. The hours and days and years that Cheatle spent over this single laborious task no one can number; but his monument is erected for all time in the rich collection of his specimens in the Museum of the Royal College of Surgeons in Lincoln's Inn-fields, as well as in the more accurate knowledge of the behaviour of the common purulent disease of the middle ear which he has bequeathed to medicine and to mankind. He was a patient worker, and a cautious theoriser, and, as he was but poorly gifted with expository powers—writing with much difficulty and speaking in public with even greater difficulty—his new teaching was long in making headway even here in England, while abroad his friends were often annoyed—as he was himself, for that matter—to find his discoveries and views, many years after their appearance, given the paternity of some French or German investigator who had apparently never heard his name."

Professional recognition of Cheatle's position was as wide as well merited. He gained the Adam Politzer Prize at the Ninth International Otological Congress, was an honorary member of several foreign otological societies, was a late president of the Otological Section of the Royal Society of Medicine, and in 1913 was president of the Section of Otology at the International Congress of Medicine. When the war broke out he was a member of the medical board of the Royal Air Force, with the rank of lieut.-colonel, and was also hon. consultant in his specialty to many of the military hospitals in the London and Eastern Commands, and was appointed aural surgeon to King Edward VII. and King George Hospitals.

Cheatle's literary work, though not voluminous, was all valuable, and proves his life-long interest in his subjects. Twenty-five years ago he wrote on sight and hearing in childhood with the late Brudenell Carter. He made a report on the examination of the ears and throats of 1000 school-children for public use; he wrote on gun deafness and its prevention; and the Hunterian Lectures at the Royal College of Surgeons of England on the "Surgical Anatomy of the Temporal Bone from Birth to Adult Life," were published in 1907 as a volume. These lectures contained a thorough, detailed and accurate description of the temporal bone both from the anatomical and surgical standpoint, the three most instructive chapters in the book setting out the relation of the lateral sinuses to the surfaces, the consistence of the outer antral wall and mastoid process, and the variations in the middle ear and antrum. The excellent illustrations made the book welcome as much to the anatomist as to the surgeon.

To "D. M.," also, we owe the following picture of the private side of Cheatle's life:—

"To those," he writes, "who knew the inner tragedy of Cheatle's life, a poignant loss by death in his early manhood, his devotion to work looked like a way of escape from tormenting memories, the reaction of a lofty mind to a sorrow ineffaceable, inexpressible. It was, indeed, in the circumstances, a salutary refuge, for Cheatle's was a proud and lonely nature, shy and slow to make men friends, though warm, responsive, and even playful with those who knew how to reach to the sensitive soul that hid behind the veil of his aloofness. When to this we can add that he was a man of fine presence, tall, straight, with clean-cut features and speaking eyes, we may succeed in conveying some faint outline of the impression his singular personality made upon those who knew and admired him for what he was no less than for what he did."

Sir Arnold Lawson writes:—

"Arthur Cheatle was one of my oldest friends. We were schoolboys together and nobody, more than myself, is now in a stage of transition. The new statutes have now come into force, and the allocation of accommodation on the new site in Bloomsbury is now exercising the attention of a committee under the chairmanship of Sir William Beveridge. Provision has already been made for the inclusion of an administrative block, a library, a great hall, and of adequate housing for the Union Society.

University College.—The examination for the Bucknill Scholarship of 160 guineas and for two exhibitions of 55 guineas each will begin on June 25th. The subjects of the examination are chemistry, physics, botany, and zoology. Entry forms should be obtained from the Secretary of the College not later than June 1st.

University of Manchester.—On May 15th the honorary degree of doctor of science was conferred on Sir Ronald Ross, F.R.S.

Dr. Louis Savatard has been appointed assistant lecturer in dermatology.

The new Robert Angus Smith scholarship of £150 for research in sanitary science is offered for competition. Particulars may be had from the registrar of the University.

In connexion with the meeting of the British Medical Association at Manchester in July, the honorary degree of doctor of laws will be conferred on Lord Dawson, and on Drs. W. J. and C. H. Mayo, of Rochester, U.S.A., and the honorary degree of doctor of science on Sir Ewen Maclean, president of the Association, and Dr. C. O. Hawthorne, chairman of the representative body.

Royal College of Surgeons of Edinburgh.—At a meeting of the College on May 15th, with Mr. Alexander Miles, the President, in the chair, the following 30 successful candidates out of 85 entered, who passed the requisite examinations between Jan. 3rd and 12th, were admitted Fellows :—

Herbert Abernethy, Robert Erwin Austin, Harold Shaw Bilcliff, Bernard Brooks Blomfield, Donald Cameron Bowie, Rangachari Padmanabha Chari, William Noble Chisholm, Johannes Gerhardus Albertus Davel, Glyn Alexander Davies, Harry Geoffrey Estcourt, John Langwell Farquharson, Donald John Davidson Henderson, Richard Anthony Highmoor, Albert Edward King, Mangalore Copal Kini, Eric Roy Lange, Charles Gordon Lewis, Alan John Grange Mackay, Vasudeo Shankar Schoholkar, Samuel Newson, William James Pannell, Lindsay Morgan Park, Lawrence Vernon Pearson, Lindsay Sangster Rogers, Madan Copal Saincher, Christopher George Schurr, Bam Narain Sewal, Graeme Gibson Talbot, James Reid Wheeler, and George Wood.

The Bathgate Memorial Prize, consisting of bronze medal and set of books, after a competitive examination in Materia Medica, was awarded to Mr. Wai Ming Tso.

The following candidates, having passed the requisite examinations, received the higher Dental Diploma :—

Cyril Grosvenor, H. D. Kendrick, and G. E. Morgan.

Royal Medical Benevolent Fund.—At a recent meeting of the committee 51 grants were made amounting to £1204. This is the largest sum of money voted in any one month since the Fund was founded. The committee also elected five beneficiaries to Alexander Lawrence Annuities, the annuities being £70, £65, £60, £60, and £52. The following are short notes on five of the cases helped by grants :—

Widow, aged 50, of M.R.C.S. On the death of her husband in June, 1928, was left with an income of £50 a year and two daughters to educate. Her husband had served throughout the war and during service began a disease which undermined his health and which led to his death at the age of 51. The Officers Association will contribute £30 yearly towards the school fees of one child, and the Fund has voted £40 for the school fees of the other. The widow is trying to augment her income by taking paying guests.

M.R.C.S., aged 60, is suffering from paralysis. His wife and child of 5 is dependent on him. Private income £128 a year. Voted £40.

Daughter of L.K.Q.C.P., aged 61, has supported herself through life as governess and companion. Of late years she nursed and kept house for a delicate married sister who has now died and she is left dependent on her brother-in-law who is suffering from advanced tuberculosis. Voted emergency grant of £10 and £26 in four instalments. R.U.K.B.A. and R.A.M.C. fund will also coöperate and help this case, which is one of complete destitution.

Widow of L.R.C.P., aged 72, on death of her husband was left with an income of £67 a year. Voted £36.

Widow of M.R.C.S., aged 80, is a feeble old lady and in very straitened circumstances. Since the death of her husband in 1912 she has had to gradually use up her capital. She has now sold her last security which has realised £220 ; she has only this left to live on. Voted £36.

Subscriptions and donations should be sent to the hon. treasurer, Royal Medical Benevolent Fund, 11, Chandos-street, Cavendish-square, W. 1.

Walsall Hospital.—It has been decided to appoint an honorary consultant surgeon and an honorary consultant physician for general work, and two junior assistant surgeons are to be added to the staff to provide opportunities for the younger medical men in the area.

Pay Beds at Acton.—The Council of Acton Hospital, W., have arranged to accept patients in private wards at a charge of £4 4*s.* weekly ; a semi-private ward will cost £3 13*s.* 6*d.* These patients may be attended by their own doctors, with whom they will arrange operation fees ; £1 1*s.* will be charged for the use of the theatre, radiographs, pathological tests, &c.

Enlargement of Addenbrooke's Hospital.—The sum of £90,000 is required for enlargement of Addenbrooke's Hospital, Cambridge, and at the launching of an appeal on May 11th Mr. C. R. W. Adeane, the President, was able to announce that £10,000 had already been received. This includes donations of £2000 each from Mr. G. R. C. Foster and Miss A. Peckover, and £1000 from Mr. Arthur Cooke, senior surgeon of the hospital. The new plans for extension provide for a block of three storeys on the north side, facing the out-patient department, and this block will contain a children's ward and beds for 20 paying patients. An additional surgical ward for women is also to be constructed, and 29 extra bedrooms will be available for the nursing staff. Certain older parts of the hospital will be reconstructed, and the total number of beds gained will be 92.

Work of Children's Hospitals in London.—In presiding last week at the annual meeting of the Queen's Hospital for Children, Hackney-road, the Duke of York stated that this institution deals with a larger number of children than any hospital of the kind. Last year there were 1818 in-patients and 32,708 out-patients. It was reported that the increased efficiency of the public health services had, during the last three years, reduced the number of out-patients.—The annual report of the Paddington Green Children's Hospital shows that the average cost of the 835 in-patients was £7 16*s.* 7*d.*, and that contributions from parents amounted to £1017. The Extension Building Fund now reaches something over £6000 towards the £50,000 required, £958 of which was produced by a wireless appeal.—The Infants Hospital in Vincent-square, Westminster, last year treated 748 in-patients, an increase of nearly 100 ; the out-patients numbered 15,551, an increase of more than 4000.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, May 27th.—8 p.m., Odontology (at the Royal College of Surgeons, Lincoln's Inn-fields, W.C.). Election of Officers and Council. Sir Frank Colyer will give a short description of the work carried out in the Museum during the past year.

Tuesday.—5 p.m., Medicine. Election of Officers and Council. 5.30 p.m., General Meeting of Fellows. Ballot for election to the Fellowship.

Thursday.—7 p.m., Electro-Therapeutics. Election of Officers and Council at the Langham Hotel, Portland-place, W.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

Friday, May 31st.—8.30 p.m. General Meeting. Paper by Col. L. W. Harrison : Review of Experimental Work in Syphilis and its Possible Bearing on Man. A discussion will follow.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL.

Thursday, May 30th.—8 p.m. (at Essex Hall, Strand, W.C.). Dr. Mather Thomson : The Sterilisation of the Unfit.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, May 27th.—2.30 to 5 p.m., Medical Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 p.m., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 p.m., Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 a.m., Dental Clinics. 2.30 to 5 p.m., Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

Friday.—10.30 a.m., Throat, Nose and Ear Clinics. 2.30 to 5 p.m., Surgical, Medical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

Monday, May 27th.—2 p.m., Dr. Riddoch : Out-patient Clinic. 3.30 p.m., Mr. Leslie Paton : Papillœdema (1).

Tuesday.—2 p.m., Dr. Walshe : Out-patient Clinic. 3.30 p.m., Dr. Critchley : Pick's Disease (Cortical Sclerosis).

Thursday.—2 p.m., Dr. Kinnier Wilson : Out-patient Clinic. 3.30 p.m., Dr. Gordon Holmes : Lesions involving the Optic Chiasma (1).

Friday.—2 p.m., Dr. Adie : Out-patient Clinic. 3.30 p.m., Dr. Symonds : Neurosyphilis (2).

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Monday, May 27th.—5 P.M., Dr. J. A. Drake: Streptococcal Infections of the Skin.

Tuesday.—Dr. W. N. Goldsmith: The Nervous System in relation to Skin Diseases.

Thursday.—Dr. W. J. O'Donovan: Skin Diseases of Animals Transmissible to Man.

Friday, Dr. W. Griffiths: Bullous Eruptions.

UNIVERSITY COLLEGE, Gower-street, London.

Tuesday, May 28th and the following Wednesday and Friday.—5.30 P.M., Prof. A. Brachet: Experimental Embryology.

Wednesday and Friday.—5.30 P.M., Prof. E. D. Wiersma: The Psychology of Dementia (First of two public lectures).

Thursday, 5 P.M., Mr. R. J. Lythgoe: Special Sense Physiology. (Fifth of six lectures).

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

Thursday, May 30th.—5 P.M., Prof. S. J. Cowell: Dietetics. (Fifth of six lectures).

UNIVERSITY OF BIRMINGHAM.

Thursday, May 30th.—4 P.M. (In the Medical Lecture Theatre, Edmund-street Building), Dr. H. Charles Cameron: Some Types of Septic Infection in the Newly-born. (Second Ingleby Lecture.)

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

Tuesday, May 28th.—3.30 P.M., (at the Jessop Hospital), Mr. Stacey: Labour Complicated by Contraction of the Pelvis.

Friday.—3.30 P.M., Mr. Finch: Prostatic Enlargement.

Appointments.

Bell, W., M.D., Ch.B. Edin., has been appointed Medical Referee under the Workmen's Compensation Act for Bradford, Keighley, Skipton and Settle County Courts.

Miller, H., M.B., Ch.B. Edin., Hon. Surgeon to the Northern Infirmary, Inverness.

Westminster Hospital: Rodgers, T. S., L.R.C.P. Lond., M.R.C.S., and Biclenky, D., L.R.C.P. Lond., M.R.C.S., Resident House Physicians. Priest, W. H. D., L.R.C.P. Lond., M.R.C.S., Resident House Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: James, W. E., L.R.C.P. Lond., M.R.C.S. (Rhayader, Radnor); and Walker, W. A., M.B., Ch.B. Glasg. (Irlam, Lancaster).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen City.—M.O.H. £1100.

Barking Urban District Council.—Asst. M.O. and Asst. School M.O. £500.

Birmingham, City Mental Hospital.—Jun. Asst. M.O. £350.

Birmingham, Dudley-road Hospital.—Jun. Asst. M.O. At rate of £200.

Birmingham and Midland Homœopathic Hospital and Dispensary. H.S. £150.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. £130.

Blackpool, Victoria Hospital.—H.S. £120.

Brighton, New Sussex Hospital for Women and Children.—H.S. and H.P. Each £50.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Cardiff Royal Infirmary.—H.S. Aural H.S. Also Cas. Surg. O. Each at rate of £50.

Carshalton, Surrey, Queen Mary's Hospital for Children.—Jun. Asst. M.O. £500.

Chester Royal Infirmary.—H.S. £120.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. At rate of £100. Also Laryngologist.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Derby County Borough.—Temp. Asst. M.O. At rate of £600.

Dover, Royal Victoria Hospital.—H.S. £180.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. Also Res. H.P. and Cas. O. At rate of £150 and £100 respectively.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

General Lying-in Hospital, York-road, Lambeth, S.E.—Res. M.O. At rate of £100.

Gravesend and North Kent Hospital.—Jun. H.S. At rate of £80.

Grimsby County Borough and Port of.—Asst. M.O.H. £700.

Harrogate Infirmary.—Jun. H.S. £100.

Hertford County Hospital.—H.P. At rate of £150. Also Hon. Surg.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100. Also Res. M.O. for Country Branch, Tadworth, Surrey. At rate of £250. Also Surg. Reg. £300.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Kingston and District Hospital.—Third Asst. Res. M.O. At rate of £250.

Lancashire County Council.—Asst. County M.O. £800.

Leeds, St. James' Hospital.—H.P. and S. £200.

Leicestershire County Council.—Asst. County M.O.H. £650.

Liverpool Heart Hospital.—Maurice Stern Research Fellowship. £150.

London Homœopathic Hospital, Great Ormond-street and Queen-square, Bloomsbury, W.C.—Surgeon in Charge of the Orthopædic and Mechano-Therapy Department.

Lowestoft and North Suffolk Hospital.—H.S. £120.

Maidstone, West Kent General Hospital.—Radiologist.

Male Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

Manchester, Ancoats Hospital.—Anæsthetist. 10*s.* 6*d.* per attendance. Also H.S. At rate of £100.

Manchester Northern Hospital for Women, &c.—Sen. H.S. Also Jun. H.S. At rate of £130 and £100 respectively.

Manchester Royal Eye Hospital.—Jun. H.S. £120.

Manor House Hospital, Golders Green, N.W.—Jun. H.S. At rate of £200.

Margate Royal Sea-Bathing Hospital.—Asst. Med. Supt. £500.

Middlesex County Council.—Asst. Dental Officer. £500.

Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer. At rate of £150.

Montrose Royal Asylum.—Jun. Asst. M.O. £325.

Newcastle, London-road Institution.—Asst. M.O. £250.

Northampton General Hospital.—Hon. Anæsthetist.

Northampton Mental Hospital, Berrywood.—Locum Tenens M.O. 7 gns. a week.

Northamptonshire County Council.—Tuberculosis Officer. £750.

Nottingham, General Hospital.—Res. Cas. O. At rate of £200.

Preston, Biddulph Grange Orthopædic Hospital.—Jun. H.S. At rate of £150.

Preston, High Carley Sanatorium, near Ulverston.—Asst. Tuberculosis M.O. £450.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.

Queen Mary's Hospital for the East End, Stratford, E.—Res. M.O. £200. H.P. and Cas. O. £150. Also H.P., Two H.S.'s and Obstet. H.S. Each £120.

Queen's Hospital for Children, Hackney-road, E.—H.P. Also H.S. Each at rate of £100.

Rangoon, Harcourt Butler Institute of Public Health.—Director. 1650 Rupees a month.

Royal Free Hospital, Gray's Inn-road, W.C.—Asst. M.O. for V.D. Clinic. £500. H.P.'s and H.S.'s. Also Obstetric District Asst. £100. Cas. O. £150.

St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C. Clin. Assts.

Salop County Council.—Asst. M.O. £600.

Shrewsbury Eye, Ear and Throat Hospital.—H.S. £200.

South London Hospital for Women, South Side, Clapham Common, S.W.—Asst. Phys.

South Shields, Ingham Infirmary.—Sen. and Jun. H.S.'s. £200 and £150 respectively.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £150. H.S. for Ophthalmic and Aural Departments. £150. Also Asst. H.P. £125.

Sudan Government.—M.O. £E720.

Taunton and Somerset Hospital.—Sen. and Jun. House M.O.'s At rate of £150 and £100 respectively.

Wakefield, West Riding Mental Hospital.—Jun. Asst. M.O. £400.

Walsall General Hospital.—H.S. At rate of £150.

Walsall and West Bromwich Unions Joint Committee Institutions, Great Barr Park.—Res. M.O. £500.

Warrington Infirmary and Dispensary.—H.P. At rate of £150.

West London Hospital, Hammersmith-road, W.—H.P., H.S., Aural S., and Ophth. H.S. Each at rate of £100.

Western Australia.—M.O.H. £756 to £960.

Willesden General Hospital, N.W.—Registrars.

York County Hospital.—H.P. and H.S. Each £150.

Zetland, County of.—School Medical Officer, &c. £700.

The Home Secretary gives notice that in consequence of the resignation of one of the Medical Referees under the Workmen's Compensation Act, 1925, for the Districts of the Abergavenny and Blaenavon; Crickhowell; Monmouth; and Tredegar, Abertillery and Bargoed County Courts (Circuit No. 24), the appointment held by him is falling vacant. Applications for the post should be addressed to the Private Secretary, Home Office, Whitehall, S.W.1, and should reach him not later than 7th June, 1929.

Births, Marriages, and Deaths.

BIRTHS.

Jack.—On April 7th, at Rawalpindi, India, the wife of Lieut. Colonel W. Morton Jack, O.B.E., I.M.S., of a daughter.

Long.—On May 15th, at Dene End, Stormont-road, Highgate, N., the wife of Dr. Harold Long, of a son.

DEATHS.

Alexander.—On May 14th, at Tigh Beg, Sutton, Archibald Spiers Alexander, M.D., aged 75 years.

Graves.—On May 10th, at Bucknell, Shropshire, Thomas William Graves, M.R.C.S., M.O.H., late of Knighton, Radnorshire.

Guillaume.—On May 19th, 1929, at a nursing home, Wakefield, after a serious operation, Ida Margaret Guillaume, L.R.C.P., L.R.C.S.E., L.F.P.S.G., L.M. (Rotunda), sometime Resident House Surgeon at the General Hospital, Barbados, and the Clayton Hospital, Wakefield, and elsewhere, beloved daughter of the late Mr. Thomas Guillaume and of Mrs. Ada Fanny Guillaume, of Umballa, Sandbanks.

Pollock.—On May 18th, at Maxwell-road, Northwood, Major-General C. E. Pollock, C.B., C.B.E., D.S.O., late K.H.S., and Deputy Director-General Army Medical Services.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

HOSPITAL APPEALS.

What policy should the organisers of hospital appeals adopt? Faced with the rivalry of keen competitors, should they be humdrum or original? Should they invite the donations of the charitable by sober statement and a reasoned enlistment of normal human sympathy, or should they seek to touch some sentimental weakness or even exploit a superstitious fear? A daily newspaper lately announced the withdrawal of a hospital appeal at the instance of the Lord Mayor of London who, as president of the institution, had thought its terms improper. The circular, we are told, set out the needs of a well-known maternity hospital, its building commitments in anticipation of financial support, and the saving of life of mothers and babies if the extended facilities are provided. To stir the imagination, the circular enclosed a pin and asked that the pin be returned with a cheque attached. So far the appeal seems unobjectionable, but there was a figurative description of the pin as a magic pin and a hint that, if the pin were not returned, a mother's life or a baby's life might be lost. What was no doubt intended as a quite legitimate play of fancy was capable perhaps of misunderstanding. The superstitious might regard it as a potent spell; the sceptical might look on it as a mere nuisance, not unlike those "chain of prayer" appeals whereby recipients were warned that to break the chain would involve liability to untold evils. And so the circular was withdrawn and the hospital organisers are left to find some new ingenuity of address. The decision to withdraw the appeal was solely a matter for the hospital concerned; if withdrawal was deemed advisable, no outside comment is necessary. Other institutions will note the incident. Our hospitals are dependent upon the generous support of the charitable public. A fancied indiscretion by one mendicant may check the public sympathy towards others.

THE COMPANIONATE MARRIAGE.

For the last 25 years Benjamin Barr Lindsey has been a Court Judge at Denver, Colorado. In this capacity he has seen the breakdown of the marriages of thousands of couples, and has set forth the conclusions drawn from this experience in book form.[1] In a preface we are informed that "companionate" marriage differs from "trial" marriage. But the difference is one of psychological emphasis rather than of form. A companionate marriage is typically one entered into by young people, and is distinguished from ordinary marriage by the fact that the couple take contraceptive measures to avoid children, and are given facilities for obtaining divorce in the event of their temperaments not proving compatible. They are thus spared having to resort to the hypocrisy and deception demanded by the existing legal procedure for divorce. The difference in psychological emphasis consists in this. The couple embarking upon companionate marriage intend that the marriage shall be a success, while those entering upon trial marriage envisage a divorce as soon as the flame of romantic passion has cooled. The book consists of a compilation of "case histories," presented in the form of racy anecdotes which contain much duologue between Judge Lindsey and others. These anecdotes make light reading. They fully bear out a generalisation made by Mrs. Bertrand Russell in an introduction, which runs as follows: "Roughly speaking, in England, you may say that you believe in almost any form of sexual freedom providing that you do not act according to your beliefs. In America, you may act as you please provided that you say that you do not believe in what you are doing."

It is by reason of its social effects rather than of its contents that this book deserves notice. It has enjoyed a very wide sale in America, and has there exerted a considerable influence. More than perhaps any other book, it has directed attention to the problem of contraceptive technique, which, it is being more and more realised, is an essentially medical problem. The amount of discussion which this book has provoked would suggest that, accompanying the prodigious mechanical changes which are visibly transforming the landscapes of America, there are now in operation social and ethical changes, less conspicuous but perhaps more profound, by which human relationships across the Atlantic are rapidly being transformed.

NEW PREPARATIONS.

Kharophen: Hypoloid Sodium Salicylate (Burroughs Wellcome and Co., Snow-hill Buildings, London).—Kharophen is an addition to the list of amœbicidal agents issued by this firm. It is an acetyl derivative of 3-animo-4-hydroxy-phenyl-arsinic acid, and clinical reports indicate that it is of real value in the treatment of amœbic dysentery. It is claimed to possess considerable advantages over other amœbicidal agents in that it is definitely tonic and non-depressant. It has been used effectively in the treatment of yaws, both in adults and in children. The preparation is put up in bottles of 25 tabloids, each containing grs. 4 (0·259 g.). The tablets are administered by the mouth, one tabloid twice a day for a course of ten days. *Hypoloid Sodium Salicylate* is a sclerosing solution for the treatment of varicose veins by injection. The preparation is issued in strengths of 20, 30, and 40 per cent., in hermetically sealed phials of 5 c.cm. ready for immediate intravenous injection in suitable cases, such as where the need for the astringing medium occurs in pregnancy or menstruation, where hypoloid quinine and urethane might be thought unsuitable

Acidophilus Bacillus Blocks, M-A-B (H. K. Mulford. Co., Ltd., Regent Arcade House, 252, Regent-street, London, W.).—This is a new form of administering the acidophilus bacillus, which normally inhabits the human intestine, predominantly that of the infant and young child. In order to facilitate mass dosage over long periods, the blocks are put up in a concentrated mass culture of Lactobacillus acidophilus in a medium of agar jelly covered with a chocolate coating, the blocks measuring about 1 × ¾ × ½ inches. These are encased in foil which, on removal, presents a sweet with the appearance and taste of a good chocolate confection. The tablets, which are known as M-A-B, are put up in boxes of one dozen, and form a portable and pleasant way of obtaining acidophilus treatment. Each block at the time of issue is said to contain some 150 billion bacilli of the Y type, the number usually present in a pint of comparable acidophilus milk. The recommended dose is from two to four blocks per day for an adult, eaten just before, or two to three hours after meals. For children the dose is half to two blocks daily according to age.

SLUMS IN MANCHESTER.

A book[1] about housing conditions in Manchester, by one who has an intimate knowledge of municipal affairs in that city, will be of value to all individuals, committees, and local authorities who take a keen interest in the slum problem. Statements made at conferences, and even in the House of Commons, often reveal a curious ignorance of many of the factors bearing on the question. Public health officials will find but little matter that is new to them. Here and there even Mr. Simon has failed to understand some of the terms and methods employed in official reports. For instance, the "Registrar-General's standard" of overcrowding is wrongly described on p. 7, and the standard based on cubic capacity, which is really used to a far greater extent by local authorities, is disregarded. Mr. Simon's book would have been of greater value if he had taken cognisance of investigations of overcrowding which have been carried out in towns other than Manchester, sometimes on slightly different lines. The use in this book of the word "re-conditioning" would not be accepted by all those who are interested in this method of dealing with unfit houses. It is doubtful, indeed, if the term has done anything towards clarifying the situation, but if it is to be used, it should not be applied to operations which can more adequately be described by terms which have already obtained the sanction of usage through their embodiment in the wording of Acts of Parliament. Of Mr. Simon's solutions of the slum problem, that of reducing the rates on working-class houses, which are better than the slum houses, has certainly much in its favour, and is in line with an idea to which the public has become accustomed by recent legislation. The proposal to make an allowance on rent according to the number of children would, on the other hand, present many difficulties, and is not likely to meet with ready acceptance. Mr. Simon may care to note that there is no medical officer of health of Camlachie as such, the place being a district in a city which is even bigger than Manchester.

TIME OF DAY IN RELATION TO CONVULSIONS IN EPILEPSY.

Our attention has been drawn to an error appearing in the paper on this subject by Dr. Mary Langdon-Down and Dr. Russell Brain published in our last issue. In the sixth line of the third paragraph on p. 1032, the words "between the hours of 8 A.M. and 2 P.M." should read "between the hours of 8 P.M. and 2 A.M."

Ingleby Lectures

ON

SOME TYPES OF SEPTIC INFECTION IN THE NEWLY-BORN.

Delivered in the University of Birmingham on May 23rd and 30th, 1929,

BY HECTOR CHARLES CAMERON, M.D., F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE DEPARTMENT FOR DISEASES OF CHILDREN, GUY'S HOSPITAL.

LECTURE I.

ON this occasion it is right that we should remember that it is to obstetricians that the study of pædiatrics owes its birth. Obstetricians were truly the first pædiatricians, the first to devote some special attention to the child, and although in pædiatric hands what was but a by-product of obstetric activities has been worked upon and developed in many new ways and by many new processes, the need for coöperation and a common understanding remains. It is clear that between the two services there can be no complete division of labour, because there can be no precise moment at which the responsibilities and interests of the obstetrician cease and the responsibilities and interests of the pædiatrician begin. At least the study of the neonatal period of life is territory common to both. The obstetrician in all adverse circumstances which may be encountered during pregnancy, labour, or the puerperium must have regard to the effects upon the infant no less than upon the mother. The pædiatrician, sometimes after a considerable interval, must often be concerned with disorders which owe their origin to disturbances beginning before, during, or shortly after birth. Because of this community of interest it seemed appropriate that I should select for consideration some aspect of neonatal disease which might be of interest to both groups of workers.

NEONATAL DISORDERS: THEIR FREQUENCY AND OBSCURITY.

At no time of life is death so imminent as at its first beginnings. In a general infantile death-rate of 82·9 per 1000 live births, more than half of the deaths (45·3) occurred in the first month of life—that is, in the neonatal period. Figures similar to these have been recorded in almost all civilised countries at the present time. To assess the morbidity-rate is not possible, but a death-rate of about 1 in 25 in the first month of life suggests how very frequently disorders not fatal must be encountered. We must remember that the mere recognition of the minor degrees of ill-health in an infant may be no easy matter; to have a clear understanding of how it is ill may be almost impossible. The immaturity and functional instability of the various organs, while favouring the development of symptoms, at the same time obscure their interpretation and diminish the information which at other times of life they may be said to convey. Symptoms such as jaundice, pyrexia, albuminuria, or ketonuria are produced with such regularity and facility that they are commonly described as *physiological*. Even in the presence of undoubted illness they afford little or no indication of the site or nature of the disturbance. The undeveloped state of the cortex cerebri and of all the controlling and inhibitory functions of the brain leads readily to the production of convulsions from the most various causes. Again, from the frequent and explosive passage of green and slimy stools we can by no means infer the presence of an infective enteritis, nor even conclude that the nature of the diet is at fault. Such stools are common in breast-fed infants who are thriving exceedingly, are not to be regarded as providing of themselves any indication for weaning from the breast, and are probably to be explained by a certain physiological hyperæmia with secretory and neuro-muscular hyperactivity, apt to occur in a bowel hitherto inactive, empty, and anæmic. Jaundice, albuminuria, pyrexia, convulsions, diarrhœa, may mean very little, or they may mean much. It is not easy to distinguish what is of grave import from what is trivial. We are apt too often to find ourselves suddenly and unexpectedly confronted with death or the danger of death.

ESTIMATION OF THE STATE OF HEALTH OF THE NEWLY-BORN.

The spinal cord and the medulla oblongata are the only parts of the central nervous system which are active at birth and for some time after birth. The cortical cells are indeed present from the first, but they are inactive because the medullation of the white fibres proceeds only slowly as infancy advances. But from the very first the medulla is in full and efficient control because it presides over functions and actions which are vital for the child's existence. An estimate of the efficiency of the circulatory, respiratory, and suction apparatus of the child may, therefore, serve directly as a measure of its general well-being and vitality. Almost all forms of neonatal disorder, cerebral birth injury, for example, states of infection of all sorts or prematurity, alike show themselves in an interference with one or other or with all of these vital functions.

The Child's Power of Efficient Suction as a Most Important Index.

It is perhaps the third of these primitive functions, the infant's power of suction, which, critically considered, constitutes the most useful general index of health and vitality. Interference with the mechanism of respiration, such as results in asphyxia livida or pallida, or the grosser degrees of atelectasis pulmonum, is of too grave significance to serve our purpose in this respect, and is most often to be explained by the presence of gross subtentorial hæmorrhage. Circulatory disturbances, manifesting themselves in attacks of cyanosis, syncope, and capillary stasis, are even more threatening to life. The blood pressure in the newly-born is in general very low. In the first few days of life systolic pressures of 70 mm. Hg, or even less, are frequently recorded. The viscosity of the blood, with its greatly increased content of corpuscles, is high; the left ventricle, not yet grown to meet alone responsibilities which in fœtal life it shared with its neighbour on the right, provides only a feeble force, while the suprarenals, apart from their tendency to suffer partial destruction from intramedullary hæmorrhage, share in the general functional incapacity of all the neonatal organs. These considerations account in some measure for the frequency with which, in the newly-born, and especially in those born prematurely, we encounter attacks of cyanosis and of stasis in the peripheral capillaries, with or without the accompaniment of multiple hæmorrhages. Persistent or repeated disturbance of respiration or circulation, however slight, is a danger signal which must always cause alarm.

But with the act of suction, for a variety of reasons, slighter degrees of impairment are common. In general, vigorous and effective suction is an indication of a vigorous and effective child. The newly-born may indeed be said, with some approximation to truth, to function only as a suction apparatus. Born with almost all other functions in abeyance, it yet possesses this one power in extreme degree and the pressure exercised by the sucking infant, otherwise so helpless, is surprisingly great. Illness of almost any sort results in a diminution in this power, so highly developed, and it becomes an additional and serious complication of all illness, even of illness otherwise trivial, that the resulting loss of suction power is apt to cause the loss of the milk from the mother's breasts.

Neonatal Disease Considered in its Relation to Lactation.

The public, perhaps too the profession, has been unduly slow to realise that when, in the early weeks or months, lactation fails, the explanation is almost always to be found in some diminution in the child's power of suction. So long as the mother can provide a nipple sufficiently well formed to permit of the satisfactory attachment of the suction apparatus, the amount of milk secreted varies directly with the stimulus applied in the infant's suction. Later, in lactation, maternal factors are of greater importance. The mother's age, constitution, general health, diet, and circumstances can then shorten or prolong lactation. But it is in the early weeks that the function of lactation is least stable and most in danger because of the extreme dependance of the young child's power to suck upon its general health.

I have drawn up a list of the conditions in the infant which are from time to time responsible for the failure to nurse, and in almost every case of so-called inability to nurse, excluding those in which the weaning is due to faulty technique or to unwillingness or over-anxiety on the part of the mother, I believe that one or other will be found responsible.

(*a*) *General Weakness.*—Great prematurity or debility.
(*b*) *Dyspnœa.*—Bronchitis, pneumonia, atelectasis, congenital heart disease.
(*c*) *Nasal Obstruction.*—Nasal catarrh, syphilitic rhinitis, narrow choana.
(*d*) *Incoördinate Suction with Aerophagy.*—Nervous unrest and crying, mental deficiency, organic disease of central nervous system, cerebral birth trauma.
(*e*) *Local Conditions in the Mouth, &c.*—Macroglossia, cleft palate, hare-lip, facial paralysis, ranula, ulcers of the mouth and palate.
(*f*) *Acute Infective Illness.*—Sepsis neonatorum, influenza, pyelitis, &c.

A consideration of this list goes far, I think, to explain the frequency with which the human infant fails in a task in which the young of other animals appear almost uniformly successful. In the first place, it is obvious that a litter provides a six or eight cylinder engine, and that if one or other goes out of action for the time being, the resulting loss is negligible. But the mother breast is dependent almost always upon the stimulus from a single infant. If the child ceases to suck, or sucks under difficulties, the involution of the breast begins at once and proceeds rapidly. The frequency of nasal obstruction from nasal catarrh, especially for the infant born in the winter months, is so great as itself to account for a considerable proportion of the cases. But, above all, in the young of no other animal do we find displayed that nervous unrest, insomnia, and violent emotional disturbance which is so common in the human infant, charm the nurse never so wisely. The suction apparatus works effectively only when the child is quiet and in repose. A too eager and purposive suction, which substitutes for the quiet, steady, and efficient reflex act an uncontrolled, incoördinate, voluntary effort, results in the swallowing of a minimal amount of milk and of a maximal amount of air. The breast, drained at first in great and eager gulps, is rapidly relinquished and the infant falls again to crying from the discomfort of the too great gastric distension. Such difficulties are formidable only for the very young infant. The older child grows adept in the art of suction and learns to overcome them.

In dealing with this all-important question of suction, I have been led somewhat to reverse the aspect from which I am considering the subject. For my contention at the moment is not so much that a study of the infant may reveal that defect in the suction upon which the difficulty in lactation depends, but rather that the power of suction affords a most valuable measure of the well-being of the child. All the activities of the newly-born are activities governed by the medulla, and our examination of the newly-born must be directed towards assessing the efficiency of the respiratory and circulatory apparatus, the power to maintain a comparatively stable body temperature, and the capacity for effective suction. The last two provide us with the readiest and most delicate index of the vital stability of the child.

CLASSIFICATION OF NEONATAL DISORDERS.

The high neonatal mortality is due to several factors:—

(*a*) Developmental defects incompatible with life.
(*b*) Gross prematurity which also predisposes to (*c*), (*d*), and (*e*).
(*c*) Sepsis neonatorum and other infections.
(*d*) Functional weakness of particular organs. Jaundice, the hæmorrhagic disorder, disorders of gastric and intestinal peristalsis.
(*e*) Birth trauma.

This neonatal mortality has not, it is said, taken part in that great fall in the general infant mortality-rate which has been so satisfactory a feature of the last 20 years. It is a mortality for which the lack of mothercraft cannot be held responsible. In part, in the grosser forms of maldevelopment and of prematurity for example, it is unavoidable. On the other hand, of recent years striking success can be recorded in the treatment of the hæmorrhagic disorder and of some forms of severe icterus by means of blood transfusion, while all improvements in the art of obstetrics must carry with them a reduction in the incidence both of sepsis neonatorum and of birth trauma.

Perhaps in this connexion I may be allowed to call attention to the quite remarkable success recently achieved by Hampson, working at Guy's Hospital, in the treatment of the grave familial jaundice of the newly-born, by means of repeated injections of the mother's serum intramuscularly. In the families studied by Hampson,[1] there had been 75 fatal cases of jaundice, while 15 infants alone had survived. Since treatment in the same families, there have been 18 cases of this form of jaundice, hitherto so fatal, with 17 recoveries. The single fatal case was seen very late. How common this form of jaundice may be it is at present difficult to say, but experience teaches us that often it is only when a successful method of treatment is found that attention is focused on the disorder and its true frequency revealed. Until 1900, for example, cases of hypertrophic pyloric stenosis were not recognised; to-day, hundreds of successful operations are performed annually.

SEPSIS NEONATORUM.

Its Greater Frequency and Severity in the Past.

To-day, in all civilised countries, as a result of aseptic midwifery and the spread amongst all classes of society of a knowledge of the need for scrupulous cleanliness in the handling of the newly-born, this one-time scourge has greatly declined both in frequency and in severity. Formerly it exacted such a toll of the lives of the newly-born as to-day may well nigh seem incredible. It is but "the shade of that which once was great" which we must be content to study—a shade, it must be confessed, which is apt to lose something of its definition if too high an illumination is attempted. This shadowy character, this want of definition and sharpness of outline nowadays makes the study and even the recognition of the condition by no means easy. The provision of aseptic childbed, if it was a work accomplished in the first place in the interests of the mother, has proved to be of equal benefit for the child. It is to the pages of old books written by men who worked in the lying-in hospitals before Lister lived that we must turn to have brought before us in all its frightfulness what the puerperal infection of the child really was. The picture of sepsis neonatorum, as we encounter it, for example, in the writings of Trousseau,[2] has been banished.

> Of 193 infants born alive, 50 died of the very same affections which proved fatal to the lying-in woman. The most frequent causes of death were peritonitis, numerous abscesses, purulent infection, phlegmonous swellings, erysipelas, gangrene of the limbs, putrid infection, or some other remarkable septic condition. The mother and child often had the same disease, but sometimes its form and seat

> were, and at other times were not, the same in both; for example, a child sometimes died of peritonitis and its mother of purulent infection, or the child of purulent infection and the mother of peritonitis. . . . The infants of 50 women who recovered after having had puerperal symptoms died of peritonitis.

Peculiarities of Septic Infection as it Occurs in the Newly-born.

While the course of septic infection of older infants does not differ greatly in degree or in kind from that which is the rule in later life, sepsis neonatorum is of so peculiar a character that it requires special consideration. That the resistance of the newly-born organism is very low is shown both by the very rapid spread of the infective process by continuity and by the urgent danger of a generalised dissemination throughout the body. Generalisation of the infection very often takes place without visible involvement of the lymphatics (lymphangitis), and without enlargement of the lymphatic glands (lymphadenitis). It is a curious clinical fact that enlargement of the lymphatic glands with or without secondary suppuration is commonly encountered in very young infants only in the occipital glands secondary to infection of the skin of the scalp. Characteristic, too, is the predominance of toxic symptoms over the infective—coma, convulsions, muscular rigidity, diarrhœa, diffuse hæmorrhages. In the most severe and fulminating cases indeed, the infective symptoms are often completely obscured in this way, and neither the original site of infection nor the secondary metastases may be indicated by any visible reaction or subjective symptom. With alarming rapidity the picture changes to that of a severe and fatal disturbance of the general metabolism of the infant, marked by stupor, muscular twitchings or convulsions, a livid or cyanotic hue of the skin, circulatory weakness, dyspnœa, diarrhœa, rapid loss of weight, dehydration of the body, and inability to suck. Even fever may be absent, and in the rapidly ensuing terminal collapse subnormal temperatures are found as often as high fever. Rigors are always absent, perhaps because of the rarity of thrombotic processes, with the single but well-marked exception of urinary sepsis. Rigors may indeed be said to be pathognomonic of pyelonephritis. Enlargement of the spleen is seldom discernible, but jaundice is characteristically common. In the urine albumin and casts are usually found. At times we meet with a typical hæmorrhagic nephritis.

The skin often shows evidence of the severity of the toxæmia. Scarlatiniform and morbilliform rashes, and especially petechial hæmorrhages, are common. Sclerema, and especially a widespread septic œdema, is often encountered. Endocarditis is not to be recognised during life, but it is an occasional finding at the autopsy. Pericarditis and empyema are much more frequent and may sometimes be recognised in life. Peritonitis is, in general, a complication of umbilical infection or of erysipelas of the abdominal wall, less commonly it owes its origin to a generalised pyæmia. Finally, in addition to the toxic cerebral symptoms we find not infrequently evidence of meningitis or meningo-encephalitis occasionally purulent but more often serous, with much œdematous swelling of the pia mater, and with a serous or serosanguineous exudate. The cerebro-spinal fluid may then be blood-stained and characteristically shows a high protein content and a greatly increased number of cells. In this condition, too, retinal hæmorrhages have been found from time to time.

The disorders, which under the name of Buhl's disease and Winckel's disease, still figure in text-book descriptions of neonatal disorders, are in reality no more than particular manifestations of sepsis neonatorum of great severity occurring in the distant past, discussed by their authors with no great clarity. Buhl,[3] a morbid anatomist, was impressed with the frequency of fatty degeneration of the liver at autopsies he conducted upon infants who had died shortly after birth with symptoms such as icterus, cyanosis, and multiple hæmorrhages, and put forward the erroneous suggestion that death was due to a fatty degeneration of the liver, comparable to that produced by phosphorus poisoning. It does not appear that the livers of these infants exhibited a higher degree of fatty change than is common in many severe infective states. Winckel,[4] on the other hand, recounted a particular epidemic of a disorder which he described under the name cyanosis afebrilis icterica, in which many new-born infants died without pyrexia but with cyanosis, jaundice and, according to Winckel, hæmoglobinæmia. It does not appear, however, from a study of Winckel's original communication that either hæmoglobinæmia or hæmoglobinuria was in fact actually identified, and, indeed, he speaks of the presence of blood corpuscles in the urine without apparently appreciating the significance of the distinction. In subsequent cases attempts to identify hæmoglobinæmia have been unsuccessful. Sepsis neonatorum is a disorder apt to present itself in many forms and guises, but it is important to recognise the underlying identity of all.

The Peculiar Liability of the Newly-born to Infection.

The explanation of the increased susceptibility of the newly-born to septic infection is perhaps to be found in part in the structural peculiarities of the skin and mucous membranes in the first weeks of life, to be discussed later, which render them much more readily permeable to bacteria, but, in addition, it has been demonstrated that the blood of the newly-born is deficient in antibodies. In practice, we find this susceptibility to infection greatly increased by the abandonment of breast-feeding. It is invariably the experience that septic infection will occur in a far larger proportion of artificially-fed than of breast-fed infants, and that the mortality in the bottle-fed, because of their lesser powers of resistance, is very much higher. Even when dealing with the localised and specific infection of gonorrheal ophthalmia in the newly-born, it was my experience, when attending the Metropolitan Asylum Board's Hospital for this complaint, that recovery in the breast-fed was achieved, under conditions and with treatment otherwise identical, in about half the time taken by those artificially fed. The bactericidal power of the serum of the breast-fed infant has been shown to surpass greatly that of the artificially fed, whether because of the protection directly derived from the mother's milk or because under the natural food, the production of protective substances by the organism itself is stimulated. Circumstances which powerfully predispose to infection are prematurity, dyspeptic and nutritional disturbances of all sorts, and congenital syphilis.

Portals and Paths of Infection.

The part played by certain portals of entry, of great importance in later childhood—the tonsil and middle-ear for example—in the newly-born is relatively inconspicuous, while that of others—the umbilicus, for example, the skin and the different mucous membranes is prominent. The number of cases in which it remains impossible to determine the exact point of entrance, in life and even after a careful post-mortem examination, is very high.

The risk of septic infection is already incurred during intra-uterine life. Occasionally cases have been reported, in modern times, with complete bacteriological investigation, of infants coming into the world dead or dying of generalised septic infection. As a rule, the infection has taken place through the placenta from a mother herself, the subject of a septic disorder. When the mother has remained unaffected, we must suppose that in her the infection has remained controlled or suppressed, and only obtained a footing in the fœtus.

Occasionally the infection has its beginning in the course of labour as a result of the aspiration of infected amniotic fluid or from contamination by pathological vaginal secretions. But much more frequently infection takes place after the birth in the first few days of extra-uterine life. In a very high proportion of cases the umbilicus is infected. Often the umbilical wound is the primary source of infection, but close observation will also show that the infection of the umbilicus is often secondary to generalised infection. Indeed, no matter where the original seat of infection may be, it is usual to find that the umbilicus becomes secondarily involved. Rivalling the umbilical wound in importance as a portal of infection are all eczematous and intertriginous erosions of the skin, which lay bare the subepithelial lymphatic sinuses, all points of decubitus, especially on the occiput, the sacrum, and the heels; impetiginous infections of the skin, which in the newly-born characteristically take the forms known as pemphigus neonatorum and dermatitis exfoliativa; all ulcerative conditions of the mouth, especially the deep-seated ulcer of the palate known as Bednar's aphtha, and all streptococcal infections of the mucous membranes—nasal, pharyngeal, conjunctival, or bronchial.

In pædiatric literature the part played by the intestinal mucous membrane as the portal of entry has been the subject of much debate. According to Czerny and his school, much of the total of sepsis neonatorum originates from the bowel. In general, however, opinion inclines to the view that the frequent intestinal symptoms, with profuse and sometimes foul-smelling diarrhœa, are secondary results of the infection.

In a proportion of the cases, as a result of a local ulcer or abscess of the skin or subcutaneous tissue, because of the low resistance, the inflammatory process extends rapidly, to form a widely spread infiltration, to open neighbouring joints, or to cause gangrene of the skin, of a finger, or of the ear. The rapidity of such a spread may be truly astounding. In a few hours a tiny spot may have become a widely-distributed inflammation. Often the spread is along the fascial layers, the so-called progressive septic necrosis of the subcutaneous cellular tissues. Almost without swelling or œdema, but with a dusky discoloration of the skin, the necrosis advances. Incision reveals no pus, but in the end extensive sequestra and exfoliated masses of necrotic subcutaneous tissue may be extruded, leaving undermined the bluish discoloured skin.

It is perhaps more important to realise that generalised septic infection in the newly-born may spread from streptococcal infection of mucous membranes, without visible ulceration, but with much mucopurulent discharge. I may quote in illustration of this a case which recently came under my notice:—

> Twin boys, born at full time and in every way strong and vigorous, were circumcised on the eighth day of life. Unfortunately, although it was not known at the time, an outbreak of severe influenza had just begun at the nursing home in which the mother and the infants lay. On the evening of the day on which the boys had been circumcised, the mother's temperature rose to 104° F. On the following day two nurses in attendance had also been attacked. On the third day after circumcision the infants' temperatures rose to 105°. On the seventh day the circumcision wounds of both had become infected, discharging pus freely, and surrounded by a considerable area of redness and œdema. On the eighth day one infant died in convulsions. The second survived for eight more days, during which time a typical condition of trismus neonatorum developed. From the morning after the first rise of temperature, and before anything amiss with the circumcision wounds was apparent, there had been in both infants profuse rhinitis, with a copious discharge of thick muco-pus.

CLINICAL VARIETIES OF SEPSIS NEONATORUM.

In individual cases and, in particular, epidemics of the generalised infection of sepsis neonatorum, as might be expected, the clinical picture is very various, so that, as in the comparable case of influenza, it has been the custom to attempt a description of several types of the disorder, differing according to the system which happens to bear the brunt of the attack. We speak of a pulmonary form, with early and severe involvement of the lungs in a bronchopneumonic infection, in which lividity or cyanosis, dyspnœa and cardiac failure are the most prominent symptoms. Often there is a peculiarly intense rhinitis, with an acrid and irritating nasal discharge, causing ulceration of the nostrils and upper lip. Or, again, we may describe a gastro-intestinal form in which severe diarrhœa, with watery, green, and foul-smelling stools, and with a very rapid dehydration of the body, is the most prominent symptom, sometimes even the meconium may have a peculiar and characteristic odour. Or, again, it may be that the preponderating symptoms are referred to the cerebro-spinal system or are visible in a widespread cutaneous involvement. It is with these two last types alone, the cerebro-spinal and the cutaneous, that I propose to deal especially.

SOME PROBLEMS OF THE NORMAL AND PATHOLOGICAL PHYSIOLOGY OF THE STOMACH.

BY VICTOR J. KINSELLA, M.B., CH.M. SYDNEY.

WITH ILLUSTRATIVE PLATE.

The Nervous Paths of Painful Stimuli.

AN excellent account of the nervous connexions of the gastro-intestinal tract is to be found in the paper published in 1920 by the late Prof. Hunter.[1] The vagus and the sympathetic are the two systems concerned and each of these includes both afferent and efferent fibres with their nerve centres in the medulla and spinal cord respectively. By means of these reflex systems gastric tonus, movement, and secretion are regulated according to the stage of digestion and the requirements of the food mass in the stomach. The extrinsic connexions play their part in the control of digestion, although the stomach and intestine have a certain measure of autonomy. It follows that there are two possible afferent paths which may be taken by painful impressions from the stomach. The first passes up the vagus to its dorsal nucleus beneath the floor of the fourth ventricle; the other passes along the sympathetic fibres to the solar plexus, then along the splanchnic nerves, through the sympathetic trunk and the white rami communicantes, then through the posterior routes of the spinal nerves to cells in the posterior horn of grey matter in the thoracic region of the cord.

By which route do the pain sensations reach the central nervous system? There are very few definite observations which help us to answer this question. Animal experiments have been chiefly concerned with the influence of the extrinsic nerves on the motor and secretory functions of the stomach. Surgeons have divided the nerves in man but have not given us an answer to our problem. In many cases both sets of fibres have been divided; relief is obtained in one case by a certain operation which fails in another case apparently similar; then, again, the conditions chiefly dealt with have been the gastric crises of tabes and the gastric neuroses, in the former of which the site of the painful stimulation is probably not in the stomach but in the nervous system, and in the latter it is not clear where the pain originates.

Hilton [2] in 1860, Martyn [3] in 1864, Lange in 1875 (quoted by Hurst [4]), and Ross [5] in 1888, recognised in their studies of referred pain the part played by the sympathetic system. But the vagus was looked upon as the chief sensory nerve of the stomach, and Ewald[6] in 1892 stated that "all conscious sensations," including pain, pass through the vagus. In recent years, however, Mackenzie's influence has swung the pendulum of opinion in the other direction, and the sympathetic has been credited with the chief, if not the only part in conveying the painful impressions from the viscera.[1 7 8 9] According to Preiss (quoted by Alvarez [10]) the vagi carry no pain fibres.

Probably both sets of fibres bear painful impulses. The sympathetic system and the spinal cord are the only direct nervous connexion between the viscera on the one hand and the skin and muscles of the abdominal wall on the other, so they probably subserve the hyperalgesia of the skin and muscles which is found in many cases. The part played by the vagus is proved, I believe, by a patient with a spinal cord lesion whom I saw recently.

The patient was a West Australian youth, aged 20, who, two years before, had met with a motor-cycle accident and had sustained a fracture of the spine at the level of the third thoracic vertebra with compression of the spinal cord. He had complete paralysis and anæsthesia below the level of a line just above the nipples, with priapism and other typical reflex disturbances. The skin was smooth, shiny, and atrophic, and the toes were markedly atrophic. He had a healing bed-sore over the sacrum. His general health was very good and he was comfortable and cheerful. A cystostomy had been performed in Western Australia. The bowels were opened every third day by an enema administered by his mother, probably at too great a pressure. The patient volunteered the information that the bowel movements were always accompanied by colicky pains referred to the abdomen.

The great interest of this case lies firstly in the fact that the painful stimuli could have been conveyed only by the vagus. It cannot be postulated that the painful impressions passed up the intact sympathetic trunk, and reached the spinal cord cranial to the lesion, because the principles of reflex symptoms which have been soundly based on anatomical and clinical data show that the pain is referred to the body segments at the level of the sympathetic connexion with the cord. In this case, therefore, if the sympathetic conducted the impulses the pain would have been referred not to the abdomen but to the upper thoracic and lower cervical segments. This case, moreover, demonstrates beyond doubt the visceral component in abdominal pain, because the parietal tissues were no longer in nervous association with the sensorium, and so there could be no "referred" element. Visceral pain need not therefore depend upon an overflow from visceral to somatic nerve cells.

Further evidence of the part played by the vagus is the headache experienced by some patients with disease of the gall-bladder or with chronic duodenal ileus. Many writers attribute the headaches to a toxic origin, but many of the patients enjoy very good general health, and some normal people (including myself) experience frontal headache after drinking very cold water, so perhaps the cause is reflex rather than toxic.

I think we can safely conclude that neither the vagus nor the sympathetic nerves monopolise the painful stimuli, but that each has its share. The sympathetic nerves certainly subserve the cutaneous and muscular hyperalgesia, and also the more superficial or the referred component of visceral pain. The vagus probably subserves the deep or truly visceral element together with the deep tenderness localised to the lesion itself. Individual differences in the nervous make-up of the individual appear to alter the clinical picture. In women the sympathetic element is more noticeable; the symptoms are diffuse and tenderness can be elicited by pressure which is not necessarily over the lesion, and which scarcely disturbs the viscera beneath. In patients of a more phlegmatic type, generally the male, the sympathetic element is less noticeable, there may be no apparent tenderness until deep firm pressure is made exactly over the lesion, and in these cases it sometimes happens that one fails in the search for a deep, tender point until the examination is made under the fluoroscopic screen, and then it is found that pain results only when the affected part —e.g., the pylorus—is actually compressed against the posterior abdominal wall; but when the viscus slips from beneath the fingers the tender point cannot be demonstrated until the organ is again pinned down. In many patients both types of tenderness can be recognised, the superficial (or sympathetic) and the deep (or vagal).

The deep tenderness localised to the lesion itself is in the case of the stomach very often placed caudally to the area of superficial tenderness which is often confined to a triangular area of parietes above the lesser curvature of the stomach and bounded on either side by the rib margins. The lesion—e.g., an ulcer of the pylorus or duodenum—may lie in Bolton's lower or middle sterno-umbilical region,[11] and the referred symptoms in the middle and upper zones (Fig. 1). Although one associates this more superficial pain, cranial to the level of the stomach, with an irritable focus in the spinal cord, the dependence of this pain and of the irritable focus in the cord upon the lesion itself must not be forgotten. This dependence of the more cranial hyperalgesia upon the lesion may easily be overlooked because the pain provoked by pressing over the lesion is nearly always referred to the area pressed upon, and not to the more cranial hyperalgesic area. But I have seen at least one patient with ulcer who indicated the upper zone and placed a leaden numeral upon it when asked to point out the site of pain provoked by pressure over the lesion lower down.

FIG. 1.

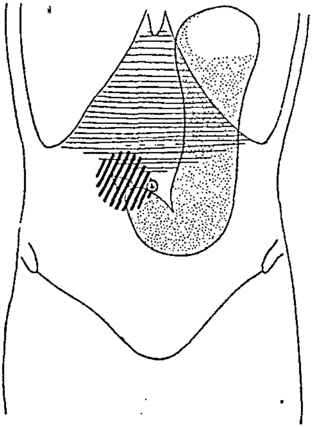

Diagram showing the distribution of tenderness often found in patients of orthosthenic or hyposthenic type with a pyloric or duodenal lesion. The referred or sympathetic tenderness is superficial and shaded lightly. The vagal or deep tenderness is shaded heavily. The more caudal position of the latter is a clinical suggestion of the slipping of the human stomach below its associated somatic segments.

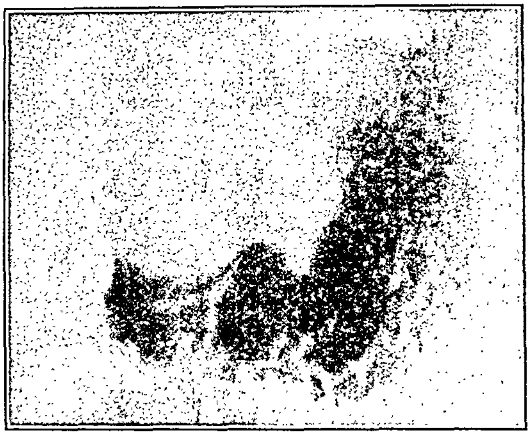
The above conception of two clinical varieties of pain subserved by different nervous mechanisms might well be tested by the surgeon who attempts neurotomy for the relief of gastric pain, and it may prove useful in indicating the nervous connexions which must be severed in any particular case. Perhaps, also, it explains some of the individual failures which have followed different methods of neurotomy.

Man's Upright Posture.

The referred pain, hyperalgesia, and muscle guarding in the upper and middle sterno-umbilical regions are looked upon biologically as reflexes having the function of protecting and resting a diseased viscus. This view is borne out by the observation that these viscerosensory and visceromotor signs are found in the presence of an inflammatory lesion, but, unless the agony is very great, they are usually absent when pain depends upon colic; in fact, the patient suffering from colic often finds some measure of relief in doubling up and pressing upon the affected part.

mucosa show, with the patient in the horizontal position, that the empty stomach is not always tubular but often a broad flattened viscus with the anterior and posterior walls in apposition, free to accommodate an increase in contents by mere separation of its walls and by making use of its potential cavity without altering the postural length of the muscle-fibres. Larger variations in the volume of contents will, of course, bring into play the tonic properties of the muscle. If the stomach is now well filled, until the patient feels full, and is again palpated, it will be found that the anterior and posterior walls can be easily pressed together again and the fluid contents displaced without the examiner experiencing any of that familiar feeling of tension in fluid-filled cavities. The stomach feels to be, and is seen to be, a bag which is not filled to its utmost capacity. If the stomach were to relax just enough to accommodate its contents and no more, we would expect to feel the fluid resistance of a well-filled bag because it is found that a latent period of some seconds elapses before the stomach accommodates its tone to its contents; in other words, one would expect an impression of tension. But in the fluoroscopic examination, and even in the radiograms (see Figs. 2 and 3), the peculiar impression of softness or relaxation is quite a distinct characteristic of the orthotonic stomach and appears to be altogether incompatible with a rise of tension either in the wall or in the lumen of the viscus.

FIG. 3.



A short orthotonic stomach, almost empty.

The appearance of stomachs akin to that illustrated in Figs. 2 and 3 was so different from the conventional description that I suspected for a time that it was due to an artefact, and that the walls of the stomach were held apart by the water in which the barium had been given, while the powder itself (although finely "fluffed"), had sedimented in the lowest part of the stomach. But by keeping a sample of the barium suspension in a glass tumbler it was found that sedimentation would not explain the appearance, which could be detected before sedimentation occurred in the tumbler. Suspension was aided by a little tragacanth in the case of Fig. 3, and this patient was of the sthenic type. When the vehicle of the meal is thicker still—e.g., bread-and-milk—the food remnants are found to lie in the pylorus when the stomach has nearly emptied itself, but the rest of the stomach cannot be visualised because the thicker chyme does not adhere in the mucosal folds. Radiography of the stomach, after very small fluid meals (2–3 oz.), therefore suggests a slight modification in Sherrington's teachings, at least in some cases, and at least in dealing with the empty or part-filled stomach. It appears that this organ very often accommodates two ounces of fluid, not by a two-ounce posture, but by a four-ounce posture, so that the contents are not always accurately grasped, but often leave a potential cavity and fail to fill the stomach as high as the cardia. The walls of the stomach above the contents of the pylorus are apparently kept pressed together by the neighbouring viscera and by intra-abdominal pressure. The postural lengthening of the gastric muscle is not required, and there is, as a rule, no sense of fullness until this potential space has been filled to the cardia. Here, then, we have the explanation of the thirsty person's capabilities. Individuals with the small stomach (e.g., my friend Dr. Apperly) cannot perform these feats. Their difficulty has been assumed to depend upon a slowness in the postural lengthening of their gastric musculature. But this explanation is not very satisfactory, for the musculature is seen radiographically to be particularly active and efficient. A more likely explanation of the early fullness is the small potential space available. It must be stressed that we are speaking only of the orthotonic stomach and that the described behaviour cannot be satisfactorily demonstrated in all cases, especially when the abdomen is hard and tense, or when the barium is administered in a thick medium such as bread-and-milk. Under these circumstances the meal will pass downwards from the œsophagus much more slowly and will pass back into the vertical part only with difficulty. The difference is probably due in the first case to the more firm apposition of the stomach walls caused by the greater intra-abdominal pressure, and in the other to the more glutinous quantity of the meal which slides down with difficulty between the apposed walls.

When the opaque meal enters the stomach it is held up for a variable time by the stomach wall, except in hyposthenic individuals, and only gradually finds its way to the pylorus. This so-called "peristole" is often said to be a manifestation of muscular tone, but this point of view needs some qualification. It must be remembered that the food makes its way down an inclined plane which passes downwards and forwards from the cardia to the lowest point of the greater curvature. This inclined plane is probably partly responsible for the "peristole," and if we tilt our screening table so that the plane becomes more inclined, we find that the hold-up of the food becomes more marked, and before the horizontal position is reached the meal collects at the fundus of the stomach as it is swallowed. As the food passes down this inclined plane its progress is mechanically hindered by the apposition of the stomach walls which depends in part, at least, upon the intra-abdominal pressure and the pressure from neighbouring viscera. As the food descends it must separate the stomach walls against these opposing forces. The slowness of descent is in direct proportion to the thickness of the meal. The tubular shape of the vertical limb of the stomach, very often seen with the patient in the vertical position, can be modified by the horizontal position, so that the viscus becomes more flattened and the "tube" two or three times broader. These observations suggest that mechanical factors play a considerable part in producing "peristole."

In the supine position the well-filled orthotonic stomach becomes broader at the cardiac than at the pyloric end, while in the upright position the pyloric end becomes as broad as, or broader, than the cardiac. The degree of tension in the normal stomach wall is therefore not sufficient to prevent alterations in the shape of the viscus by the slight change in fluid pressure brought about by changes in posture. Moreover, the stomach empties more rapidly when the patient lies on the right side and less rapidly when on the left side. The duodenal cap is best filled when the subject lies prone, and use is made of this fact in routine radiography. The influence of gravity in changing the shape and emptying of the stomach is further illustration of the absence of tension or of resistance in the stomach wall, and of the fact that

CLINICAL INTERPRETATION OF AIDS TO DIAGNOSIS.

MR. J. B. MACALPINE: PYELOGRAPHY.

merely mechanical as well as physiological factors are of importance.

It is often seen, as in Fig. 2, that the tension of the stomach wall is not sufficient to support a column of watery fluid in the vertical limb of the stomach. Different observers have investigated intragastric tension in man; Kelling (quoted by Sherrington) found that *it tended to remain at 8 cm. of water.* A feeling of fullness is produced when the tension reaches 10–22 cm. of water (Apperly [17]), 12–14 mm. of mercury (Hurst [4]). But probably these experiments do not reveal the degree of tension in the gastric wall, because the pressure within the stomach depends not only upon the tension of its walls but also upon the intra-abdominal pressure, so that to arrive at the tension in the stomach wall we must subtract from the above figures the intra-abdominal pressure. When the stomach is experimentally distended it is found that only very small rises of intragastric pressure can be brought about. In Kelling's experiments the pressure was 10 c.cm. of water after injecting 500 c.cm. of air and water, and this pressure then fell to 8 c.cm., at which it remained. The *injection had produced, therefore, a rise of but* 2 c.cm. of water above the normal intragastric pressure. Hurst injected air into the stomach until a sensation of fullness was produced and the pressure rose only 2 mm. of mercury. Apperly rapidly injected air into the stomachs of eight healthy students and found that a sensation of fullness was produced approximately after 30 seconds (personal communication), when he had injected 250–1200 c.cm. of air and the pressure had reached from 10–22 c.cm. of water. In an endeavour to produce pain by distending my own stomach with Apperly's apparatus I found that fullness was produced after 30 seconds, and 10 seconds later nausea and retching, which terminated the experiment. By this time 425 c.cm. of air had been injected. These experiments illustrate *that even when extreme means are used only small* rises of intragastric pressure results, and that when these rises are brought about the subjective sensations produced are fullness and later nausea. The occasional production of pain by extreme distension has been referred to in a previous communication.

In view of the above outlined experimental and radiographic observations on gastric tone and the potential gastric space, it seems very unlikely that muscle tension in the wall or lumen of the stomach should be the cause of pain in the natural course of disease, unless it be found that the diseased stomach differs from the normal stomach in its motor behaviour, and that the stomach in pain differs from the pain-free stomach. I have previously reviewed the evidence that there is no such difference and have *now only to add the testimony of Ortmayer* [18] *and* Palmer.[19] There is no evidence in these cases that gastric tonus has failed in its functions of preventing tension. Dr. S. F. McDonald, of Brisbane, has drawn my attention to congenital hypertrophic stenosis of the pylorus, in which painless peristaltic waves visible through the abdominal wall can be seen advancing against the stenosed pylorus. If any condition could produce the requisite alterations in tension it is this, and yet the child may lie quite placidly while these waves are observed. To those *who adhere to the hypothesis of "muscle-pain,"* there remains only the possibility suggested by Bolton that the "fine changes in muscle-tension responsible for the pain cannot be appreciated by our methods." But it is difficult to understand how painful stimuli could be transferred to the adjacent nervous elements by changes in the muscle-fibre so fine as to cause no visible disturbance in the filling, size, shape, or emptying of the viscus. If it is through the exposure of nerve-fibres in the ulcer, with consequent abnormal irritability, why does the *acute ulcer cause no pain? Why is not the tension,* and with it the pain, modified by every peristaltic wave? It cannot be that the waves succeed each other so rapidly than a continuous sensation is produced, for no such peristaltic behaviour is a necessary accompaniment of the pain; moreover, gastric sensations which are known to depend on peristalsis—viz., hunger pangs—are intermittent (Carlson), and therefore unlike ulcer pains.

To summarise, there is little or no evidence that uncomplicated peptic ulcer causes disturbance of muscular tension, nor is there much evidence that *such disturbance, even if present, would cause pain.*

The Part Played by Acid.

That acid is the normal stimulus of the pain in peptic ulcer has been doubted ever since Hurst reported in 1911 *that he had injected large quantities* of acid into ulcerated stomachs without causing pain. But Palmer [19] has recently revived the hypothesis and has succeeded in producing pain in 84 out of 100 patients by pouring acid into their stomachs, but he failed in the case of 25 patients. Even in the first group, 80 of the 404 experiments failed. It is apparent from the work of these and of many other investigators that acid sometimes causes pain when brought into contact with an unhealed ulcer, and sometimes it does not. Palmer has pointed out that at times the active ulcer is insensitive to the normal stimulus—i.e., the patient has a remission of his symptoms—and during these periods the ulcer is more likely to be insensitive to the artificial stimulus as well. These observations, and many others summarised by Alvarez, *make it clear that the acid* is not the direct cause of the pain. Other objections to the acid theory suggest themselves. Recently a patient under our care with a penetrating ulcer, proved later at operation to be adherent to the pancreas, suffered from steady pain throughout a test-meal, the free acidity rising from 0 to 50, and falling again to 2. Palmer reports three cases of ulcer pain with no free acid at the time of pain. One ulcer was simple, another syphilitic, and a third carcinomatous. In another of his patients we find *no pain, with a free acidity of 33; 45 minutes later* severe pain, with an acidity of 35, and 20 minutes later no pain, with an acidity of 43. Fenwick, quoted by Hardy [20] says that it is common in long-standing hyperchlorhydria for the free HCl to fall gradually until subacidity is obtained, while the painful sensations increase rather than diminish. It is of importance also to remember that treatment, whether medical or surgical, may relieve symptoms and yet cause no decrease but even an increase in the acid curve (Hardy,[20] Crohn and Reiss,[21] Sherren [22]). How can the acid hypothesis explain the absence of pain in acute ulcers? How can it explain the pain in lesions with no breach in the gastric mucosa? How can it explain those cases in which food and alkalis gradually lose their power of relieving the pain?

A further objection to an acceptance of the acid hypothesis is the extreme measures which have been required to produce the pain in the experimental studies; 200 c.cm. of 0·5 per cent. HCl is administered, and if the pain is not produced this dose is repeated at half-hourly intervals.[19]

It is believed that a high degree of gastric acidity will "intensify and prolong the duodenal reflex contraction of the pylorus, as well as induce strong contractions in the duodenum itself" (Carlson,[23] Reynolds and McClure[24]). Palmer, however, found that the acid "produced slightly more spasm of the duodenum than did the neutral solution, but the difference was relatively small."

In order to investigate the effect of a high acidity on the motor functions of the stomach, I made a careful fluoroscopic examination before and after acid in 15 subjects who kindly consented to the experiment. The subject first swallowed an Einhorn tube, and in most cases the tip of this was made to lie just within the cardiac orifice. About *50–100 c.cm. of aqueous barium* suspension was then swallowed, and the stomach movements were observed for 5 to 15 minutes, and then 100–200 c.cm. of 0·6 per cent. HCl, sometimes with some barium in suspension, was injected down the tube and its effects observed for 30 to 40 minutes. The fluid already in the stomach would dilute this acid. In one case no visible effect was produced by the acid. In the other 14 cases, after an interval of two to five minutes, peristalsis ceased and spasm was observed at the pyloric end of the stomach (Fig. 4). This disturbance lasted for only a few minutes in some cases, in others it lasted for more than half an hour. The spasm varied in degree. In four subjects a powerful contraction obliterated the duodenum, the pylorus, and the pyloric antrum, so that barium could not be forced out of the stomach by palpation; in one the pylorus became spigot-shaped; in one case a J-shaped stomach became "steer-horn"; in the rest the spasm was less striking because only the immediate region of the sphincter and duodenum was involved, the barium could not easily be forced through the pylorus and the stomach emptied less rapidly, and it was found that the duodenum and uppermost coils of jejunum, previously well filled with barium, were now no longer visualised because they were no longer kept well filled by the stomach. In most cases the barium which had already left the stomach lost the feathery appearance typical of the jejunal coils and became aggregated into solid little masses, as though squeezed by powerful tetanic spasms of the intestine (Fig. 5). These findings agree with the clinical observations of prompt relief produced by acid in the gastrogenous diarrhœa of achylia.

These varying motor effects possibly suggest an explanation of the varying clinical effects produced by acid in ulcer patients. The different degrees and kinds of pain suggest that acid does not act as a direct irritant. At times the agony is so severe that the patient groans, perspires, and rolls upon the floor. In these cases it is probable that a sensitive ulcer has come within the grasp of a powerful spasm like that illustrated in Fig. 4. Intermediate degrees of pain probably depend upon intermediate degrees of sensitivity in the ulcer, and upon intermediate degrees of motor disturbance. The failure of the acid to produce pain will depend upon an absence of sensitivity in the ulcer at the time of the experiment, or upon an absence or minor degree of motor disturbance caused by the acid. Palmer found that the pain was produced without any relation to pylorospasm or other disturbance, but I believe it possible that he has overlooked the minor degrees of localised spasm in which the chief clue to the spasm is the absence of barium in the upper coils of small intestine. In Fig. 9 of his paper is the radiogram of such a case. The appearance suggests that in the distal part of the duodenal cap there is a spasm which has foreshortened the cap by about half its normal length, and has prevented the filling of the jejunal coils. The spasm may last only for a few minutes, but after it has disappeared the ulcer may still remain painful. Palmer found that the pain would sometimes not disappear for 30 or 40 minutes after the stomach was emptied or the acid neutralised.

Palmer's work clearly shows that the sensitivity of the ulcer will largely determine the effect produced by acid, and I believe that the sensitivity of the ulcer depends largely upon alterations in the circulation which are caused either by fluctuations in the inflammatory process or else by ever-changing circulatory phases in the digestive and interdigestive cycles

Conclusions.

In attempting to explain pain in disease of the abdominal viscera Mackenzie has stressed an irritable focus in the spinal cord; Lennander and Morley have dealt with the parietal peritoneum and the mesentery; Hurst and Ryle have suggested functional alterations in the tension of the visceral muscle. The kymographic school have suggested powerful peristalsis; Sippy and Palmer have directed their attention to the acidity of the gastric contents. It is, indeed, remarkable that all possible parts surrounding the disease have been fully considered, while the tissue actually diseased has been comparatively neglected.

All the hypotheses advanced to explain peptic ulcer pain have their shortcomings, and in many instances their supporters point these out and express the belief that there must be some other factor. This factor, the missing piece, in fact the main piece, in the jig-saw puzzle, is the diseased tissue itself. If its importance is recognised, the parts played by other factors will fall easily and naturally into their proper places. The inflammatory reaction and rise in tissue tension in the affected part is the cause of Mackenzie's irritable focus in the spinal cord; pylorospasm and powerful peristalsis, while not usually painful themselves, may cause pain by squeezing inflamed and sensitive tissues and so producing the colicky type of pain occasionally met with in peptic ulcer; excessive acidity cannot of itself cause pain except by increasing the tonic grasp of the gastro-duodenal musculature upon a sensitive ulcer.

The observations recorded in this paper have resulted from the routine investigation of patients in Mr. Devine's clinic, and it is with pleasure that I acknowledge my indebtedness to Mr. Devine. My thanks are due also to the many friends, including Dr. F. L. Apperly and Dr. J. G. Hayden, who "lent me their stomachs" (as Dr. Apperly puts it), for some of the work which was more experimental than clinical.

Summary.

1. A case is reported of purely visceral pain subserved by the vagus nerve, the patient having a complete transverse lesion of the spinal cord in the upper thoracic region.

2. It is pointed out that two components of abdominal pain can be distinguished clinically, that their relative importance differs in different subjects, and that they are probably subserved by different nervous connexions, the truly visceral pain by the vagus, and the referred pain by the sympathetic. This conception may be of help in the operation of neurotomy for gastric pain.

3. Man's upright posture has modified the position of his stomach in relation to its associated somatic segments and to its reflex symptoms. This may have some bearing upon certain types of gastric neuroses.

4. Biological considerations suggest that the tissue reactions against disease are the adequate stimuli for pain. These reactions are inflammatory infiltration and powerful peristalsis. Clinical and experimental data support this conclusion.

5. A radiographic study of the stomach by a special method suggests a modification of the conventional idea of the empty stomach as a narrow tube with its walls kept in firm apposition by muscular tone. A potential gastric space often exists and enables the stomach to accommodate a certain amount of contents, differing in different subjects, before a postural lengthening of muscle fibres is required.

6. Radiographic study confirms the experiments of the physiologists who found that postural tone prevented alterations in the tension of the hollow viscera.

7. Hydrochloric acid caused marked motor disturbance of the stomach, duodenum, and jejunum in the majority of 15 subjects. The significance of (5) (6) and (7) in regard to pain is discussed.

8. The diseased tissue itself as a direct cause of pain has been largely overlooked. A recognition of its importance will clear up many difficulties in explaining abdominal pain.

TREATMENT OF MALARIA WITH DIMEPLASMIN.

By RICHARD GREEN, M.B., B.S.,

ACTING MALARIA RESEARCH OFFICER, INSTITUTE FOR MEDICAL RESEARCH, KUALA LUMPUR, FEDERATED MALAY STATES.

THE new drug named dimeplasmin represents an endeavour by the manufacturers of plasmoquine to produce a further synthetic remedy, of the so-called plasmin group, which would be as effective as plasmoquine for malaria, but would be less toxic. The Havero Trading Co., who are the Calcutta agents for the I.G. Färbenindustrie, requested the Institute for Medical Research, Kuala Lumpur, to investigate the therapeutic value of dimeplasmin in malaria as, although the drug had been found effective in destroying the plasmodia of bird malaria, its value in human cases had not been determined. We were therefore supplied with a quantity of this new drug together with (unpublished) details of preliminary animal and bird experiments made with dimeplasmin by Dr. Roehl and Dr. Eicholtz at Elberfeld.

Dimeplasmin was received in the form of white tablets which had a somewhat bitter taste. The weight of each tablet was approximately 0·4 g., and it was said to consist of dimeplasmin as a base combined with a "high molecular organic acid," so that 0·5 g. of the salt contained 0·2 g. of dimeplasmin base. It is to be noted that this drug is in the experimental stage and is not for sale.

It was found at Elberfeld that dimeplasmin base compared favourably with plasmoquine hydrochloride in its destructive action on the plasmodia of bird malaria. A wide range of dosage was employed, commencing with the quantity just sufficient to destroy the parasites and ending with the largest dose tolerable. With plasmoquine hydrochloride the effective dosage varied between 1 and 33 units. A similarly wide plasmodicidal range of between 1 and 30 units was obtained with dimeplasmin base.

Animal Experiments with Dimeplasmin.

Eicholtz estimated the limits of tolerance of dimeplasmin by giving the drug to animals by various routes. In addition a comparative study of plasmoquine hydrochloride was made at the same time.

He found that dogs could tolerate by mouth up to 200 mg. per kg. body-weight of dimeplasmin base, but that larger doses gave rise to toxic symptoms. Plasmoquine hydrochloride by mouth in doses exceeding 20 mg. per kg. body-weight produced symptoms of poisoning.

Injections of 100 mg. per kg. body-weight of dimeplasmin base given subcutaneously to cats did not produce methæmoglobinæmia, whereas plasmoquine hydrochloride in similarly injected doses of 2 mg. per kg. body-weight did so, and 5 mg. brought about lethal blood changes. Dimeplasmin base given intravenously to cats produced a slight depression of blood pressure, but plasmoquine hydrochloride similarly given definitely lowered the blood pressure and affected the rhythm of the heart.

On these experiments the manufacturers were able to state that: 1. Dimeplasmin has a destructive effect on the plasmodia of bird malaria and in this respect compares favourably with plasmoquine. 2. It is therapeutically active in birds within wide limits. 3. It is less toxic than plasmoquine and does not produce methæmoglobinæmia.

It remained, therefore, to ascertain its dosage and therapeutic effects in human cases of malaria.

Malaria Cases Treated with Dimeplasmin.

The drug was given at Kuala Lumpur to 11 malaria cases. Five of these had subtertian, four had benign tertian, one had quartan malaria, and the other a mixed infection with *Plasmodium vivax* and *P. falciparum*. All these patients were male Tamils; their ages ranged between 18 and 30 with an average of 22·6 years. The lowest body-weight was 81 lb. and the highest 113 lb.; average 95·4 lb. (43 kg.).

The patients were under our observation twice daily when the drug was given, precautions being taken to see that each dose was actually swallowed. Temperature and pulse-rates were recorded four times each day. The urine was examined daily for albumin and for the presence of quinine which might have been given by mistake in hospital, but this precaution was useless, as a white cloud formed when Mayer's reagent was added to the urine of patients taking dimeplasmin, similar to that observed in cases taking quinine.

Thin and thick films from each patient were examined daily for malaria parasites, the number of parasites in all stages per 100 leucocytes in the thick films being recorded from day to day. Spleen measurements, blood pressure readings, and hæmoglobin percentages were estimated every second day.

The makers suggest that a commencing oral dose of 0·4 g. dimeplasmin base per day be given to adults. In a person weighing 100 lb. (45·3 kg.) this would represent 8·8 mg. per kg. body-weight per diem. The agents state that up to ten tablets a day may be given with safety. Our tablets weighed 0·4 g. each, and, as it was specified that 0·5 g. of dimeplasmin contained 0·2 g. of dimeplasmin base, the administration of ten tablets a day to a person weighing 100 lb. would represent a dose of 35·2 mg. of the base per kg. body-weight per diem.

In our series the dosage of dimeplasmin base varied from an initial daily dose of 0·2 mg. to 12·9 mg. per kg. body-weight, rising each day to a final and fixed dose on the fifth day and thereafter of 25·1 to 34·6 mg. per kg. body-weight per diem.

Results of Treatment.

As will be seen from the Tables here given the administration of dimeplasmin in the dose specified did not destroy the parasites or materially affect the course of the malarial symptoms.

James [1] says: "In the great majority of cases of uncomplicated malaria the general course is towards recovery." In estimating the effect of any new drug on cases of malaria an acquaintance with the course of untreated malaria (as fully described by James) would thus appear to be almost essential, otherwise the diminution in the number of parasites and cessation of fever—if these occur as part of a naturally acquired immunity—may be ascribed to the effects of the drug. From the histories given in our series of cases treated with dimeplasmin it was improbable that any of the patients was suffering from his first attack of malaria, and in some cases fever had already been present for 20 days or more. The comparative decrease in the number of parasites in Cases 1, 2, 4, 5, and 7 was of interest, but could not be regarded as due to the effect of dimeplasmin when considered with the above statement, the other findings and the continued persistence of the asexual parasites.

Cr. = crescents.

Spleen measurements were made every second day with the patient in a recumbent position. In Case 2 the edge of the spleen was not palpable during treatment. In Case 1 no appreciable difference was noted. In Cases 3, 4, 6, 8, 9, and 10 the edge of the spleen receded somewhat, and in Cases 1, 5, 7, and 11 the spleen enlarged during treatment.

The *percentage of hæmoglobin* in the blood of each patient was estimated with a Dare hæmoglobinometer every second day and sometimes more frequently. In Cases 1, 7, and 11 there was a fall of about 10 per cent. in the hæmoglobin during dimeplasmin treatment. In the remaining cases no appreciable difference was noted.

Blood Pressure.—Dimeplasmin appeared to have no effect on the systolic or diastolic blood pressure, both of which were estimated at periods varying from ½ to 1½ hours after giving the drug.

Toxic Symptoms.—On the sixth day of treatment Case 8 complained of burning and pricking sensations of the eyes, combined with photophobia and some dimness of vision. These toxic symptoms increased in severity until the ninth day, when the dimeplasmin treatment was stopped. During the next 24 hours these symptoms, presumably due to dimeplasmin, disappeared.

Urinary Reactions.—When Mayer's reagent is added to the urine of patients taking quinine a whitish opalescent cloud forms which, if due to quinine, disappears on heating and reappears on cooling. A similar reaction was observed with the urine of patients taking dimeplasmin. Some difference was established, however, by contrasting the time of appearance and disappearance of this reaction after giving five grains of quinine bihydrochloride and five grains of dimeplasmin base on two separate occasions to a healthy male adult weighing 150 lb. and subsequently testing the urine at frequent intervals with Mayer's reagent.

The excretion of dimeplasmin did not begin until four hours after administration, but it continued for the next 24 hours. On the other hand, after giving quinine a positive reaction was obtained with the urine 40 minutes later. This reached its maximum intensity in the urine passed three and a half hours later, but the last faint traces of quinine had disappeared from the urine within 12 hours from the time of administration.

Summary.

1. Dimeplasmin is said to be effective within wide limits in destroying the plasmodia of bird malaria, but when the drug was given to 11 cases of human malaria in doses well within the therapeutic limits no evidence was obtained to show that it had any effect on the parasites or the malarial symptoms.

Dr. J. P. Fitzpatrick, medical officer to the District Hospital, Kuala Lumpur, has kindly afforded facilities for the trial of this drug in malaria cases. For permission to publish this paper and for his advice I am indebted to Dr. G. V. Allen, Acting Director, Institute for Medical Research, F.M.S.

SANOCRYSIN TREATMENT OF PULMONARY TUBERCULOSIS.*

BY FREDERICK HEAF, M.D. CAMB.,
MEDICAL SUPERINTENDENT, KING EDWARD VII. MEMORIAL SANATORIUM, WARWICK.

THE series which I describe in this paper consists of 97 cases of pulmonary tuberculosis treated with sanocrysin since 1925 at the Warwickshire Sanatorium. Of these 87 were adults and 10 were children. The series includes patients in all stages of the disease except the very advanced, and the majority had failed to respond satisfactorily to routine treatment. The adult cases had positive sputum at the commencement of treatment, and eight of the children showed definite pulmonary lesions by abnormal physical signs and radiographic shadows. The remaining two children were hilum cases with tuberculous cervical glands. In treating adults we have modified the dosage which

TABLE I.—*Sanocrysin Dosage (Adults).*

Injection.	Amount.	Day.	
1st	0·10 g.	—	
2nd	0·25 g.	5th	
3rd	0·35 g.	12th	
4th	0·50 g.	19th	Interval increased or decreased according to patient's weight.
5th	0·60 g.	26th	
6th	0·75 g.	36th	
7th	0·85 g.	50th	
8th	1·00 g.	64th	

Maximum dose tolerated is repeated every two weeks (weight permitting) until the case is arrested.

---

* A paper read at a meeting of the Tuberculosis Association.

I published in 1926 and 1928 by lengthening the interval between each injection (Table I.).

During the fortnightly intervals the patient is kept in bed for a few days immediately after the injection, and then allowed to resume his exercises. One to three tablets of digalin are given immediately after each injection. The length of the interval is now decided by the weight of the patient. During the last year we have suspended treatment in cases when there was loss of weight after sanocrysin. As soon as a patient begins to lose weight we suspend treatment until the decline in the weight curve has stopped, when we recommence with a dose about 0·2 g. less than the last one. A rise of one or two degrees in temperature immediately after the injection is not considered unfavourable, but we try to avoid completely any shock reaction. By this method we obtain a rise in weight and an improvement in general condition throughout treatment. Doses varying from 0·5 g. to 1·0 g., according to the gain in weight, are continued if possible until the sputum is negative and symptoms have disappeared. This may mean a long period. By our "non-shock" methods I think we have been as successful as other observers in obtaining elimination of tubercle bacilli from the sputum, rapid clearing in the X ray picture, and decrease in the physical signs in a good percentage of cases. From recent literature it seems that the majority of cases respond well to treatment, particularly with respect to the above three points, to which I ought to add one which has been noted constantly in our work—the decrease in the sedimentation-rate of the red blood corpuscles. This, unfortunately, is only permanent in a few cases.

TABLE II.—*Immediate Results of Sanocrysin Treatment.*

Stage.	No. of cases.	T.B. (—).	Clinically arrested.	Improved.	Worse.	Died.
I. (T.G.) ..	9	8	8	1	—	—

Sanocrysin and A.P. combined treatment (all stages) ..	15	7	7	5	2	1

A.P. = artificial pneumothorax.

There seems to be good evidence from the figures in Table II. that the drug has a distinct value in bilateral cases in turning the balance from a bad to a favourable result when used in conjunction with collapse therapy.

There may be some difference of opinion as to which cases are suitable, but we have found that, provided the renal and cardiac systems are normal, you can treat cases in any stages of the Turban-Gerhardt classification regardless of fibrosis, and obtain temporary improvement, if the physique and general condition is good and there is an absence of symptoms of abdominal tuberculosis. In Stage III., however, there is practically no permanent improvement. For this reason I think it a waste of good money to treat Stage III. cases with sanocrysin.

It is very difficult to determine the permanency of the good immediate result of sanocrysin, as each case returns to such different home conditions that comparisons are almost impossible.

Table III. gives the remote results according to the stage of the case. Although the Stage I. cases continue to keep fit many of the Stage II. cases have relapsed, and all except three of the Stage III. cases have died within two and a half years of leaving the sanatorium. Comparison of these figures with the after-histories of patients on routine treatment shows that no advantage has been gained by treatment with sanocrysin except in cases which were clinically arrested on discharge from the sanatorium—i.e., in whom symptoms had disappeared and tubercle bacilli were not found after five sputum examinations. It appears that unless the patient attains this desirable condition he will derive little or no permanent benefit from sanocrysin.

Sanocrysin Compared with Artificial Pneumothorax.

In order to see how sanocrysin results compared with those of artificial pneumothorax, I took the first 51 cases which had had the latter treatment at the sanatorium. I excluded cases in which the collapse treatment was given to stop an hæmoptysis or cases in which treatment had to be abandoned owing to adhesions, and "last-resort" cases. Curiously enough, I found I had nine Stage I. and 42 Stage II. cases amongst the 51. From this I think it fair to assume that the cases were comparable with the 51 sanocrysin cases under examination. Table IV. shows that the immediate and remote results obtained from the artificial pneumothorax treatment are considerably superior to those from sanocrysin.

The Treatment of Children.

Four of the ten children treated had positive sputum, four had definite physical signs accompanied by abnormal radiographic shadows in the lungs, and two were hilum cases. In two cases only could the diagnosis be disputed and both these had definite tuberculous glands of the neck. All the children had had long periods of routine treatment, and for some weeks had made no progress or gain in weight, and therefore could be considered at a standstill when sanocrysin treatment was commenced.

The dosage we employ for children is shown in Table V.

TABLE V.—*Dosage of Sanocrysin for Children.*

Injection.	Amount in grammes.	Day.	Injection.	Amount in grammes.	Day.
1st	0·05	—	5th	0·25	40th
2nd	0·10	10th	6th	0·30	54th
3rd	0·15	20th	7th	0·40	68th
4th	0·20	30th	8th	0·50	82nd

Maximum dose tolerated is repeated at fortnightly intervals (weight permitting).

With these doses the patients have been entirely free from any undesirable symptoms during treatment, and, what is more remarkable, every case has shown a good increase in weight throughout the time when the injections were being given. The child seems to tolerate very large doses without any ill-effects; most of the children between 5 and 8 have received 0·5 g. and have still maintained and increased their weight. The children are kept in bed for four to six days after each injection and then allowed to go to school as usual. In every child to whom prolonged treatment has been given we have noted increased appetite, decrease of symptoms, and improved general condition. No cases with abdominal symptoms have been treated.

TABLE VI.—*Results of Sanocrysin Treatment in Children.*

10	14	+ve	,,	8·0	27	24	9/16	24/45	(—)ve

Conclusions.

(1) Providing the case has fairly good physique and no abdominal tuberculosis and that other vital organs are normal it is reasonable to assume that the immediate results with sanocrysin will be good and that the patient will benefit by the treatment.

(2) It is particularly useful in bilateral cases treated by collapse therapy, and the patient need not develop shock symptoms or a febrile reaction in order to obtain full benefit from the treatment.

(3) By suitable dosage all shock and unfavourable symptoms can be avoided, and the patient's weight should increase throughout treatment, although large doses are given.

(4) The remote results are only encouraging in those cases which lose their tubercle bacilli and become clinically arrested after treatment.

(5) Sanocrysin is well tolerated by children, and most encouraging immediate results have been obtained in children suffering from pulmonary tuberculosis who did not respond to routine treatment.

Clinical and Laboratory Notes.

SOME PHARMACOLOGICAL ACTIONS OF BANISTERINE (HARMINE).

BY J. A. GUNN, M.D., D.SC. EDIN.,
PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF OXFORD.

IN a recent note in THE LANCET (April 13th, p. 769) I drew attention to published observations which tend to support, from the pharmacological viewpoint, the chemical and other evidence of the identity of the alkaloids banisterine and harmine. No complete comparison of the pharmacological actions of the two alkaloids was possible, largely from want of knowledge of some of the effects of banisterine; and suggestions were made as to some crucial experiments which might be made by anyone who possessed banisterine to make this comparison sufficiently complete. Upon the publication of this note E. Merck generously and voluntarily sent me not only a small supply of banisterine hydrochloride to enable me to perform the necessary experiments, but also an advance proof of articles to appear in next "Jahresbericht," dealing with the chemistry and pharmacology of the alkaloids in question.

In this paper I wish to record briefly the results of some experiments with banisterine. As the identity of the alkaloids has been recently confirmed by microcrystallographic methods as well as in other ways, it seems hardly necessary to enter into the pharmacological resemblances in great detail, and the few experiments I wish to record are intended not only to emphasise the identity of pharmacological actions, but also to clear up some disputed points in regard to these actions themselves.

Action on Uterine Muscle and Spleen.

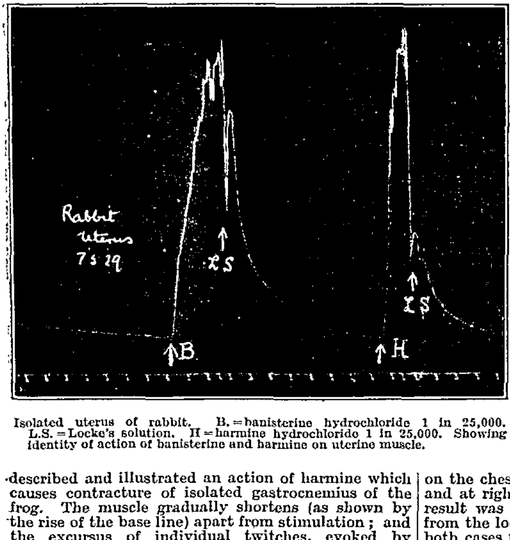
In my original papers (references are given in the previous article) I described and illustrated the action of harmine and harmaline on the uterus, and ascribed it to a stimulant action on uterine muscle, similar to that produced by quinine. In the proof of the Jahresbericht which I have received, Kreitmair states that, from the occurrence of menorrhagia following the clinical use of harmine, attention was drawn to its action on the uterus. It was found, in rabbits, that neither harmine nor harmaline had any stimulant action on the isolated uterus but caused contraction of this organ in the intact anæsthetised animal, when the alkaloids were injected intravenously. The conclusion was drawn that harmine and harmaline have no peripheral action on the uterus but that the contractions are induced by central stimulation.

Apart from the inherent improbability of any such action (for the uterus seems to be singularly uninfluenced by central stimulation), the assumption is based upon experimental error, because both alkaloids have a powerful action on the isolated rabbit's uterus. In my experience it is an action that is unfailingly exhibited on the exsected parous rabbit's uterus with concentrations of from 1 in 5000 to 1 in 50,000. Fig. 1 shows the effects of banisterine and harmine on the isolated uterus of a rabbit which had been recently pregnant and was in active lactation. At the arrow marked B, banisterine hydrochloride was added to the Locke's solution in the bath containing the uterus, in an amount to make the concentration 1 in 25,000. This caused a contraction of about 6 cm.'s height on the tracing. After about two minutes the banisterine solution was run off from the bath and replaced by Locke's solution, whereupon the uterus rapidly relaxed and in four minutes had reached its normal level of tone. Harmine hydrochloride was then added to the bath in an amount to make the concentration 1 in 25,000. This evoked a contraction of the uterus as nearly as possible identical in height with that which had previously been produced by the same concentration of banisterine. In a similar experiment on another segment of the same uterus, 1 in 50,000 of each alkaloid produced a contraction giving rise to an excursion of 4 cm. on the tracing. It is clear from these experiments: (1) that both alkaloids produce similar effects, quantitative and qualitative, on the uterus; and (2) that the action in both cases is a peripheral one on the uterine muscle. The identity of action of the two alkaloids was also confirmed by their effects on the spleen. Both produced similar relaxation of the isolated rabbit's spleen in concentrations of 1 in 10,000.

Action on Voluntary Muscle.

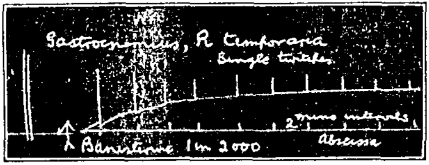
A third action which seemed useful for this comparison is that on voluntary muscle. I have described and illustrated an action of harmine which causes contracture of isolated gastrocnemius of the frog. The muscle gradually shortens (as shown by the rise of the base line) apart from stimulation; and the excursus of individual twitches, evoked by electric stimulation, diminishes. This leads to "paralysis" of the muscle in the contracted position. This effect is produced in a few minutes by concentrations of 1 in 1000 or greater, and more slowly by concentrations down to 1 in 5000. Fig. 2 shows exactly the same effect produced by banisterine 1 in 2000. The muscle was immersed in Ringer's solution and could be stimulated electrically when desired. Two normal twitches are shown as lines on the slowly revolving drum. At the arrow-mark, Ringer's solution was replaced by banisterine hydrochloride, 1 in 2000 dissolved in Ringer's solution. Almost immediately the muscle began to shorten and the height of induced contractions to diminish. The same strength of stimulus was used throughout. The effect of banisterine is identical with what I have previously described with harmine.

FIG. 1.



Isolated uterus of rabbit. B. = banisterine hydrochloride 1 in 25,000. L.S. = Locke's solution. H = harmine hydrochloride 1 in 25,000. Showing identity of action of banisterine and harmine on uterine muscle.

FIG. 2.



Isolated gastrocnemius of frog. Showing gradual shortening of the muscle and diminution of induced contractions produced by banisterine hydrochloride, 1 in 2000. The same effect is produced by harmine.

In my previous note I pointed out that, if Lewin's observations were correct, there seemed to be some difference between the actions of harmine and banisterine on the central nervous system of the frog, but suggested that possibly Lewin had confused a local contracture of the back muscles with a strychnine-like *opisthotonus*. Experiments with banisterine have confirmed this suggestion. Harmaline does, as I have shown, produce a slight and transient increase of excitability of the spinal reflexes in the frog, and this may also occur with harmine. The chief effect, however, is one of paralysis of spinal reflexes, and there is nothing at all comparable to strychnine convulsions. The opisthotonic posture which Lewin described as occurring with banisterine and as persisting after death is due, as I anticipated, to the contracture of the muscles of the back resulting from local action of the injected solution, which must be at least more concentrated than 1 in 1000 to get the required dose into a convenient bulk for injection. However, that the posture assumed is due to this and not to any central action was easily proved by the following experiment. Two frogs, *R. temporaria*, each weighing 10 g., were given a dose of 0·005 g. dissolved in 1 c.cm. Ringer's solution. This represented 0·5 g. per kg. and the concentration of the injected solution was 1 in 200. In the one frog the injection was made into the dorsal lymph sac, in the other into the ventral lymph sac. In the former opisthotonic curvature of the back was produced, whereas in the latter the head was flexed on the chest and the arms were held rigidly in front and at right angles to the body. In both cases the result was due to rigidity of the muscles resulting from the local action of the injected solution, and in both cases the peculiar posture was maintained after death. The opisthotonus is clearly, therefore, not due to any action of banisterine on central nervous system; and the posture assumed, depending as it does upon local contracture of the muscles, varies with the site of injection. The same result was obtained with harmine.

Identity of Banisterine and Harmine.

The pharmacological, like the chemical, evidence for the identity of banisterine and harmine is, therefore, now sufficiently complete. This has been shown in regard to lethality, symptomatology, and to effects on isolated tissues such as the uterus, spleen, and voluntary muscle. This identity is of practical importance in two directions. In the first place, as has been elsewhere emphasised, harmine is at the present time more easily obtainable than banisterine, so that it can be more easily procured for clinical use, should uses for it be established. In the second place, owing to the chemical researches of Perkin, Robinson, and others, an accurate knowledge is to hand even of the structural composition of the harmala alkaloids and of many of their derivatives, some of which may prove of greater therapeutic value than harmine itself. I have, in the past year, for example, made estimations of the actions on the uterus of the three alkaloids and of quinine in relation to their general toxicity, with a view to discovering whether any one of the former might be more effective as an ecbolic than quinine. The final decision on this and other points must, however, rest upon clinical evidence which is not yet available.

I wish to express my grateful thanks to the firm of Merck for their kindness in giving me the supply of banisterine which made these experiments possible.

TREATMENT OF TUBERCULOSIS BY "BENZYL CINNAMIC ESTER"

(THE METHOD OF JACOBSON).

ITS USE IN LARYNGEAL TUBERCULOSIS.

BY H. GAINSBOROUGH, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL
AND
P. J. JORY, F.R.C.S. ENG.,
SURGEON TO EAR, NOSE, AND THROAT DEPARTMENT, ST. GEORGE'S HOSPITAL; LARYNGOLOGIST TO MOUNT VERNON HOSPITAL.

IN a previous note one of us[1] gave an account of investigations on the treatment of tuberculosis by Jacobson's solution of "benzyl cinnamic ester," together with a record of cases treated in this country. The results, particularly in certain groups of cases, have been promising, and it was thought worth while to continue the investigations on cases which could be controlled, if possible, by visual examination. With this idea in view we treated cases of laryngeal tuberculosis, a condition in which the progress of the disease could be observed accurately and the functional results could be estimated. Dufourmentel and Sebileau[2] in 1924 published an account of tuberculous laryngitis treated by this method, describing two cases in detail. They stated that they obtained encouraging results in most of their cases, especially in the relief of hoarseness, pain, and dysphagia, and they noted regressive changes in the local condition. Caboche[3] reported to the Congrès d'Oto-Rhino-Laryngologie in 1927 both functional and anatomical improvement and also improvement in the patient's general condition.

We selected cases in which the condition appeared to be either stationary or definitely getting worse, while they were under observation at the sanatorium, so that we dealt with a group of cases in which the general prognosis was very poor. The method of treatment was that described in the previous paper (1928) and consisted of a series of daily intramuscular injections of 0·25 c.cm. of Jacobson's solution for 12 days, followed by a rest of 15 days. After three series had been given, a rest of one month was allowed before resuming treatment. Unfortunately, owing to the closing of the sanatorium, we were unable to continue the treatment of these cases for more than three months, but we feel, nevertheless, that the results are sufficiently definite and encouraging. In no case did any unpleasant reaction occur.

Case Reports.

CASE 1.—Male, aged 43, had had hoarseness for three years, and showed ulceration of the left cord, injection of the right cord, and marked arytenoid swelling, worse on the left side. He had active fibro-caseous tuberculosis throughout both lungs, but was afebrile. The laryngeal condition was stationary. After three months' treatment there was marked improvement in his voice and general condition. The arytenoid swelling diminished and the movement of the cords improved. Five months after cessation of treatment he was back at work as a carpenter and the voice was stronger.

CASE 2.—Male, aged 29, had had hoarseness for about four months and had been in the sanatorium for three months. The larynx showed ulceration of the left cord, which was immobile, and swelling of the left arytenoid. The condition was stationary. The upper two-thirds of both lungs showed advanced disease. The evening temperature went up to 99·8° F. By the end of the first series of injections he had become afebrile and expectoration had ceased. Locally the arytenoid swelling had diminished and the cord movement had improved. Pain had also diminished. Throughout the period of treatment the improvement continued, the pain in the throat disappeared, and the laryngeal condition became inactive in appearance.

CASE 3.—Female, aged 44, had a six years' history of "laryngitis." The larynx showed ulceration of the right cord and swelling of both arytenoids. Besides hoarseness, there was some dysphagia and pain in the throat, shooting up to the ear. The laryngeal condition had been getting worse during five weeks' previous observation in the sanatorium. The general condition was very poor indeed, and there was extensive disease of the lungs, with much cavitation on the right side. Dysphagia disappeared and pain diminished during the first series of injections, and very considerable improvement occurred in the general condition; expectoration diminished and the voice became much stronger. Locally there was diminution of ulceration of the cord, almost to healing, and the arytenoid swelling had decreased.

CASE 4.—Female aged 16. The history was suggestive of phthisis during the past two years. Hoarseness began while in the sanatorium; at first there was only œdema of the arytenoids, but later there was ulceration on the anterior surface of the right arytenoid and the swelling of both cartilages increased. There was no pain or dysphagia and very little sputum. The pulmonary disease was extensive and bilateral. At the end of three months' treatment the hoarseness had much improved. There was at first diminution of the arytenoid swelling—the anterior surface of the right arytenoid became smoother—but there was some return of swelling about three weeks after the last series of injections. The patient became afebrile and expectoration practically ceased.

CASE 5.—Female, aged 20, gave a history of hoarseness for a few weeks only. There was swelling of both arytenoids with slight ulceration and injection of the cords, and some discomfort in the throat. The upper half of the right lung was diseased, with considerable pleural thickening. Between the first and second series of injections there was a severe attack of acute tonsillitis, followed by a rapid consolidation of the lower lobe of the right lung and accompanied by considerable pyrexia. By the end of the third series of injections the patient was afebrile, the discomfort in the throat had gone, the laryngeal condition showed improvement, cord movement was better, the arytenoid swelling had diminished slightly, and no ulceration could be seen.

CASE 6.—Female, aged 23, gave a history of phthisis for three years, but laryngitis was first noted while in the sanatorium and during three months' observation was gradually getting worse. At first there was only arytenoid swelling and injection of the left cord, but later the posterior part of the left cord and the arytenoid became ulcerated. There was a good deal of pain in the throat and some dysphagia. There was extensive disease in both lungs, and the temperature was unstable. During the treatment the pain and dysphagia vanished; at the end of three months there was less swelling of the arytenoid but the improvement was not very marked.

CASE 7.—Male, aged 41, had had hoarseness for five years and had been aphonic for a few weeks. He had had tuberculosis of the right hip since the age of 3. There was a discharging sinus in the groin, and the head of the femur was completely destroyed. There was tuberculous disease throughout both lungs. The larynx showed an infantile epiglottis; at first there was only swelling of the arytenoids, but this increased and the arytenoids and cords became ulcerated. He was practically afebrile. After two series of injections there was some decrease of arytenoid swelling and some recovery of voice, but during the third series he *became worse, the laryngeal œdema increased until tracheotomy* was required, a large abscess developed in the right thigh, and the patient died of lobar pneumonia.

Conclusions.

Improvement of the laryngeal condition, in varying degree, was observed in all the cases, but in Case 6 the favourable change was slight and in Case 7 improvement was not maintained. The functional results corresponded, but the most striking feature was the disappearance of pain and dysphagia during the treatment. Remembering the severity of the cases and their previous failure to improve, our results suggest that such benefits as were obtained were the result of the treatment. All cases remained with sputum positive at the end of the treatment. Improvement in the patient's general condition was noteworthy in the first four cases. It is not proposed to discuss the lung changes in detail, but progressive changes in radiographic appearances were noticeable as a result of the three months' treatment in all the cases except 4 and 7. The changes were increased hardening of the shadows and in Cases 2 and 3 some increase of translucency of the lungs.

In conclusion we have to thank the Honorary Physicians of the Mount Vernon Hospital for permission to use their cases, and also Dr. W. G. Kinton for his continual help and courtesy.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF EPIDEMIOLOGY.

AT a meeting of this Section on May 24th, Dr. S. MONCKTON COPEMAN, F.R.S., Vice-President, being in the chair, Dr. A. JOE read a paper on

PUERPERAL FEVER AND PYREXIAS.

He said that between the date on which the new regulations came into force (Oct. 1st, 1926) and Sept. 30th, 1928, 219 cases of puerperal fever and pyrexia had passed through the North-Western Fever Hospital. These cases he had classified, adopting the plan of Mr. James Wyatt in the Metropolitan Asylums Board Report. This was as follows: (1) local uterine infections; (2) pelvic or general peritonitis; (3) pelvic cellulitis; (4) general infections of the blood stream. For the purpose of the present survey he had added two more classes: (5) infections of the urinary tract; (6) a miscellaneous group, comprising mental disturbance, constipation, breast troubles, and various conditions which had appeared to be accidental to the puerperal state.

The 219 cases seen in the period named were ranged as follows: Group 1, 71 cases; Group 2, 47; Group 3, 11; Group 4, 20; Group 5, 12; Group 6, 58. Of the 47 cases in the second group, 23 had pelvic and 24 general peritonitis. Of the 20 blood infections, 12 had septicæmia, 8 pyæmia; three cases of septicæmia and one of pyæmia had general peritonitis in addition. The urinary infection cases were practically all due to *B. coli*. The deaths due to peritonitis constituted 36·1 per cent. of the total mortality; they were due to general peritonitis. Dr. Joe said he was surprised at the smallness of the figure for pelvic cellulitis; it might be a remote effect. One death occurred among the 11 cases and this death was due either to acute lobar pneumonia or to general tuberculosis. Death occurred in 10 out of 12 general septicæmic cases. Among the 149 cases in Groups 1 to 4, 32 were fatal, giving a percentage mortality of 21·4.

Details of Cases.

To give an idea of the circumstances attending the fatal cases, Dr. Joe related particulars of a number of them. Of the 32 puerperal deaths, 7 were the result of septic conditions supervening on abortion. In one a coroner's jury found a verdict of wilful murder, while two others were adjudged to have resulted from improper interference. Apart from the abortion cases, 11 of the remaining 25 were primiparæ, 3 were multiparæ; and one died before she could be questioned. Among the primiparæ, ten had instrumental delivery, six had lacerations of the birth canal, one had a slight tear. In the multiparæ nine had normal labour, four instrumental. In 11 cases no vaginal examination was made before the confinement; 50 women in all had sustained damage to the birth canal. Dr. Joe contended that in order to form some rational basis of prevention of puerperal fever it would be necessary to make a careful study of such details as he had investigated. It was disturbing to find, in a considerable series of cases, that 20 per cent. of the maternal deaths had supervened upon abortion, a fraction of them having been due to illegal interference. This proportion would probably have been found to be still higher if all the patients could have been cross-examined. 34·4 per cent. of the total number of deaths occurred in primiparæ; the factor of trauma seemed to bulk largely in these deaths. Still, it was impossible to overlook the experience of the group of multiparæ; in both the fatal and the recovered cases, the multiparæ outnumbered the primiparæ, and in the majority of the former cases the labour was apparently free from any such trauma as gross laceration. Thus, even if, by the exercise of complete obstetrical precautions, avoidable trauma could be eliminated in primiparæ, they would still be exposed to the same order of risks as were multiparæ. Cases of pyelitis, he held, were responsible for a certain proportion of the mortality. The miscellaneous class constituted 20·4 per cent. of the total, and they were cases which, but for the operation of the new regulations, would probably have escaped notification. The cases in the intercurrent disease group showed a liability to incur *bronchial complications.*

The Dick Test.

The question of the causal organism was one of very great importance. Every worker on the subject had held that the chief organism responsible for these cases was a hæmolytic streptococcus. The weight of evidence was against the likelihood that a specific strain was concerned. The normal habitat of this organism seemed to be the nasopharynx of people subject to catarrh. The source of infection could be narrowed down to the nasopharynx of the patient herself and those of her contacts during labour. There had been coincident outbreaks of scarlet fever and puerperal fever in maternity homes. The organism in the puerperal cases might be confined to the uterine lymphatics. If the main reservoir of the hæmolytic streptococcus was the nasopharynx, droplet infection was a mode of transmission over which only partial control could be expected. Mr. H. Burt-White had recently published a paper which indicated that there might exist a connexion between sensitivity to the hæmolytic streptococcus and the incidence of streptococcal infections in the puerperium. At the time that paper appeared a number of Dick tests had been carried out in the wards of the North-Western Fever Hospital. These had now been extended, and the results were available. Cases were tested on admission by the intercutaneous administration of 1 in 200 and 1 in 1000 dilutions of Dick toxin. Controls were done by a similar injection of inactivated toxin. They were practically consecutive cases, only a few being discarded because they had received large doses of antistreptococcus vaccine before arrival. 23 per cent. were found to be positive, 77 per cent. negative to a dilution of 1 in 1000. The figures obtained from 103 cases tested did not support the sensitivity suggestion. Among 77 adults in the general population of ages ranging from 20 to 40 years, 22 per cent. were Dick positive.

From the 103 cases to which the Dick test had been applied Dr. Joe took 22 practically consecutive ones and isolated the hæmolytic streptococcus from them: it was obtained from the cervix in the local uterine infections, and in the cases of pelvic peritonitis, from the exudate of general peritonitis cases and from the abscesses in pyæmic cases. Among 12 local uterine infections 4 patients were Dick positive, among 4 patients with pelvic peritonitis 2 were Dick positive, and of 2 patients with general peritonitis 1 was Dick positive. Three patients with septicæmia and one with pyæmia were all Dick negative. Thus it would seem that the invasion by the hæmolytic streptococcus was not restricted to the Dick positive cases. Experience in regard to the use of antistreptococcal sera for streptococcal lesions generally prepared one for the failure of this method in the kind of cases under review.

Discussion.

The CHAIRMAN said that this question of maternal morbidity was of the very greatest importance; it was rather a blot on our boasted improvements in the field of preventive medicine that so little improvement in the figures had been secured over a considerable period of years. It was desirable that by the most intensive investigations all information possible on the various factors concerned should be gleaned and classified. The work of Dr. Joe and his colleagues at the North-Western Fever Hospital had certainly done much in this direction. A very large amount of work, from the bacteriological and epidemiological points of view, had been carried out at the Pathological Department of the Ministry of Health, and in the various laboratories associated with that work. The exact place in causation occupied by the hæmolytic streptococcus must be cleared up if advance was to be made in the prevention and cure of this important disease. As to treatment, to his knowledge the use of turpentine, internally as a medicine and externally as stupes, or as enemata for puerperal fever, had been tried with considerable success in a small number of cases, and he wondered whether, in default of anything better, it would be worth while testing this treatment in an institution where the results could be definitely controlled.

Dr. F. F. CAIGER said that little benefit to the human race seemed to have resulted from the amount of work which had been done, clinically and in laboratories, in connexion with puerperal sepsis. Forty years ago, when as resident accoucheur at St. Thomas's he had 600 confinement cases, he had lost only one patient. In Switzerland the main attention seemed to be devoted to guarding against thrombosis; and even in the cases which appeared to call for some treatment, gymnastics was largely enjoined. For practical improvement in the results in puerperal fever he considered that one must look to the laboratory.

Dr. L. COLEBROOK congratulated Dr. Joe on the results of his Dick tests, which were similar to those obtained in other parts of the country. The idea must now be abandoned, he thought, that the Dick test could be regarded in the same light as the Schick test in diphtheria. There seemed to be no connexion between the Dick sensitiveness and the liability to infection by the hæmolytic streptococcus. He thought with Dr. Joe, that probably the toxæmia was not the most important side of puerperal fever. Attention must be focused primarily on the bacterial invasion.

Dr. PHYLLIS DIXON asked whether Dr. Joe had to work upon a select group of particularly severe cases. She had found *Streptococcus pyogenes* in infected cases, and considered that many other infections than those due to streptococci were definitely morbid.

Dr. J. A. BRINCKER asked whether attempts had been made, in the cases under review, to ascertain what particular type of streptococcus was present. Did the cases which were Dick negative profit by the use of antistreptococcus serum?

Dr. HAROLD BUTLER said it had been made clear that the responsible organism was the hæmolytic streptococcus, which started in the nasopharynx and wandered about the body. He had once suggested that infection of the vagina might have sprung from the anus, but had been informed that fæces did not normally contain these organisms. Dr. A. F. Hurst, however, had shown that some 4 per cent. of all people went through life with a lack of acid secretion in the stomach. Those people could not sterilise the food in their stomach; therefore, he argued, if women with this achlorhydria had in the fauces, and swallowed, the hæmolytic streptococcus, it would appear in a virulent form in the fæces and could easily infect the adjacent vagina. Dr. Hurst had shown that in these people the organisms usually found in the large bowel travelled upwards and were found in the stomach. Many subjects of even virulent puerperal fever had suffered no traumatism, and such factors as he had mentioned might well have a bearing.

Reply.

Dr. JOE, in reply, said treatment scarcely came into his province, but after seeing a large number of cases his conclusion was that in cases which seemed liable to die, nothing so far tried seemed successful in averting that end. In some, laparotomy and drainage of the peritoneal cavity saved life; in a few, antistreptococcus serum appeared to give a good result. He agreed that everything possible should be tried, whether it seemed to have a rational basis or not. The cases he had seen were not selected in any way. He agreed with Dr. Butler that the transfer of organisms from the anus to the vagina was a possibility. Though the hæmolytic streptococcus was not a normal denizen of the colon, it might easily be so in subjects of achlorhydria.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

THE MAUDSLEY LECTURE.

ON May 22nd the Maudsley Lecture was delivered by Prof. C. SPEARMAN, F.R.S., in the Botanical Theatre of University College, London, the chair being occupied by Prof. J. SHAW BOLTON (Macclesfield), the President. The subject of the lecture was the

Psychiatric Use of the Methods and Results of Experimental Psychology,

and Prof. Spearman began by confessing that psychology was passing through a crisis. Half a dozen theories had, he said, been advanced, for each of which the name the "new" psychology was claimed. The authors of these systems regarded them as superseding the older views. Yet the great majority of psychologists held to the experimental method, and continued the spade work by which they were accumulating material to which any theory must in the long run conform. The theories, old and new, were not so antagonistic as many contended. Each represented some partial truth, its weakness consisting in what it overlooked and denied. Much of what in latter days was set forth as revolutionary was in reality very old material to which new nomenclature had been attached. What was needed was a more intimate collaboration between psychiatry and psychology.

On the relationship between mind and body he took up a definite attitude. Some averred that the body alone was worthy of serious scientific consideration, that it alone had causal significance, the mind being no more than an epiphenomenon. Others declared that the body was but one of the dreams which the mind had created for itself. His own view was that the mind and the body must each be studied first in and for itself, and then the relationship of each to the other. To-day, he would confine himself to terms of mind. Psychology, like all genuine science, must be based on principles, not on a mere observation of details. These principles were partly ultimate concepts, partly ultimate laws. The primary purpose of concepts was to array the material into perspicuous classes. The laws linked these concepts together. One conceptual achievement, over two thousand years old, was the division of mental processes into three classes: (1) cognition (or knowing); (2) affection (or feeling); (3) conation (or striving). The connexion between the last two was so intimate that it was difficult to keep them distinct; but failure to recognise the line of demarcation between cognition and the other two had been answerable for many grave aberrations. The doctrine of sensationism he dismissed as inadequate for psychiatric purposes. Still, within a limited field—that in which a patient had himself noticed something abnormal, or some ground existed for suspecting some sensory disturbance—sensations could play an important part in psychopathology.

Passing beyond the region of sensation, what, asked the lecturer, remained? The answer throughout the ages had taken the form of postulating "formal faculties." The most widely adopted of these were "apperception," "attention," "memory," "imagination"; together with some such supreme ruler as the "intellect," or "intelligence," or "reason." There was a variety of meanings attached by different people to each of these terms. To be acceptable, these "faculties" should indicate not merely a class, but a functional unity, so that wide-ranging generalities could be predicted of it. A person may be adjudged to be suffering from deficient power to concentrate his attention. A very large foreign railway company required every prospective employee to submit himself to a test which consisted of making the subject look over a list of figures (numbers), then look at a smaller list at the back of the paper, and tick off those occurring in both lists. If the man left many of the proper numbers unticked, he was considered to have a deficient power of concentration. The fallacy of such a conclusion, however, was that he might be capable of deep and prolonged attention to matters more to his liking. This might perhaps be true of the other supposed faculties also. Psychologists had accordingly changed their line of attack; they were now trying to find which, if any, of the faculties functioned in a unitary manner, rather than increasing the number of the faculties. This search for faculties which functioned in a unitary way had been richly rewarded; and it had shown, too, that many supposed faculties had no real foundation. In rare and valuable cases genuine faculties had been discovered—i.e., those in regard to which measurements made with one kind of material gave measureable evidence with regard to further kinds. He asked that these genuine faculties should now be tried out on differences of a pathological order.

Measurements of General and Special Ability (*G. and S.*)

In the sphere of "intelligence" light was afforded by way of mathematics. After groups of persons had been submitted to tests of ability in various mental operations, it was sought to ascertain how far the ability for any one of these operations tended to go with corresponding ability for the others. To estimate such correspondence there was available the great mathematical device of Galton, known as the "coefficient of correlation." This showed not only that the correlations had positive values, but that these values tended to fall into that peculiar arrangement which had received the name "hierarchy." There followed the further mathematical discovery that only when such a hierarchy occurred, each measurement for each ability of each individual could be divided into two factors, one being constant for all the abilities at issue, though largely varying as between one person and another. The other factor varied, not only from individual to individual, but also—at random—from one ability to another. These two factors had been designated, respectively, G (general ability) and S (special ability). G was a genuine faculty—i.e., one possessing functional unity. Dr. B. Hart had shown that G was just the factor which was predominantly influential in the pathological state known as amentia or dementia. Prof. Spearman pointed out, however, as a warning, that the ability to measure a person's G did not necessarily mean that the true nature of what was being measured was known. Evidently, then, the nature of the G was still the centre of a good deal of controversy. The first great advance in this matter of the psychology of individual differences was due to a very recent advance which had been made in general psychology. It had traced back the original genesis of all items of mental content to its source, and it had received the name "noegenesis." These noegenetic processes seemed to fall wholly and exhaustively into three sharply divided classes. The first could be formulated by saying that a person had, more or less, power to observe what went on in his own mind: he not only felt, he knew that he felt; he not only strove, but he was aware of the striving. The second of the processes was that when a person had in his mind two or more ideas he was able to bring to mind relations between them. In the third kind of process, when a person had in mind any idea together with a relation, he had, more or less, power to bring into mind the correlative idea. Prof. C. L. Burt had, he said, made a brilliant invention, the test of "analogies." For example:

Behind is to In front as Past is to ?
Black is to White as Clumsy is to ?

Here the "Black" and the "White" had to create in the person's mind the idea of oppositeness; and then this idea together with that of "Clumsy" had to evoke the correlative idea of "Skilful."

These three elementary processes entered into the structure of the mind much as certain types of cells made up the growing parts of the physical organism. There remained the thorny question as to how the G, which was a constant factor in all these noegenetic processes, could be conceived in physiological terms. To him, the most plausible suggestion so far was that it corresponded to some general psychophysical "energy" of the cortex, or some part of it, such energy being capable of being switched from one region to another. Many physiologists said they could not discover such energy, but their search had been in the periphery of the nervous system, where, indeed, the mental results showed it was not present. Those physiologists who dealt with the nervous system as a whole held a different view, for example Sherrington, who, writing in 1902, said: "One of the most helpful of the assumptions we can use in dealing with the problems of the nervous system is that which regards it as more or less a reservoir of energy." At present, however, this was no more than a working hypothesis. The G itself, however, together with its noegenetic character, seemed to be as firmly established as almost anything in science. The current methods of measuring it needed to be a good deal modified for psychiatrical purposes. The intelligence test of Binet, for instance, would be of but little service. One defect of this and similar tests was the dependence of the result not purely upon noegenetic power, but largely on previous education. A further defect was that it could not be used more than once. Psychiatric usage required that one should be able to measure the G repeatedly, as, for instance, in following up the state of a patient throughout some treatment.

The S's were the specific factors in ability: those which explained why and how far one person was better at doing one thing, and another person was better at doing another. Investigation of some of these S's had supplied Sir Henry Head with the foundation of his great work on aphasia. The physiological interpretation of these S's harmonised with and was demanded by what had been found for G, as no energy could exist without engines within which to work. If the cerebral cortex possessed a general energy, then the different parts of the cortical structure must supply the different engines. This was just what was required to explain the S's.

Perseveration.

The basis of this faculty, denoted by the letter P, lay in the familiar fact that mental effects tended to outlive their original causes. These left behind some residual excitement; after hearing a melody one might be haunted by it; when changing from one form of work, one might not be able for some time to dismiss the first subject from the mind. Had this any functional unity—i.e., was the person suffering most from haunting melodies likely to be he who experienced the greatest inertia in passing from one form of work to another? Did this residual excitement tend to go hand in hand with persistence of purpose? In general, the new experimental methods replied in the affirmative—i.e., that there did exist a functional unity, though not over persistence of purpose. One of the students at the College, Mr. Stephenson, had shown recently that an increase of perseveration was the most striking effect of imbibing alcohol; another student, Mr. Pinard, had found that the degree of perseveration in a child was a fundamental factor in rendering him "difficult" to handle. Thus, P was likely to be one of the chief diagnostic instruments in child clinics. It was necessary to remember, however, that part of what was usually attributed to perseveration consisted of an inhibited flow of ideas, a loss of "fluency." In manic and melancholic states these two seemed to be affected together, but in the normal state they seemed to vary independently.

Other Influential Factors in Cognition.

Flügel had discovered another unitary factor in cognition, that of *oscillation*. It consisted in the fact that the cognitive output of a person never persisted at a perfectly uniform level; it continually fluctuated up and down. On applying to this phenomenon the same mathematical technique as to G, it was found that here, too, the function was unitary—i.e., the person who presented the largest oscillation for one kind of mental operation also tended to have the largest oscillation for other kinds. This, represented by O, constituted, with G and P, a dominant triad. As to the importance of this O in states of mental disorder, this was, Prof. Spearman said, an almost virgin field of investigation, and it might bring forth results of unsuspected value. No other factor had so far been revealed which possessed such a width of range, but there were some broad enough to have great importance, perhaps particularly in mental disorders. A notable instance was the forming of mental "dispositions." On once folding a piece of paper, it would ever after be more easily foldable in this crease than elsewhere—i.e., it had acquired a disposition to fold in that place. It seemed that upon analogous dispositions depended all our remembrances, our stored-up knowledge and habits, and therefore most of our behaviour. The question arose whether this ability to form dispositions tended to accompany the previously mentioned other kind of retentiveness, perseveration. A further question was: Was this disposition-forming unitary within itself? Much information was being accumulated, but the research would be enormously advanced if the psychiatrists would collaborate. A further instance was conative control: What power had we over the course of our own ideas?

Psycho-analysis was a contribution of experimental psychology, and was, in fact, invented by Galton. Essentially, it was nothing more than associative reproduction freed so far as possible from conative control. It was abundantly explained elsewhere and was therefore not dealt with in this lecture.

Conation and Affection.

In the domain of striving and feeling, one came upon what was the more conspicuous in psychiatrical practice. Only in a small proportion of cases was a patient sent to a mental hospital, or even to a clinic, because of enfeeblement of his cognitive power; primarily he came for diagnosis and treatment because those about him could no longer tolerate his conation and affection. Here the ideal would be to test out the actual strength of each of a person's main conations, each spring of action or instinct. The conative side of mind had also been found to possess a general factor: it was such as to favour stability of resolution, evenness of temper, conscientiousness and trustworthiness, while it repressed vanity and selfishness. It seemed to be, in fact, a revival of the old-fashioned "Will," and was denoted by the letter W. It could not, however, be submitted to exact experimental measurement.

To carry out the collaboration required between experimental psychology and psychiatry, Prof. Spearman suggested that a carefully chosen group of patients be submitted to observation and measurement of every feasible kind; then the data could be arranged in an orderly and scientific system. It really meant the discovery of what goes with what and what follows what. On the answer to these two questions, in the last resort, depended all diagnosis, prognosis, and therapeutics.

MEDICO-LEGAL SOCIETY.

AT a meeting of this Society held on May 23rd the chair was taken by Sir WILLIAM WILLCOX, the President, who opened a discussion on

ACUTE ARSENICAL POISONING.

He said that improvements in technique and the extensive use of arsenic in the treatment of disease had added very greatly to our knowledge in the last seven years. Extremely minute quantities could be detected and measured and the clinical pathologist was now able to detect arsenic poisoning, almost without the help of the analyst, from the post-mortem appearances: acute swelling and degenerative changes in the kidney and liver and other organs, the condition of the gastro-intestinal tract, and the preservation of the blood and viscera. An inquiry in Sweden had shown that arsenic was present in the body of most normal people, and amounts of 1/100th of a milligramme per litre were to be found in the urine. The finding had been repeated in this country. Arsenic was a normal constituent of the urine, and the recent inquiry into ethyl petrol had shown that lead was also present in the majority of ordinary healthy people. Moreover, arsenic had recently been found in certain foods. The epidemic of poisoning from beer in 1900 had led to the appointment of a Royal Commission, which had fixed a legal limit for the amount of arsenic a foodstuff might contain: 1/100th of a grain per pound or gallon. Since this time there had been few cases of arsenic poisoning from food. Some kinds of fish, however, contained much more arsenic than the legal limit— for instance, sole contained 1/10th of a mg. in 100 g. This arsenic was probably not arsinous acid but some organic compound; it might, however, easily arouse the suspicions of a toxicologist. Crustacea, oysters, and other shell-fish contained 20 to 40 parts per million of arsenic, and the poison had also been found on apples as the result of spraying the trees.

Mrs. Llewellyn, a woman of 63, had died after a period of indifferent health during which she had suffered from arthritis, dilated heart, renal disease and ascites, and attacks of diarrhœa and vomiting. She had been a second wife and there had been jealousy between the two families. Two months before her death an examination of the urine had revealed the presence of 0·6 mg. of arsenic per litre—i.e., the maximum normal limit. She had been very partial to fish. After her death 0·4 parts per million of arsenic had been found in the heart and liver, 0·8 in the kidney, and two parts in the hair. The presence of arsenic in the hair had indicated that she had been taking it for a long period, and the fact that only a very small amount (0·06 parts per million) had been found in the ascitic fluid had negatived the possibility of a fatal dose of arsenic causing the symptoms in the last days of life.

Arsenic had been chosen as a homicidal poison since time immemorial, as it was tasteless and fatal in very small amounts, and the symptoms it caused closely resembled those of organic disease. It should not be described as an irritant poison, for its irritant effects were by no means the whole danger. Arsenic was a tissue poison and poisoned all the organs of the body, causing rapid pulse and heart failure, jaundice, albuminuria and casts, and the patient who recovered from the diarrhœa and vomiting was by no means out of the wood; he might be damaged for life. The after-effects were regarded far too lightly.

In the Pace case the victim had evidently had one dose of arsenic to cause the acute diarrhœa and vomiting which had set in on July 24th, and at least one or two more doses to cause the vomiting to continue until August 10th; he had then gone into the infirmary with peripheral neuritis and had returned home improved in general health. He must then have had another dose to cause diarrhœa, vomiting and collapse on Christmas Day, and at least two more to induce another attack five days later and the third fatal one. So altogether he must have had five fatal doses, and enormous quantities had been found post mortem. The arsenic had probably been obtained from sheep dip, which contained 20 per cent. of it. The suggestion had been made that it had been taken with potassium permanganate, but examination of the organs for manganese had shown no more than the normal amounts, so that this suggestion had been negatived.

Prof WALKER HALL described some experiments he had made on the

Action of Sheep Dip on Tissues.

Sheep dip, he said, was easily obtained, in sealed packets in the form of a yellow granular powder, by anyone known to have the care of sheep. It consisted of arsenic trioxide, sodium carbonate, and ground sulphur, and a packet contained about 2850 grains of arsenical components, or 1400 minimum fatal doses. When prepared according to the directions it yielded a 0·2 per cent. solution of arsenic trioxide in sodium dihydrogen arsenate. The toxicity of this was about half what it would be without alkali. There was very little danger in handling the solution and cutaneous absorption was a bogy. He had rubbed the dry dip on his hand and soaked the hand in the solution without experiencing any symptoms, or finding any excess of arsenic in the urine. Sheep dip in solution could be easily mixed with food or drink, but it was very difficult to take in powder form because of the sulphur.

Single and repeated doses of sheep-dip solution had been given to rabbits, which had been killed in 6, 12, 24, and 48 hours. The doses had been equivalent to about 7 g. for a human being—a quantity often exceeded by the suicide or poisoner. Within six hours 95 per cent. of the arsenic had been absorbed, and by 12 hours 9·8 per cent. had disappeared from the stomach and intestines. When the solution was given without being freed from the sulphur the yellow granules all passed from the colon within 24 hours, without loss. Six hours after a single dose minute hæmorrhages had taken place in the gastric mucosa, and these were more numerous after 12 and 24 hours, or after similar repeated doses. The stomach wall was gradually and progressively contracted and after 12 to 24 hours the viscus was hard and tense. This contraction was more pronounced with repeated doses. Hæmorrhages did not appear in the intestines until after 12 hours, but were widespread after 24 hours, and with repeated doses were more generalised. The arsenic did not produce contractions in the small intestine, perhaps because nearly all of it was absorbed through the stomach. Hæmorrhages did not appear in the colon until after 24 hours and were not more marked with repeated doses. The cells of the liver were less distinctly outlined after 12 hours and the cytoplasmic structures stained more diffusely. The nuclei showed altered chromatin; Kupfer's cells were beginning to swell and their nuclei were more granular than usual, but the bile channels were unaltered. After 24 hours the liver cells showed signs of serious damage, the outlines were indistinct, vacuoles were numerous; early fatty changes were evident; nuclei were necrosing; œdema and passive hyperæmia were general; Kupfer's cells were swollen and proliferating; and the duct cells were swollen. With repeated smaller doses these features were less advanced, but the Kupfer's cells showed a greater activity and many mononuclear and polynuclear cells were present in the dilated sinusoids. Myocardial cells, 6 to 12 hours after the fatal dose, showed little or no change in the striæ or nuclear appearance. At 24 hours some of the cells showed defective striation and nuclear changes; others had lost their staining capacity and appeared to be necrosing. With repeated doses there was œdema and proliferation of interstitial cells; the myocardial cells had lost their striæ and were becoming granular. The morbid appearances of the other organs at this period were mainly those of capillary damage, passive hyperæmia, œdema, and hæmorrhages. After six hours the blood-vessels were almost unaltered, but after 12 hours there were many dilated capillaries and some diapedesis; the appearance became more marked after 12 hours and with repeated doses. The renal vessels did not show much change until 24 hours.

Discussion.

Dr. J. H. RYFFEL mentioned the variations of toxicity of arsenic in different foods. It was apparently more poisonous in beer than in fish; possibly there was some noxious association between arsenic and alcohol. One form of acute arsenical poisoning was caused by arseniuretted hydrogen, which might be produced in large quantities by the action of acids on impure zinc—e.g., glass. It caused the patient to turn a copper colour, due to a mixture of hæmolysis and jaundice. The latter was a special feature of poisoning from this form of arsenic. The lævulose test was a fairly satisfactory one for demonstrating the damage done to the liver.

Mr. EDWARD HINCKS described the various chemical methods for detecting and estimating arsenic. The mirror method was very simple in principle, but far from simple in practice. The organic material in the arsenic component must all be destroyed and hydrogen must be developed on the surface. To avoid the risk of pockets of arsenic in zinc, electrolytic processes had been devised to elaborate the hydrogen. Theoretically they were ideal, but the platinum cathode had proved rather insensitive, lead was very sensitive but had to be renewed frequently, and on the whole the most successful was a liquid mercury cathode in which a new surface could be obtained by tapping. Mr. Hincks handed round mirrors showing how quantities from one to nine millionths of a gramme could be detected by the latest modification of the Marsh test, which he regarded as the safest and most satisfactory method for the toxicologist. The mirrors could be kept permanently in hydrogen, or could be sublimed into arsenious oxide, to which chemical tests could be applied. Antimony and selenium could be distinguished from arsenic with certainty. The objection to the mirror method was that it depended on visual judgment, and although hundredths of a milligramme could be weighed on a micro-balance this would not necessarily bring the result much nearer the truth. The method was subject to a percentage error of ±10, which was lamentably great. It was therefore better to use an ordinary gravimetric method where concentration of arsenic was high. In surgical terms the detection of arsenic remained "a major operation."

Mr. H. E. COX, in answer to a question, said that there was no spectroscopic test for arsenic. The lines were all in the extreme ultra-violet, where they could not be seen. The work of the Swedish Commission was worthy of intensive study, as the amount of arsenic found in the normal human body was still grossly underestimated. He emphasised the difference between organic arsenic combined with proteins as in fish, which was non-toxic, and the added arsenic, which was very dangerous.

Mr. K. B. EDWARDS pointed out that no cases of arsenical poisoning had occurred as a result of using fruit-tree spray for destroying disease in trees. He asked whether it was really an arsenical poisoning.

Prof. WALKER HALL, in reply, pointed out the peculiarly selective action of arsenic, both for tissues and individuals; and Sir WILLIAM WILLCOX said that, so far as he knew, no case of poisoning from apple-tree spray had occurred; the arsenic had been detected in the course of routine food and drug analysis.

Corrigendum.—In Dr. Graham Forbes's remarks at the R.S.M. Section of Tropical Medicine (THE LANCET, May 25th, p. 1094) for dysentery read *diphtheria.*

ROYAL INSTITUTE OF PUBLIC HEALTH.

WHITSUNTIDE MEETING AT ZÜRICH.

THE annual congress of the Institute, held at Zürich from May 16th–20th, afforded, as we noted last week, excellent opportunities of obtaining direct information on medical problems peculiar to Alpine countries and on the state of the Swiss public health. In the sectional meetings the broad international aspects of health and disease were uppermost.

In the Section of State Medicine a discussion on

Rheumatism as an International Problem

was opened by Dr. J. VAN BREEMEN (honorary secretary of the International Committee on Rheumatism, Amsterdam), who, while agreeing that at present it was impossible to adopt a uniform international nomenclature to distinguish the diseases comprised under the heading of rheumatism, held that much benefit would be derived from the organised study of four factors: focal infections, the rheumatic diathesis, abnormalities in the blood circulation of the skin, and the effect of environment. He presented a series of rheumatic cases of various types in all of which the skin temperature was low; a special instrument for taking the temperature was demonstrated. Attention was called to the value of physical therapy in spite of the presence of considerable abnormality of structure. Early treatment *must* be secured; in the Rhine Provinces any contributor to a sick fund who has suffered from rheumatism for some months must be sent for examination to a supervisory medical officer who, if necessary, sends the patient to the Landesbad. Dr. Breeman suggests a methodical investigation of the causes of rheumatism in miners, taking especially into consideration the dampness of the mine and the character of machines used.

Dr. WARREN CROWE (London) showed lantern slides illustrating early osteo-arthritic changes produced in rabbits by the injection of certain varieties of streptococci derived from the roots of infected teeth; their action was greatly enhanced by the presence of a focus of infection artificially produced by the subcutaneous injection of infected agar. Dr. Crowe pointed out the general applicability of specific vaccine treatment; stock vaccines of a sufficiently polyvalent character hold out great promise.

The paper of Prof. CMUNT (Prague) dealt with the promising results obtained by using the cutaneous vaccine treatment introduced by Paul of Vienna; 836 patients had been vaccinated, most of whom were given no other treatment. The use of cuti vaccine had the advantage of detecting focal infections such as dental sepsis and appendicitis, which could at once be treated radically.

The Slum Problem.

Mr. B. S. TOWNROE (Hampstead) pointed out that in Great Britain the "unhealthy area" or "slum" is defined by the Housing Act of 1925; a more descriptive definition is to be found in the writings of Sir George Duckworth. Unhealthy areas might consist of property which was structurally sound, and therefore worthy of complete repair; the repair could be effected by local authorities, voluntary associations, or by private landlords. Some areas consisted of property which was almost worn out but which, owing to the absence of alternative accommodation at a rent that the occupants could pay, had to be reconditioned to last for a further temporary period. The present problem is to so reduce the cost of building that the dwellers in such areas could afford to occupy new houses. State subsidies, he held, inflated building costs, created a class of municipal tenant whose rents were dependent upon the votes of popularly elected municipal councillors, and encouraged pauperisation. Subsidies can only be defended as temporary expedients but are still needed for slum clearances.

Councillor E. D. SIMON (ex-Lord Mayor, Manchester) pointed out that post-war housing legislation for the poorest class of workers was eminently unsatisfactoy. Even the Wheatley subsidy, which was designed to allow houses to be let at restricted rents, has not brought new houses within the reach of the large poor family. The minimum rent at which non-parlour houses with three bedrooms can be let by local authorities is 11*s.* a week inclusive of rates. The labourer with three or more dependent children needs a house at not more than 8*s.* a week. To bridge the gap between the rent of the Wheatley house and what the labourer can afford, Mr. Simon suggests a "children's rent allowance" to be made in the form of a rebate in the rent, but only in the case of those families who could not otherwise remove from the slums into a decent house. If this rebate were 1*s. per child each week in the case of all families* whose income is less than 60*s.* a week, and who have three or more children, the cost would only amount to the relatively small sum of five million pounds a year.

Prof. BERNOUILLI (Zürich) regretted that by withdrawal of the Government subsidy building societies in Switzerland had been thrown back on to their own resources; the erection of houses intended for a single family had almost entirely stopped. The result will be that speculative builders will step in and erect the less hygienic type of house—the apartment house—which costs less to build and, at the same time, produces a higher rent.

Health Propaganda.

The paper of Prof. H. HUNZIKER (Basle) gave an insight into the stage of development of school medical work in Switzerland with its 25 autonomous Cantons. In addition to the large towns 300 out of 3000 communes possess a school doctor. The new Federal tuberculosis legislation requires the regular medical supervision of teachers and children in schools and similar institutions. School nurses are employed apparently more in the French-speaking part of the Republic than elsewhere—in Lausanne there is a school nurse for each school district. Instruction in hygiene is given in a verbal form by the school teachers chiefly, but from the very beginning school doctors have done excellent work by giving teaching on such special subjects as the prevention of goitre, infestation by intestinal worms, dental decay, and alcoholism. Instruction on sex and the dangers of venereal disease is given at the end of the child's school life by a doctor; in the case of girls by a woman doctor. Dr Hunziker considered that the teaching of infant welfare in schools had brought about the very low infantile mortality (35–45) in Basle, Zürich, and Berne. University extension courses in hygiene were well attended in Switzerland.

Dr. HÄBERLIN (Zürich) gave an account of his five years' experience of writing popular health articles in the lay press. Appreciation had been expressed in the shape of letters and verbally; that interest had been aroused was shown by the large number of questions asked. Numbers of the newspaper containing the articles on hygiene had a larger sale than the others. He was convinced that the ordinary newspaper was a much better vehicle of propaganda than a special health propaganda periodical. The variety of the subjects dealt with was evidently very great; they included the dangers of the use in common of a glass for drinking; the hygienic value of the lake of Zürich; warm or cold baths; douche or bath. Advice as to the recognition and self-treatment of diseases was rigorously excluded.

Dr. J. J. **Paterson** (East Berks) regretted the ephemeral character of such articles, and suggested that book form was almost essential.—Dr. W. E. S. **Finny** stated that it was the duty of the Kingston-upon-Thames public librarian to collect such articles and paste them in a book which was available for the public.—Mr. C. M. **Kohan** (London) thought that even health publicity, which was entirely satisfactory, does actually create in a by no means small proportion of the laity an idea that they can diagnose and treat their own complaints or hypochrondria. The point of contact of health propaganda with commercial enterprise which can give actuality to health principles and commercial exploitation which seeks to enlist the enthusiasm of a pioneer movement for its own ends, must be clearly watched.—Col. P. **Draudt** (League of Red Cross Societies) pointed out as an example of the extent of its preventive work that in 12 countries alone the Red Cross had provided 568 tuberculosis dispensaries, 53 sanatoria, 115 preventoria, and 281 colonies. In India a large number of brochures and pictorial posters had been distributed. The Japanese Red Cross had got together a popular hygienic museum which was a model. In some parts of the world children with their own money, often gained by work, had contributed towards playgrounds and holiday camps for their weaker brethren.

Alcoholism as an International Problem.

Dr. **Hercod** (Director of the International Bureau against Alcoholism, Lausanne) referred to the strong pressure put by the liquor trade on such prohibition or partial prohibition countries as Iceland and Norway by nations such as Spain, Portugal, and France, who desired to export wine and spirits. In spite of the efforts made to control the export of spirits to Central Africa, notably the Convention of Saint German-en-Laye concluded between several colonial powers for the purpose, only moderate success has been attained. Smuggling of liquor is not confined to America—it is going on all around the Baltic Sea; Finland, Norway, Sweden, and Denmark have jointly concluded the Helsingfors Convention with States from which spirits are brought into their territory. In accordance with a resolution passed by the League of Nations Assembly, the Health Organisation is collecting statistical information on alcoholism, giving prominence to the effect of alcohol of "bad quality," and the Economic Committee is considering the adoption of some international measures against the smuggling of liquor; wine, beer, and cider are expressly exempted from consideration by the terms of the resolution.

Industrial Hygiene.

In a paper on occupational dermatoses Dr. **Prosser White** (Wigan) laid down certain conclusions. In a person artificially or accidentally sensitised to a foreign protein, a minimal quantity will excite a reaction This reaction may be more severe, extensive, and lasting than in a non-allergic individual. In trade processes this form of acquired protein sensitisation is rarely encountered. Acquired or true protein sensitisation eruptions do not last indefinitely nor does a fresh exacerbation break out in the absence of a fresh contact with the allergen. Sensitiveness to the different vegetable and inorganic chemicals is generally an inborn quality of the skin; this anomaly of development is elicited by vegetable products. The specific agents which cause skin cancer bring about the cutaneous changes, whether applied locally or inhaled or ingested. The halogen acnes are probably always an "excretion dermatosis." True sensitisation plays no part in the eruptions caused by the inorganic irritants. Given proper treatment and absence of the irritating agent, occupational eruptions, allergic or otherwise, with the exception of those caused by substances such as arsenic, tar, oils, &c., which produce deferred effects, heal up as rapidly and in as short a time as any other sore or injury of equal extent and severity. Absence of healing means that we are dealing with an internally produced skin trouble such as eczema, seborrhœa, or a mycosis and not a traumatic skin disease. Until medical referees recognise these facts when dealing with occupational affections of the skin their verdict cannot be "succinct, definite and categorical," or "just to both sides." The first three requirements are laid down by Judge Sands as essential in any certificate issued by a medical referee. Given a reasonable period of freedom from any chance of exposure to an irritant an inflammatory, periodic (recurrent) affection of the skin, characterised first by erythema, papules and vesicles, and later by scaly, weeping, or crusted patches associated with itching or burning and with indefinite or irregular edges is a "diathetic skin disease"; it should not be called a "dermatitis," much less a "trade dermatitis." Such cases should be periodically re-investigated by an expert experienced in the recognition of both the endogenous and exogenous skin eruptions.

Dr. G. **Quin Lennane**, at the Battersea Tuberculosis Dispensary, recently dealt with several cases forming part of a group of patients suffering from silicosis contracted in a local factory, the diagnosis of which was not made until the post-mortem examination. The "factory" only employed about 15 girls who were all engaged in making scouring powder—seven fatalities occurred; only two had tuberculous lesions. Dr. Lennane held that unless more inspection was carried out by the Home Office the duty should be handed over to the local health authority, which, indeed, was the appropriate authority to undertake such inspection.

Dr. G. A. **Haydock** (York) had found that young girls employed at Messrs. Rowntree's works, who had suffered from acute rheumatism, were not suitable for collective piece employment, but that they could maintain an average output if given work in which they could be allowed to adopt their own extremely irregular rhythm which, he considered, was the result of rheumatism rather than an anxiety neurosis.

Prof. F. **Schoofs** (Liége) referred to accidents occurring to workmen who entered tanks where ordinary motor spirit is stored. Exhaust gas from motors may contain as much as 10 per cent. of carbon monoxide. If the engine is allowed to run for a considerable time in a closed garage the exhaust gases, which also contain unburnt volatile hydrocarbons may cause unconsciousness followed by severe headache or even death. In a fatal case carbon monoxide was found in the blood.

Health of the Swiss Army.

Colonel **Hauser**, M.D. (Chief Medical Officer of the Swiss Army), explained the measures adopted in the recruitment and conservation of the health of the Swiss Army, in which all able-bodied men are required to serve seven weeks during their first year as a recruit and subsequently twelve days yearly for seven years. A travelling medical board tours the various centres to examine the young men; especial attention is paid to the detection of tuberculosis, X rays being used wherever possible. Much reliance is placed on the sprinting test which serves to detect not only heart and lung trouble and flat-foot, but also nasal defects and kidney lesions. Valuable statistical material relating to goitre is obtained; owing to its wide spread men with slighter degrees of the disease must be accepted for service during which iodine in small doses is administered. Shortly after recruitment the men are vaccinated against small-pox; all the more necessary because in several of the Swiss Cantons there is no compulsory vaccination

Dental work is carried out; prophylactic gargling is compulsory. Men who have run the risk of infection with venereal disease undergo prophylactic treatment. Care of the feet is taught; before joining up the men are given the Army formalin foot powder "Arfol"; a 5 per cent. paint of formalin in alcohol is also used. To prevent trouble consequent on riding, the seat and inner side of the thighs are painted with a weaker solution (2 per cent.).

Tuberculosis.

Much interest was taken in the Swiss University Sanatorium established at Leysin. Each university and technical high school student pays 10 francs a year as part of his or her fees towards the University Insurance Fund and each member of the teaching staff 20 francs. If a student or teacher contracts tuberculosis he is treated at the sanatorium at a charge of 36*s.* a week. The patients are given facilities to continue their studies in a less intensive form; the Swiss universities allow a year spent at the sanatorium to count as a term. Students from non-Swiss universities are admitted, as far as space allows, at a rate of about 10*s* a day; it is hoped that the accommodation for these foreign students will be extended. At Leysin Dr. Rollier, in the treatment of surgical tuberculosis combines heliotherapy with occupation therapy which, however, must be under constant medical supervision. A case of Pott's disease is able to work without any difficulty in the ventral position, of hip disease in the dorsal position. For tuberculosis of the upper limb machines for the one armed are used. An International Factory Clinic has been established for the poorer class; using electrically driven machinery and special tools, the patients make the small parts of machines and spare parts of watches; commercial studies are also made.

Dr. R. C. **Wingfield** (Frimley) considered that the absence of adequate arrangements for after-care of patients treated in sanatoria constituted a serious weakness of English tuberculosis schemes.

Dr. **Otto Amrein** (Arosa) pointed out that in order for the tuberculous to benefit by treatment at high altitudes a certain measure of resistance must be present. An increase in the number of crepitations sometimes occurs as the result of increased altitude. A rise of temperature is due at times to syphilis or malaria. The presence of fever, he held, did not contra-indicate the journey to high altitudes, but patients with a temperature of above 101·5° F. with a pulse-rate of 120 or higher not responding to complete rest in bed are not suitable for high altitudes. Other contra-indications include obstinate dry pleurisy and usually both abdominal and urogenital tuberculosis. Where an artificial pneumothorax has been made on return to lower altitudes more frequent refills are necessary. Patients from northern countries should not visit places with a relaxing climate on the way home. English patients ought not to return home before the end of May.

The paper of Dr. F. **Haeberlin** (Davos) dealt with adjuvants to artificial pneumothorax treatment. X rays and thorascopic inspection enable the physician to decide as to the possibility of dividing pleural adhesions endoscopically using the electric cautery. Pleural adhesion affecting large areas may possibly be counteracted by filling the pleural cavity with oil.

Climatology.

Prof. **Walter Hess** (Zürich) gave a short account of the work carried out at the different Swiss Alpine research institutes—Monte Rosa with its two allied institutes, Campana Regina Margherita and Angelo Mosso; at the Davos Institute with its two sections, one at Muottas Muraigl, the other at Gornergrat, where investigations are being made as to the biological value of the Alpine climate in relation to tuberculosis; at Arosa, where the utility of ultra-violet light is studied, and Dr. Gotz, the director, is also collaborating in the ozone investigation association organised by Dr. Dabron Oxford, and finally, the High Alpine Research Station on the Jungfraujoch which, it is hoped, will receive international support.

Prof. **Senn** (Basle) attributed the increased metabolism at high Alpine climates to the increased permeability of the protoplasm in strong light.

Dr. F. **Lindholm** (Davos) referred to the improved climatological table brought out by van Oordt and Dorno, which, in addition to data relating to the mean daily fluctuations of temperature, gives information as to the frequency of interdiurnal changes and the dates on which the daily mean temperatures reach 10° for the first time, these events corresponding approximately to the phænological beginning of spring and autumn. Investigations have shown that the temperature of the air and its cooling power do not stand in close relation. The north European coast stations have the highest and the tropics the lowest cooling power; the sheltered mountain valley of Davos stands almost midway, and like the tropics exhibits the least seasonal fluctuations. Dr. Lindholm suggested that records of the cooling power of the air might eventually afford useful information in connexion with the occurrence of epidemics. He pointed out that our climatological knowledge of radiation, whether of the sun, sky, or earth, although of extreme climato-physiological importance was still very scanty. At Davos, investigations have shown that the essential characteristics of the radiation of high altitudes as compared with low include an increase of short waved and especially ultra-violet radiation and a greater uniformity of the total intensity both in the course of the day and the year. The diminished quantity of ozone present is held to play some part in these phenomenon.

In the Section of Pathology, Bacteriology, and Biochemistry, Prof. **Karl Wegelin** (Berne) read a paper on

Endemic Goitre,

pointing out the special characters of the disease in Switzerland. There is, he said, an early epithelial hyperplasia not seen in the milder form found in Holland, Norway, and North America. Primary exophthalmic goitre is rare in Switzerland; a diminution of thyroid secretion is the usual condition. The proliferation of the epithelium occurs in fœtal life; in the child a diffuse parenchymatous goitre is seen from which usually at the age of puberty either a diffuse colloid goitre develops or an adenoma. Malignant growth in old adenomata is by no means rare. The relative and often the absolute iodine content of the goitrous thyroid is diminished, but probably the condition is not entirely due to the lack of iodine in the environment and aliment; in Switzerland goitre is unknown in wild animals; in other countries when the disease is endemic an adequate amount of iodine is available. The prophylaxis of endemic goitre must begin in the fœtal stage of life; sufficient iodine must be given to the mother throughout pregnancy. Later, preventive measures consist in administering iodized salt and giving tablets of iodide of potassium or sodium during school age. The fact that ossification is always very late or even absent in certain centres in cretinism was well brought out by lantern slides.

Typhoid and Paratyphoid.

Prof. W. J. **Wilson** (Belfast) referred to the extent to which paratyphoid had replaced typhoid infections in the British Isles; the experience of Dr. J. E. McCartney (M.A.B.) was that typhoid fever had become so uncommon that cases were not recognised so early as formerly; he considered that when any obscure infection was noted the laboratory worker should be called in immediately to see the patient clinically and to decide what specimens should be obtained to establish a diagnosis.

Meat Inspection.

Lieut.-Colonel T. **Dunlop Young** (City of London), speaking on imported meat, said that formerly, owing to the scarcity of beef, mutton, and pork in Great

Britain, live animals were brought from the Continent; those were at first allowed to be sent to, and sold at markets throughout the country, but it was observed that contagious diseases were introduced by them and then they had to be killed at the ports of landing. Later, owing to the introduction of refrigeration of meat, meat was brought from the U.S.A., Argentina, Australia, and New Zealand. Gradually the livestock trade ceased until at present there is practically no importation of livestock. As the demand for imported beef, mutton, and pork increased, it was observed that the carcasses of the best types of animals sold at highest prices; this was pointed out to the breeders and feeders in the various exporting countries, with the result that Great Britain became the pedigree stock farm of the world from which the best types of animals have been exported to the U.S.A., South America, Canada, Africa, Australia, and New Zealand.

Prof. A. **Krupski** (Zürich), giving an account of meat inspection in Switzerland, said that fattened beasts and meat and meat products imported into Switzerland must be inspected at the frontier by special veterinary officials.

Bovine Tuberculosis.

Dr. H. **Baer** (Zürich), giving his experience of the immunisation against bovine tuberculosis with B.C.G. and Friedmann vaccines carried out in the Canton of Zürich since 1924, said that the Friedmann vaccine has caused neither local nor general disease; the course of the disease was not influenced unfavourably. The post-mortem examinations, however, do not show any certain therapeutic or protective effect produced by the Friedmann vaccine. The B.C.G. vaccine does not cause any disturbances of the general condition of the animals although some developed permanent swellings at the place of injection. The results of the clinical examinations of bovines revaccinated two to three times seem to demonstrate a certain increase of resistance against tuberculous infection; the number of port-mortem examinations made were, however, too small yet to warrant a definite conclusion.

The paper of Lieut.-Colonel J. W. **Brittlebank** (Manchester), on tuberculosis among bovines, expressed his view that the grading of milk failed to contribute in any appreciable degree to the diminution in the extent of the disease. In England those districts which have been concerned with dairying as their principal branch of agriculture for the longest period have amongst their cows the highest incidence of tuberculosis. He believed a widespread policy of reconstruction of farm building to be essential; this could be spread over a number of years; Government loans should be available. Efforts should be concentrated on the dairy cow. Routine clinical examinations of all dairy stock should be made by veterinary surgeons to detect cases of open tuberculosis; the tuberculin test detected in many instances the presence of á tuberculous lesion which had no public health significance.

Milk.

Reference was made by Drs. J. B. **Orr** and **Gerald Leighton** to the Scottish milk-feeding investigation in schools. Dealing with 1282 public elementary schoolchildren in 1927 and 1157 in 1928, the results showed that the group given whole or separated milk daily in seven months grew ¼ inch taller, and from ¾ lb. to 1 lb. heavier than the children who received no milk. A somewhat surprising result was that practically the same increase occurred with separated milk as with whole milk.

Dr. H. E. **Magee** (Aberdeen), speaking on some effects of heat, said that physico-chemical examination showed that, of the total calcium 26 per cent. is in diffusible form in raw milk; 20 per cent. in milk heated to 70° for 30 minutes, and 15 per cent. in milk boiled for an hour. It is believed that the differences are due to the formation of colloidal $Ca_3 (PO_4)_2$ which explains the rise in calcium noted. Heat lessened the stability of the colloids. In balance experiments with growing animals retention of Ca, P, and N was greater in the case of sour and raw milk than in heated milk. Addition of soluble calcium to the heated milk increased the retention of these elements. In feeding experiments with calves fed on cow's milk, the animals receiving fresh milk throve better than the control groups receiving pasteurised milk. The addition of soluble calcium to pasteurised milk removed the detrimental effect of the heating. Heat caused the disappearance by volatilisation of 20 per cent. or more, according to the duration of the heating, of the total iodine of milk. The ratio of diffusible to non-diffusible iodine was the same in raw as in heated milk. Approximately 83 per cent. of the total iodine of separated cow's and goat's milk was found to be in diffusible form.

Reviews and Notices of Books.

THE SCIENCES AND PHILOSOPHY.

Gifford Lectures, University of Glasgow, 1927 and 1928. By J. S. Haldane, C.H., M.D., F.R.S. London: Hodder and Stoughton. 1929. Pp. 344. 15*s.*

The ignorant reader would be glad if each volume of Gifford lectures which is published contained some account of the origin and purpose of a foundation which has produced so many noble contributions to natural theology. Dr. Haldane's book is a notable number of a distinguished series. Anything which he writes will be attentively received by those who know what he has done for the advancement of physiology and medicine, partly by way of exact experiment (which is not uncommon), partly by way of rigorous thinking (which is rare). What he has to say on philosophy has at any rate this appealing quality, that it comes from one who has a lifelong practical familiarity with experimental science. There need, however, be no draft on our respect and affection for an appreciation of this statement of his mature views on the philosophy of the natural sciences. The book obviously stands on its own merits, and it may be said at once that most of it at any rate is within the tolerably easy understanding of those who have not enjoyed the advantages of a Scottish education in philosophy. There are, he says, four kinds of knowledge, that is four sciences: mathematical, physical, biological, and psychological. Each of them is in its way an interpretation of our experience of the world, but they seem in many ways to contradict one another. If we hold by one kind of interpretation, we obviously leave out some of our experience and our view is incomplete; if we hold by them all, we include all our experience but our view is incoherent. What is the solution? Mathematics deals with ideal abstractions which plainly have little to do with reality. The physical sciences give a self-contained interpretation which, as physicists themselves have come to realise, is necessarily incomplete because it cannot embrace large and prominent facts of experience. Biology does not think of reality as a series of independent bodies, but as a unity which includes both organism and environment, and in which structure and activity are mutually dependent. None of these ways of looking at the world gives us a satisfying picture. Psychological knowledge, on the other hand, deals with interest and values which extend into the past and into the future and are beyond space and time relations. Mathematics, physics, and biology represent our imperfect attempts to bring these spiritual values into an objective form which we can apprehend. The only final reality is the universe of spiritual interest and values, which is what the language of religion calls God.

Few of those who read Haldane and Priestley's classical paper (*Jour. Physiol.*, 1905, xxxii., 225) will have imagined that this would be the final conclusion deduced from the study of human respiration.

But one of his audience in Glasgow said when she got home: "I thought he was going to talk about God, but he talked about nothing but kidneys"—an unconscious tribute to the fundamental nature of Dr. Haldane's philosophy.

HISTORICAL INTRODUCTION TO MODERN PSYCHOLOGY.

By GARDNER MURPHY, Ph.D., Instructor in Psychology, Columbia University. London: Kegan Paul, Trench, Trübner and Co., Ltd. Library of Psychology and Scientific Method. 1929. Pp. 470. 21s.

THE respectability of psychology has been doubted on the one side by philosophers, who grant it no independence, and on the other side by those scientists, particularly the physiologists, who state that its data are only positive when stated in terms of neurology, and have no definite significance when expressed in the vocabulary of mind. Both these views are false, and Dr. Murphy's scholarly survey of the evolution of psychology from the fourteenth century does a great service in exposing their fallacy and in showing the importance of this branch of human study. Quite apart from the illustrious names that are scattered through its pages, the survey shows to what extent the sciences of physiology and biology are indebted to those who were primarily concerned with the study of the senses and the elementary processes of the mind. The early chapters of the book deal with the background of the science and with the fundamental discoveries and theories that have given direction and a bias to its methods. Most important are the sections which bridge the gap between the purely introspective psychology of the late eighteenth centuries and the psychology of our own day, derived from the laboratory, and from the field of psychopathology and of education. This period was occupied by the pioneer work of W. C. Weber, later of Wilhelm Wundt, and behind lay the background of the great English and Scottish thinkers, such as Bain, Reid, and Hamilton. Later came the theory of evolution and the advent of the biological standpoint. In the third part of the work the various aspects of modern psychology receive attention. In a book which attempts to deal justly with all developments of psychology in 500 pages space must be allotted with a sparing hand, but it is unfortunate that only a chapter could be devoted to the "enfant terrible" of psychology—psycho-analysis, since recent views in this particular branch are not adequately discussed. Dr. H. Kluver has added two full chapters on contemporary German psychology.

The whole book is well written, and though many names and many works have escaped consideration, few important contributions to modern psychology have been altogether ignored. As a general introduction to the subject it should be appreciated by students in all faculties as well as by the individual whose interest in the development of our knowledge of psychology is quite apart from academic studies.

THE MEDICAL DEPARTMENT OF THE U.S. ARMY IN THE WORLD WAR.

Vol. IV.: *Mobilisation Camps and Ports of Embarkation.* Washington, D.C.: U.S. Government Printing Office. 1928. Pp. 494. $1.75.

THE minute detail set out here is of great value; the inclusion of a brief standard programme for a future mobilisation, if this should ever be required, would have been welcome, since the story shows that a slight misdirection of effort involved a laborious recovery involving much loss of time. This volume discusses the preparation of camps for the training of soldiers, the conveyance of the army to Europe, and its return home. The sites for the camps had to be selected, they had then to be planned and built, which meant the collecting, feeding, housing, and doctoring of perhaps 14,000 labourers, not under military discipline, for a couple of months; there followed the administration of a divisional camp for some 35,000 soldiers, with their conveyance, free from infectious disease, on healthy transports to Europe. Just as the organisation had got into its stride came the armistice, when the army with all its sick and wounded began to pour back, all so eager to get to their homes that no excuse would be accepted for delay. Yet no infectious disease could be allowed to slip through, and no one patient was to be sent home feeling that he had not had proper attention. So the Hoboken Embarkation Camp, which began with two medical officers and ultimately employed a thousand, passed 1,160,534 men through to Europe, examining 1,767,624 men, detaining 9812; it was the rule for each man to be examined on the actual day of sailing. One group of 26,000 were examined daily for six days, owing to delayed departure of the ship.

Points of general interest are as follows. One man was "issued with" a shaving-brush he did not use for 18 months; yet even after that delay it seems to have given him anthrax. Tetanus bacilli were found in one of 498 samples of surgical catgut. The U.S. Army Medical Department includes the Veterinary Corps, so horse ships are discussed. In this connexion we read: "The most common cause of death (of horses aboard ship) was pneumonia. It occurred . . . in the remote corners of the animal compartment where the ventilation was not functioning properly." That is evidence that must not be forgotten when the relation of pneumonia to ventilation in barracks is considered. A full account is given of a social hygiene campaign around the Embarkation Camp at Newport News, and of its result in limiting venereal diseases as long as the war was on; after the armistice things fell back rather into the old ways for want of active popular support. The feeding of the invalids returning on hospital trains was not satisfactory until entrusted to coloured cooks loaned by the Pullman Company; and the use of paper cups and dishes on these trains permitted a reduction of staffs. For the benefit of junior medical officers in future it may be mentioned that the routine examination of men proceeding overseas included: hair for lice; eyes for inflammation; nose and throat for exudates; chest, back, and abdomen for rashes; also venereal inspection. It is noted that latent chronic gleet could often be detected immediately after a two-hour march with no opportunity for micturition, and that gonorrhœa was simulated by malingerers with the aid of condensed milk.

The book is a record of assiduous, successful work, reflecting credit on its compiler.

THE HISTORY OF BIOLOGY.

By E. NORDENSKIÖLD. Translated from the Swedish by L. B. EYRE. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1929. Pp. 629. With 32 portraits. 25s.

BASED on a course of lectures given at the University of Helsingfors in 1916–17, this work was originally published in Swedish in 1920–24. We are grateful that it has now been translated; it is the only available book of its kind, reaches a very high standard, and makes thoroughly interesting reading. Classical antiquity, the Middle Ages, and the Renaissance occupy the first 120 pages, the seventeenth and eighteenth centuries the next 180, the nineteenth century and later the rest of the book—well-chosen proportions. The print is small and close, so that the mass of scholarly information which the author presents is very large. Botany seems to be relatively neglected; pathology and bacteriology have about the space which their present importance in general biology deserves. The translation would have been improved by more thorough technical revision; *Drosophila* is not a parasite, "analine associations" is curious English for aniline dyes, "ink-fish" is an unfamiliar name for cuttle-fish, "mechanistic" and "mechanical" seem to be confused, some sentences are hardly intelligible. The index, too, needs considerable expansion. These are, however, small defects in a very notable pioneer attempt.

THE LANCET.

LONDON: SATURDAY, JUNE 1, 1929.

TRAINING FOR THE PUBLIC HEALTH SERVICE.

THE London School of Hygiene and Tropical Medicine has issued a pamphlet outlining the course of study to be entered upon in October of this year for the diploma in public health. The appearance of this pamphlet serves as a reminder that this great school of preventive effort, conceived on the lines of the report of the Athlone Committee in 1921, and made possible by the large benefaction of the Trustees of the Rockefeller Foundation, is about to enter upon its full programme of work. We learn, in fact, that the new home of the School in Bloomsbury immediately adjacent to the University site will be opened by the PRINCE OF WALES in July. The incorporation in the new School of the old School of Tropical Medicine in 1924, and the fact that tropical hygiene and research have an arresting and picturesque character, have to some extent obscured the fact that the London School of Hygiene and Tropical Medicine have been slowly building up, concurrently with the growth of the fine structure in Portland stone which is to be their future home, the organisation which is to carry out the first conception of the School as a centre of public health training.

On the laboratory side, the subjects of bacteriology, of chemistry as applied to hygiene, and of parasitology as applied to public health, all contribute to the wholly admirable course of study for the diploma which is set out in the new syllabus, in addition to providing for advanced courses of study and research in the various subjects; this is true also of the subjects of epidemiology and vital statistics. The laboratory work is clearly designed to take its place as an aid to the solution of the general problems of public health which will confront the prospective medical officers of health, rather than as an end in itself. The course of study as a whole, with the regulations of the General Medical Council in view, extends over a period of 12 calendar months divided into three terms of 12 weeks each, and can be fully covered by students prepared to give five afternoons weekly from 2 till 6. This arrangement will be of particular advantage to practitioners who during this period of qualification for the diploma have other calls on their time during the mornings. The whole of the lectures and demonstrations on the theory and practice of public health administration and the principles of sanitary law find their place in that part of the course of study for which the professor of public health is responsible, and the course embraces some 40 visits to places of public health interest. It is an interesting new departure in this scheme of study, and typical of the whole underlying intention to secure the very best results, that the practical work under a medical officer of health, which is an essential part of the period of training, has been arranged in two selected areas as part of the School's organisation; the necessary instruction in infectious diseases and hospital management is also provided for, as well as lectures and demonstrations in applied physiology and lectures and practical classes in sanitation and sanitary engineering.

The course of study is so designed that those wishing to do so may proceed to the new academic diploma in public health instituted by the University, and it is at the same time clear that those responsible for the course have in mind the importance of turning out men for the public health service thoroughly well equipped for the career which is in front of them. This British school stands at the door of opportunity of building up a great international reputation. The excellent work that the University and the Board of Management have done in the appointment of the team of professors and other scientific and administrative staff promises well for the establishment of this reputation. In the field of public health, particularly, new ground is broken, and a great advance made on anything previously attempted, and there is a real promise that men bearing the hall-mark of a University diploma and equipped with a first-rate practical training will carry the good report of the new School to the far corners of the earth.

THE SURGERY OF LOW BACK PAIN.

THE causation and treatment of what is known as low back pain has of recent years been much debated, especially among surgeons in America. In this country it has been thought till lately that pain in the back and hips is seldom due to any anatomical abnormality. Improved means and methods of radiography, however, as well as evidence coming from the United States, have somewhat modified this opinion. The interest taken in the subject justified the British Orthopædic Society in selecting Deformities of the Lumbo-sacral Region of the Spine as the subject for the Robert Jones Gold Medal and Prize in 1927. The essay which gained the prize, written by Dr. JAMES F. BRAILSFORD, of Birmingham, was published in the April number of the *British Journal of Surgery*. His research has been a thorough one, based on a study of over three thousand radiograms and has included clinical examination of those patients whose radiograms showed abnormality. Moreover, Dr. BRAILSFORD has investigated, by dissection and X rays, the lumbo-sacral region of 40 post-mortem subjects, and has, further, examined and photographed specimens in the museums of the Royal College of Surgeons and of the University of Birmingham. His conclusions are thus founded on anatomical data and will carry weight with surgeons and pathologists.

In seeking the cause of low back pain with a view to relieving it by operation or otherwise, it must be remembered, as Dr. BRAILSFORD says, that developmental irregularities may be present and demonstrable, without giving rise to symptoms, and also that even when irregularities and symptoms are present together they are not always in the relation of cause and effect. The deformity most frequently associated with a developmental defect in these three thousand cases was scoliosis due to asymmetrical sacralisation of the fifth lumbar transverse process. But apart from such curvature this developmental anomaly may lead to narrowing of an intervertebral foramen and acute neuralgia in the distribution of the nerve in question. The deformities due to developmental irregularities which alter the alignment of the vertebræ tend to become more pronounced with age. He concludes further, that symptoms and deformity following injury to the lumbo-sacral region in which osteo-arthritic changes have occurred may be more pronounced than would be expected from the degree of trauma; also that carcinoma and Paget's disease of the lumbo-sacral spine produce definite changes in the bone which can be recognised in a radiogram before any clinical deformity is apparent, and that the pain associated with these conditions may be referred by the patient to a recent injury. As to spondylolisthesis, about the cause and frequency of which displacement of the body of the fifth lumbar vertebra there have been and still are such great differences of opinion, Dr. BRAILSFORD's experience leads him to the conclusion that it is a relatively rare deformity. The convincing description which he gives of the characteristic appearance of antero-posterior and lateral radiograms leaves no room for the suggestion that the condition has been overlooked in any of his cases, or that ante- or post-mortem section would have shown a greater frequency of the condition.

From the other side of the Atlantic comes the report of an inquiry on somewhat similar lines, directed from the point of view of operative surgery, and based chiefly on findings at the time of operation and on post-operative clinical experience in cases of developmental abnormalities at the lumbo-sacral juncture, causing pain and disability.[1] Dr. HIBBS and Dr. SWIFT have supplied an account of all the patients without exception who have been subjected to a certain operation for one definite class of symptoms; since these records cover a sufficient interval of time after operation they are of solid value in enabling us to estimate the true scope of a comparatively new operative treatment. The 147 operations in question were performed from two to thirteen years ago, between October, 1914, and January, 1927. The technique used was that of lumbo-sacral fusion by Hibbs's method of joining the laminæ of the vertebræ immediately above and below the lesion. It was performed for the relief of low back pain and disability which was thought to be due to some purely mechanical defect at the lumbo-sacral juncture, the result of an anatomical variation and not of injury. The sexes were almost equally represented in the series. Seventy-three per cent. were entirely relieved, 14 per cent. were relieved, and only 19 were unimproved. This in such a troublesome class of affections is a gratifying result. Low back pain has been very often attributed in the United States to sacro-iliac subluxation, often, as it has seemed to us, on slight grounds. It is significant that Dr. HIBBS and Dr. SWIFT state "that in all these patients no evidence of sacro-iliac pathology was recognised."

These two publications are useful as throwing light upon a subject which up to the present has been somewhat obscure, owing to the difficulties only recently surmounted of obtaining adequate X ray pictures, and also to the relative infrequency of opportunities of directly examining the parts affected, either during life or after death. Improved apparatus and the skill of radiologists and the ingenuity and enterprise of surgeons have to a great extent now triumphed over those difficulties. The researches of Dr. BRAILSFORD and those of the American surgeons have points of contact, especially on the subject of the pathology of spondylolisthesis. There were 23 cases of this deformity in the series showing it to be a relatively common one. Moreover, the authors state that "There was found uniformly to be a separation of the laminæ of the fifth lumbar from its pedicles," whereas Dr. BRAILSFORD finds such a solution of continuity of the neural arch to be rare. More extended operative experience and further radiographic investigation will doubtless settle this and other doubtful points.

◆

THE INSTITUTES OF MEDICINE.

THE curriculum grows longer and longer, and yet there seems to be no more time than there used to be for all that is judged to be necessary for the student's salvation, and no time at all for the leisure he needs to "walk with God" (as a Spaniard would say) and educate himself. Discussions on how to use the years to the best advantage go on without end, all sorts of plans are proposed, there seem to be as many perfect routes to qualification as there are cures for rheumatism. But in these discussions there is one obvious trend. We hear little of too much time being spent on surgery or gynæcology or oto-laryngology; it is nearly always the laboratory sciences which are suspect, whose methods are criticised, whose value is doubted. The physiologists in particular are accused of forgetting that their students are destined to be medical men, and of setting out to train them to be investigators of abstract science rather than practitioners. There is, in short, a current of opinion about that it might be well to return to some extent to the old plan whereby boys were taught to treat sick people on Mr. Squeers's plan of cleaning windows—by doing it. It is difficult to judge exactly how seriously these proposals are made; we believe that all experience shows them to be ill-judged. The laboratory sciences have rightly been called the institutes of medicine for two distinct reasons: one concerns the body, the other concerns the spirit. In the first place, a certain amount of knowledge of chemistry, physics, biology, anatomy, and physiology is a technical necessity to any but a quack practitioner. To define the minimum which is "necessary," is as impossible as it is to draw a sharp line between quackery and respectability, but in general the more a man knows of such things the better doctor he will be. The proportion of the curriculum devoted to them is a matter of common-sense compromise and reasonableness. The second consideration concerns the quality rather than the quantity of laboratory work. If chemistry and physiology are to be taught from an exclusively medical point of view, the student will lose some of his best experience—the atmosphere of disinterested idealism and his contact with the great men that move in that atmosphere. Not all laboratories have the atmosphere, and many of them unfortunately lack the great men, but talking to middle-aged and elderly medical men of their student life one cannot but be impressed by the frequency with which they mention a professor of botany or anatomy or physiology as the personality which opened up a fresh world to them which they have always treasured and been grateful for; it is from science teachers as often as from clinical teachers that the student has learned that it is worth while to know about things.

Dr. L. B. WILSON, the director of the Mayo Foundation, has lately been examining this point by questionaire and statistical analysis[1] and his results in America fully confirm the clear impression of casual conversations in this country. To substitute "surgical anatomy" and "medical physiology" for what we have now, would be frankly to degrade them and to deprive the student of what contributes substantially to make the good doctor—the wise humane man who knows that the complement of being able to tell the number of the stars and call them all by their names is to comfort those who are broken in heart and give them medicine to heal their sickness.

Annotations.

"Ne quid nimis."

THE HOME AMBULANCE SERVICE.

THE work of the Home Ambulance Service carried out under the guidance of a special committee of the Joint Council of the Order of St. John and the British Red Cross Society is well known to our readers. The importance of the service rendered and its increasing scope are discussed in the ninth annual report of the Joint Council. Actually the Home Service Ambulance Committee is ten years old, for it existed for a year before it came under the control of the Joint Council in 1920. These ten years have seen many changes in the public need for conveyance during ill-health. The number of patients attending hospitals, more especially for radiographic examination and various forms of treatment in the electrotherapeutic departments, has greatly increased. Without an efficient ambulance service a large proportion of these patients would have been unable to take advantage of the latest forms of treatment. The other change which has come over the country is the alarming incidence in road accidents; but this report pleads that if the developments of transport are responsible for an increasing number of accidents to life and limb, to transport must also be credited a considerable share in the restoration of health to the sick. It was the custom in the early days of the Home Ambulance Service for ambulances to be lent for use in the larger towns, but a large number of the municipal authorities have now established their own ambulance stations, thus permitting a wider extension of the service in rural districts. It is not always realised by those who benefit from an organisation which enables them promptly to obtain an ambulance almost anywhere in England and Wales by the use of a telephone that all this transport work is quite unpaid. Those who have volunteered for the work must submit to disturbance of their hours of business and to interruption of sleep. In fair or foul weather the ambulance call must be answered without delay. Those who give first-aid service on the roads surrender their holidays and week-ends to the task of helping the injured or to the even more tedious one of waiting prepared for accidents. The report points out that too often these highly skilled, yet unpaid, services are accepted as a matter of course and receive but scant reward in the way of praise and thanks. A recent development of the activities of the Home Service Ambulance Committee is the mobile X ray service which, though primarily designed for use in and around London, has occasionally been called upon to go as far north as Cumberland. It is admitted that a poor or indifferent X ray photograph is almost worse than none at all, and it has been the object of this X ray service to achieve and maintain a very high standard of results. Many small hospitals, whose finances do not permit of the installation of satisfactory plant, take advantage of this service. Arrangements have been made with the British Institute of Radiology whereby the films produced by the mobile X ray plant together with the history of the case are submitted to a consulting medical member of the Institute whose considered opinion is forwarded with the radiograms to the doctor in charge of the case. The mobile apparatus can be converted from a diagnostic into a treatment unit in a few seconds, and in the event of any breakdown a second car fully equipped can be put on the road without delay. The Home Service Ambulance Committee and the helpers inspired by the central organisation deserve the utmost credit for the inauguration and development of a service of national importance.

SOME MALARIA INVESTIGATIONS IN AFRICA.

AN antimalarial Commission was founded in Egypt in 1916 to ensure such coördination between various Government Departments as would make for progress in a campaign against malaria. Following a preliminary report issued in December, 1918, its first report,[1] dated 1928, deals with the period 1919 to March, 1925. It is a truism that no pipe distribution of water to a town within the area of malarial endemicity should be undertaken until a complete system of drainage to carry off all surplus water has been established, otherwise it will multiply anopheline breeding places and malaria will increase. On an immense scale this is just what is tending to happen in Egypt. The great extension of agricultural irrigation during the last two decades, with which agricultural drainage has not kept pace, has resulted in raising the water table and producing many outcrops of infiltration water. It is control of this infiltration water which constitutes the most difficult antimalarial problem in Egypt. Although by law rice culture, which implies irrigation, may now be interdicted within two kilometres of any town or village, it has been found more satisfactory merely to control it. The incidence of malaria has been ascertained by a wide spleen survey. The spleen index is generally low, infrequently over 5, but varying between 0 and 32, and often shows striking local differences; endemicity is greatest in the Suez Canal zone and in the oases. In the former, drainage and filling have been carried through with the cordial coöperation of the Suez Canal Company. The oases present a special problem. They are depressions in the Lybian desert, Siwa being indeed 55 feet below sea level with spleen-rates between 23 and 61, and watered by springs, either natural or flowing through deep artesian wells, with wooden shafts often reaching a depth of 450 feet. These springs, too, supply irrigation channels, the water finally reaching the nearest hollows and there breeding anopheles freely. When the antimalaria work began in 1916 the oases had just been recaptured from the Senussi. Soon they were brought within 12 hours by car of civilisation, so that the risk of diffusion of malaria into Egypt became considerable. In the two largest of them, with their population of 26,000 in scattered villages and with their peculiar levels, complete control of mosquito breeding proved impossible with reasonable expenditure; use has been made of the palliative filling of hollows, of quinine, and of the distribution of the fish *Cypronodon dispar*, a voracious feeder on mosquito larvæ, which was left behind when the sea receded in past ages. In Siwa, however, complete control has been possible, with a consequent fall in the spleen-rate from 23 to about a tenth of that figure; the birth-rate exceeds the death-rate, a condition new in the history of the place; and the trading Bedouin Arabs, who used to shun Siwa at night, now sleep in the village square. Another valuable publication by the Commission is T. W. Kirkpatrick's "Mosquitoes of Egypt," a monumental work which deals with the classification of over 30,000 specimens collected throughout Egypt and which will form a fund of information from which all who follow him will freely draw, when malaria control by "species sanitation" is more widely attempted in Egypt. In the Second Report,[2] the reconstituted Commission describe the continuation of their predecessor's work whose results in Egypt proper, for instance at Kom Omro, on the east bank of the Nile north of Aswân, have been of such striking value to a country in which most of them no longer work.

[2] Report No. 2. (1925–26). Pp. 20. Price P.T. 10.

At the other end of the continent, the South African Union's Institute for Medical Research has played its part in the Union's malaria problems by a mosquito survey in eastern and northern Transvaal, carried through by A. Ingram and B. de Meillon.[3] It is believed that the two main local carriers of malaria are *Anopheles gambiæ* (*A. costalis*) and *A. funestus*, particularly the former, since during an epidemic at Rustenburg, it was captured in houses, gorged with blood, and is much the more numerous of the two during the malaria season. Two observations, published since this report was made, suggest hesitation in accepting these conclusions. J. Schwetz[4] has shown in the Belgian Congo that the percentage of infected mosquitoes in his particular catches were, for *A. gambiæ* 18, *A. funestus* 4, *A. nili* 13, and *A. marshalli* 8. The two last are among the 14 anopheline species reported from the Transvaal, and have now to be added to the list of malaria carriers; so that when species sanitation is investigated in South Africa these two mosquitoes also will have to be considered. The second significant observation, by L. W. Hackett,[5] relates to malaria in Sardinia, where anopheline density during the malaria season was negligible, although two months earlier it had been heavy. When, then, it is noted of Brits, in the Transvaal, that during the malaria season of 1926 *A. gambiæ* and *A. funestus* were absent, it need not signify that they are not important local carriers, but it does show the vital importance of carrying a local survey over a whole year.

BIOPHYSICAL ASSISTANTS.

WE are glad to see that the Society of Apothecaries of London, at the instigation of the British Medical Association, is taking steps to establish a roll of persons of guaranteed training and competency to whom medical men can confidently issue prescriptions for treatment by electricity or irradiation. An approved course of training will be required of all technicians who desire to be placed on the register, and all applicants after May 31st, 1930, will be required to pass an examination; the details of the requirements in these respects have not yet been issued. Meanwhile, following the tradition of similar schemes of qualification, technical assistants of approved standing and experience may be admitted to the roll, the main requirement being two or three years' practice in an approved institution. This is by no means an extravagant demand and it may possibly prove to be too lenient. Registered members on the roll will on their side undertake to conform to various professional obligations, the most important being that they will not undertake the treatment of any patient except under the direction and control of a registered medical practitioner.

The mechanical and technical apparatus of medicine has become so complicated that there is bound to be a progressive movement in the direction of this scheme for technicians of biophysics—a queer name, though it is hard to think of a better one. Pharmacy has long since shown the way and has realised a high and rising ideal. The clinical laboratory is catered for by the Pathological and Bacteriological Laboratory Assistants Association which, in collaboration with the Pathological Society, issues certificates of proficiency to technical assistants who can satisfy stringent requirements of training and knowledge, tested by examination. This association is of particular interest because it was founded by the assistants themselves without any very clear demand from outside, and it has progressed to its present position of authority and usefulness along the lines of an old-fashioned trade-union. In some ways this seems to us a rather better plan than that undertaken by the Society of Apothecaries. Once the right standard is set, the members of a technical association may be trusted to guard their qualifications as jealously as any outside body, and we hope that in the end the biophysical technicians may have a large share in the conservation of their own roll. In any case we wish the movement success, and look forward with interest to the publication of the conditions of training and examination which will come into force next year.

THE SALFORD V.D. SCHEME.

IMPORTANT changes in the scheme whereby the city of Salford attempts to cope with the venereal disease problem were made on April 1st, 1928, and the report of the first nine months of work has now been issued by the medical officer then appointed. From 1917 till April, 1928, a treatment centre was housed in the out-patient department of Salford Royal Hospital. It was open only on four days a week for a limited time, though intermediate treatment could be obtained daily during one hour by women and during two hours on three days in the week by men. The medical officers, four in number, attended during 12 hours each week on a part-time basis, and there was no official director. The municipal clinic established last year to replace this centre was placed under the supervision of Dr. E. T. Burke, who is responsible to the medical officer of health. Dr. Burke works on a whole-time basis, as does also the assistant V.D. medical officer, Dr. F. W. F. Purcell; they attend the clinic for at least 60 hours per week. It is open for five days from 8.30 A.M. till 8.30 P.M. each day, on Saturdays for 5½ hours in two separate periods, and on Sundays for 6 hours in two separate periods. The clinic is housed in premises specially arranged and equipped for venereal disease work alone. Six beds are already available for in-patient treatment, but more beds are said to be required. The main principle of the clinic as now organised is that the unit to be treated is not the individual but the family. Thus, if a child is suffering from venereal disease, every effort is made to get the parents and other members of the family to attend for examination and, if necessary, for treatment. Statistics are given to show that the number of cases dealt with in the nine months (1220 new cases, 35,503 total attendances, and 26,155 intermediate attendances out of a population of 247,600) compares favourably with that of other treatment centres concerned with a similar size of population. Dr. Burke attributed the immediate success of the clinic to the fact that the treatment is given in an institution specially organised for the purpose by a staff of workers whose whole time is devoted to their duties. In his view such a clinic is more able to render efficient service than one attached to a general hospital, and the patient is quick to realise the fact. When there is a medical school in a town it is essential that the clinic should be within the teaching hospital, but he holds that it should be a distinct department and not a mere annexe to the general out-patient department. It should be linked up with the other teaching activities of the school, and the medical officer in charge should have the full status of honorary member of the staff. The question of defaulters is discussed in the report. During the nine months under review 433 letters were sent to patients who had ceased their attendance at the clinic prematurely—that is, when their superficial and obvious symptoms had disappeared, but before they were officially discharged. These letters brought just under a third of the defaulters back to the clinic, and of these, 116 are still attending. Twenty-eight of those returning have since been discharged, 6 were transferred, and 10 returned for a period only. Six reported that they were under their own doctor, and 13 gave other causes for their absence. Of the rest, 118 had given wrong addresses, and from 137 no reply could be obtained. Examination of the case cards of all the defaulters showed that 71 individuals ceased attendance while still in a highly infectious state. In Dr. Burke's view the demand for some powers of compulsion to ensure that all persons suffering from venereal disease shall submit to treatment and shall continue with it until they are not infectious is increasing, and he holds that the question of compulsory treatment, not compulsory notification, is one which must soon claim serious attention by local authorities, for at present a great deal of the money spent is being wasted by the defaulter. The objections to the institution of compulsory treatment for one set of diseases alone, and the difficulty of deciding on a standard of cure for syphilis or for gonorrhœa acceptable to the profession as a whole are not discussed by Dr. Burke, whose enthusiasm for the unfettered development of the campaign against venereal disease may blind him to the wider issues involved. It is satisfactory to note that the laboratory reports performed by Dr. G. J. Crawford, the city bacteriologist, have always run parallel with the clinical findings, and expectations have been of inestimable value in the diagnosis and in the control of treatment. When the clinic was opened, an invitation was sent to every practitioner in the city to inspect the premises, and it was also pointed out that by attending at the clinic for tutorial purposes a practitioner could qualify for the free issue of arsenobenzol compounds with which to treat cases of syphilis. So far only one practitioner has availed himself of this privilege. Certain practitioners, however, make full use of the facilities provided for diagnosis and treatment. Routine courses of treatment for the various stages of syphilis and gonorrhœa are set out in the report, though it is noted that the routine for gonorrhœa is at present undergoing revision. The criteria of cure adopted at the clinic for syphilis, except neurosyphilis, are as follows: (1) Iodides are given for two weeks preceding each Wassermann test. (2) A negative blood Wassermann should be obtained every three months for one year after the cessation of treatment. Two years after the cessation of treatment the blood and cerebro-spinal fluid must be negative after provocation.

THE ANTIVIRUS OF BESREDKA.

THE communication, reported in THE LANCET of last week, which Prof. Besredka had made in absentia to a section of the Royal Society of Medicine was somewhat sharply discussed by many of those present. It was unfortunate that Prof. Besredka was unable to reply to his critics in person. Besredka's recent work has been concerned with two distinct issues which unfortunately have become rather confused: (1) the value and use of local inoculation and the extent of local immunity; and (2) the possible prophylactic and therapeutic value of the substance he calls antivirus, which is, in effect, a filtrate of broth in which organisms have grown until for some reason or other their existence has terminated and they have begun to die out. This decline is an invariable phenomenon in bacterial growth and has not unnaturally been attributed to the exhaustion of food substances which, of course, must be a contributory factor. It is more than possible, however, that this is not the whole story, since such exhausted media will often readily support organisms of another species and sometimes those very closely though not specifically related to the first organism. Besredka assumes the production of a specific substance in the course of bacterial growth which acts inimically upon the organism and finally inhibits it. This is his "antivirus," and to it he attributes a very definite therapeutic value. The other matter, which occupied Besredka's attention at an earlier date, is the important question of local immunity and the possibility of local inoculation—whether, for example, immunity to anthrax is a special function of the covering layer of the body, or a general function through all its tissues and, similarly, whether immunity to local intestinal disorders, such as dysentery, can be obtained by local application to these same tissues as effectively or more effectively than by the better known process of subcutaneous inoculation. This is a very wide and important problem of which the bearings are not yet by any means worked out. Certain experimental work, especially that upon the virus diseases, strongly suggests that tissue affinities are important functions in determining infections and that their relation to immunity is therefore of great importance. Unfortunately, in Besredka's more recent writings and in the minds of many of his readers, these two distinct and separate issues have become blended and confused. The question of local immunity, which is essentially one capable of experimental investigation, has become shrouded with the obscurity attendant upon the evaluation of clinical results obtained by the use of antivirus in treatment. This last, as Besredka's critics have rightly pointed out, is a matter for clinical judgment and opinion, and therefore from the scientific point of view is much more difficult to handle than the clearer problem of local resistance and immunity. The confusion of these issues, which to our mind should at this stage be considered separately, has arisen from Besredka's belief that the direct application of his antivirus to the tissues will promote a local immunity such as in his earlier work he claimed to result from the application of living organisms. Prof. Besredka has not produced sufficient evidence to convince us that his antivirus has the power he believes it to possess, but obviously the only satisfactory method of determining its activity is that of actual and extensive clinical trial. Nor should the wider problem of estimation of the influence of site and tissue constitution upon susceptibility to infection, which his work so largely involves, become obscured in any controversy on therapeutic results, since its development is of fundamental importance to the whole of medicine.

TRAINING OF GENERAL PRACTITIONERS IN TUBERCULOSIS.

IN most countries the experts in tuberculosis complain that the general body of medical practitioners do not get properly trained in the diagnosis and treatment of tuberculosis in its various forms; and these complaints are not without justification. Dr. S. Vere Pearson at the Zürich meeting (which we report elsewhere) set out the chief reasons for this neglect of what is still a common disease in spite of the decline in its incidence. These are two-fold: (1) the lack of clinical material in most of the teaching hospitals; and (2) the absence of teachers interested in and expert at the diagnosis and treatment of this malady. In England and in many other countries tuberculous patients are excluded from the wards of the teaching hospitals, even more than they used to be twenty years ago, owing to the fact that the diagnosis and treatment of tuberculosis in its various forms has come into the hands of those medical officers who are managing the State medical services specially devised to deal with this disease. Occasional exceptions are to be found, the most brilliant being in Scotland, where the influence of Sir Robert Philip has brought about a better state of affairs. In the University medical schools of Edinburgh and Glasgow practically all the students go through the tuberculosis department and receive instruction in this specialty. Another exception is afforded by the few teaching hospitals which have a tuberculosis department (it may be a dispensary under the public health tuberculosis schemes also) attached to them, as at St. Thomas's and Guy's Hospitals in London. Again, at Manchester there are two University teachers who are expert in tuberculosis, one of whom is also an officer under the public health authority. Dr. Pearson admitted the overloading of the medical curriculum with subjects, the teachers of which are clamouring for recognition, but he contended that no disease is better suited than tuberculosis for teaching those principles of hygiene and medical practice which should form the foundation of a medical education. Nevertheless in England and in most other countries where there are special post-graduate courses in tuberculosis, these courses are not, as a rule, attended by general practitioners, but by those who are already in this specialty or about to take it up. Grants of money are made out of the funds of the local authority, supplemented to the extent of 50 per cent. by central funds towards the expenses of such courses for medical officers attached to the public health service. But so far as Dr. Pearson has been able to ascertain, no country save Norway (the province of Bergen) has allotted money from public funds to subsidise general practitioners to gain a knowledge of sanatorium treatment. The result is unfortunate in producing a feeling of grievance among general practitioners that the treatment of tuberculosis has been taken out of their hands.

THE EVOLUTION OF PÆDIATRICS.

Of the many factors which have modified the scope and the activities of the general physician in the present century, one of the most potent has been the evolution of pædiatrics as a specialty. Those who were privileged to hear Dr. F. J. Poynton's presidential address on May 24th to the Section of Disease in Children at the Royal Society of Medicine were given an interesting survey of this process in the past, together with some shrewd deductions about its effect upon the future. Taking as his subject Some Phases in English Pædiatrics as Viewed by a General Physician, Dr. Poynton did not approach it in the spirit of a mere laudator temporis acti, but extended to those who follow him an appreciation no less generous than his tributes to the teachers from whom he acquired his art. He depicted the contrast between the work of the physician at the close of the last century and at the present day, both in respect of the material at his disposal and the problems which it presented to him. In former times opportunities for clinical observation were exceptionally great; a vast amount of material was available; epidemic diseases were the cause of an enormous mortality, and the nature of many common children's diseases was as yet unrevealed. The physician of this time could thus acquire a broad outlook on disease, and get an idea of the value of detailed observation. His knowledge and methods were individual; hence it is not surprising that some of the greatest teachers of clinical medicine belonged to this period. Their discoveries were the result of wide experience, combined with that power of careful observation and criticism which belongs to the highest order of intelligence. Cheadle's recognition, in 1878, of the identity of infantile scurvy with the adult form, which he had observed during protracted journeys in Canada, was an instance both of the opportunities and the achievements of his time. Nowadays, a large amount of clinical material has been removed as a result of advances in treatment and prophylaxis, while the process of specialisation has made it impossible for the physician to carry out more than a portion of the necessary investigations. The sciences of bacteriology and biochemistry, having new ground to break, have made comparatively greater advances, and a tendency has arisen to regard "research" as belonging more properly to the laboratory than to the bedside. The physician has to some extent been driven to shift his ground, and become a collector of uncommon cases rather than an investigator of those which are of greater importance to the community.

While he recognises that specialisation is bound to increase, and that methods of investigation and research must reach a complexity which will place them still further beyond the attainments of any individual, Dr. Poynton maintains his faith in the continued utility and fruitfulness of clinical observation, and supports its claim for recognition as an important element of research. The interaction of the organs of the body will always make it imperative that the body should be studied as a whole; if the greater number of physicians become increasingly absorbed in pursuing special lines, it may come to pass that the real "specialist" of the future will be the physician who has knowledge of general disease.

In considering the changing position of the pædiatrist who is a member of an honorary hospital staff, Dr. Poynton discussed with great acumen the problems which arise from his relation with the public services, such as the municipal clinics and the Ministry of Health. Children, more than any other section of the community, are a concern of the public services, and already there are signs of some difficulty in apportioning the exact functions of the clinics under the direction of the local authorities and of the childrens' hospitals. Theoretically, the one may be intended for the supervision of normal children, and the other for the treatment of sick ones, but in practice the distinction is not easily drawn. From the point of view of the public, there is much to be gained from the development of these services, and the pressure of public opinion will compel the Ministry of Health to extend its activities. In combating chronic diseases such as rheumatism, in which the child must be under observation and periodic treatment for a number of years, Dr. Poynton thinks that collaboration between the hospitals and the public authorities should be particularly fruitful; yet there is always danger of diminished efficiency resulting from lack of continuity in the methods of treatment adopted. The medical advisers of the public services will provide a highly organised machine for prevention and treatment of disease, but medical teaching, he said, is not a natural product of organisation, and must be provided by a body such as the children's hospital, maintaining its independence but ready to collaborate and advise. An important part in the maintenance of unity and coöperation between these two groups of pædiatrists might be played by the Section to whom this address was delivered, which includes representatives of public services and of hospital staffs, but is independent of both.

OHARA'S DISEASE.

Dr. Hachiro Ohara has recently reported two cases of tularæmia in a father and son who infected themselves by skinning and dressing a rabbit. The special feature of these cases was that in both the primary site of infection was in the nostril, with local swelling and inflammation and enlargement of lymphatic glands. Ohara recalls that he independently described cases of tularæmia and experimentally transmitted the disease to human beings in 1925. Francis and Moore suspected that these first cases described by Ohara were of the same nature as tularæmia which had been very thoroughly investigated in man by McCoy and Chapin in 1910, by Wherry and Lamb in 1914, and by Francis in 1919 and in a number of subsequent studies in the United States. Francis and Moore proved the identity of the disease in Japan and America by obtaining agglutination of *Bacterium tularense* with serum from Ohara's cases which he had sent at their request. The clinical form taken by cases of tularæmia is very varied on account of the different means by which infection is acquired and the different sites of inoculation. "Deer-fly fever," in which the primary lesion was on the neck or other exposed part, was known and believed to be due to the bite of *Chrysops discalis* before Pearse described cases in 1910. In the United States 407 cases had been described by 1927 and four types of the disease had been noted. In three of these types there was obvious glandular enlargement which was associated with a papule or ulcer on the skin in 272 cases, with a primary lesion on the conjunctiva in 25, and with no recognised primary lesion in 16; the fourth type was described as typhoidal in nature without glandular enlargement and was observed in 24 cases. The disease in man is most commonly due to handling and skinning infected rabbits and hares. It is said to occur over a considerable area in Japan and is very widely distributed in America but so far is unknown in Europe. *B. tularense* was discovered by McCoy and Chapin in ground squirrels in 1912. Francis has summarised the history of the disease in the De Lamar lectures for 1926-27. He points out among the special features of the disease that it is extremely infectious, especially for laboratory workers, that the serum of patients agglutinates *Bacillus abortus* and *B. melitensis* as well as *Bacterium tularense*, that the bacterium can penetrate the uninjured human skin and that the number of species of naturally susceptible animals and of insects which can act as vectors is very large.

ESSENTIAL THROMBOPENIA TREATED BY LIGATURE OF THE SPLENIC ARTERY.

It is agreed that certain conditions characterised by a tendency to hæmorrhage can be either completely cured or greatly improved by removing the spleen. The rationale of this treatment was set out by Dr. W. Cramer in our issue of May 18th (p. 1048), and it is sufficient for our present purpose to recall that a clinical entity is now recognised in which the purpuric hæmorrhages are associated with and presumably due to a primary thrombopenia caused by an excessive destruction of the blood-platelets by the spleen. Owing to the condition of the patients in this disease there is a considerable operative risk involved in treatment by splenectomy—a fact to which we drew attention in a leading article in the same issue. It has, therefore, been suggested that a less severe operation should be substituted for it—namely, ligature of the splenic artery—and in a recent paper F. van Goidsenhoven[1] reports the results in two acute and ten chronic cases of the disease. The clinical histories, which are given in detail, seem to justify the author's conclusion that the therapeutic effects of the two methods of treatment are essentially the same. The minor operation is, therefore, clearly indicated when the condition of the patient is so bad that the major operation would involve serious risk. Van Goidsenhoven doubts whether removal of the spleen has *any* therapeutic advantages over ligature of the splenic artery and pleads for a more extensive trial of ligature to decide this point.

CHORIONEPITHELIOMA IN A MALE.

The puzzling manifestation of malignancy described as chorionepithelioma in a male is so rare that every case is worthy of record. Dr. J. Tansey and Dr. L. Utz, of Sydney, describe[2] such a case which occurred in a young man aged 25. The primary site of this type of tumour is usually the testis, but in the present case the testes were normal, though small, and the site of the primary tumour was in the left lung with numerous metastatic nodules in the right lung. The tumour nodules were hæmorrhagic and microscopically presented the appearance of a chorionepithelioma, both syncytial cells and Langhans cells being observed. These features are illustrated by microphotographs. It is interesting to note that there was enlargement of both breasts, and it is stated that sections of the breast showed "well-marked acini, dilated ducts, and some evidence of chronic mastitis." The disease developed very rapidly with pain in the chest, general weakness, and loss of weight. A fortnight after the first onset of pain there was a brisk hæmoptysis and in a little over two months the patient died. There are obvious difficulties in accounting for the origin of this tumour, especially as there was no evidence of teratomatous elements elsewhere. The explanation given by the authors is based on the well-known observation of Schmorl that chorionic cells may frequently be found in the pulmonary capillaries of women who have passed through a normal pregnancy. The authors ask: "Is it too much to expect that these same cells could occasionally enter the fœtal circulation and lodge in the pulmonary circulation of the fœtus?" They do not, however, stay for an answer, and at once proceed to assume that these cells remain there as "chorionic rests," which later undergo a malignant transformation. It seems simpler to make the admission that no adequate explanation of such a condition can at present be given if it is certain that the malignant tissue is derived from chorionic cells.

HOSPITALS AND THE KING'S RECOVERY.

Hospital Sunday falls this year on June 2nd, and the Lord Mayor of London, as president of the Metropolitan Hospital Sunday Fund, has sent a letter to clergy and ministers of all denominations suggesting that collections taken in the churches on that day should form part of the national thank-offering for the King's recovery. The whole of the amount paid into the Hospital Sunday Fund collection will be distributed to the hospitals and charities of London in the usual way, but on this occasion the part played by medicine and surgery in His Majesty's restoration to health will be in everyone's mind, and it is hoped that the general gratitude will find expression in an especially generous response to the annual appeal. A further opportunity for supporting the voluntary hospitals will, of course, be given to the public on Sunday, June 16th, the day appointed for national thanksgiving in the churches. It is proposed that the proceeds of offertories on that day, too, should go to the hospitals, and in order that all the people, whether churchgoers or not, should be invited to contribute, the British Hospitals Association has asked Lord Mayors and mayors throughout the country to appeal in the press for the benefit of their local institutions, making it clear that those who respond are taking part in the national thanksgiving. The lists in the provincial press are to be closed on Saturday, June 15th, so that the total amount collected by this means and through the churches may be announced early in the subsequent week. Donations intended for London hospitals may, if desired, be sent directly to King Edward's Fund for London, Worcester House, Walbrook, E.C.4, whilst those destined for hospitals elsewhere may, if desired, be sent to the President of the British Hospitals Association, at 19, Berkeley-street, W.1.

THE SUPPLY OF DENTAL PRACTITIONERS.

At the final session of the Second Dental Board its Chairman, Sir Francis Dyke Acland, spoke feelingly of the supply of dental practitioners. Ever since the Board completed its arrangements for the Dentists Register and was free to settle down to its proper work, it has devoted itself as a primary object to giving facilities for a larger number of students to enter the dental profession. It began by enabling 144 ex-Service men to continue courses of training which they had entered upon with the help of grants from the Board of Education and up to the end of last March the Dental Board had awarded 348 other bursaries. At that date 247 of these 492 assisted students had qualified and 213 of the new diplomates are known to be satisfactorily settled in practice. The Board has also made loans of a total amount of nearly £3000 to 51 students in the final stages of their courses and of this money some £2300 has been repaid. Seven years ago Sir Francis propounded the following question: if before the war the annual entry of about 250 students maintained a practising list of about 5000, how large an annual entry will be required to maintain a practising list of about 13,000? The Dentists Register now contains about 14,000 names, while the annual entry to dental schools is only about 250. If the Register is to be maintained at this number with so limited an entry the average practising life of a dentist, as Sir Francis pointed out, must be extended to over 70 years, which, as Euclid might have said, is absurd. The truth is that an annual entry to the dental schools of well over 500 is required to keep up the Register. The anxieties of the retiring chairman of the Dental Board will be shared by many who are equally concerned with him for the dental health of the nation, although they may not have the accurate information which has brought the Dental Board to this conclusion.

---

[2] Medical Journal of Australia, March 30th, 1929.

THE WELSH NATIONAL MEDICAL SCHOOL.

THE renaissance of the Welsh National Medical School is likely to be the outcome of the final discussions between the Cardiff Royal Infirmary and the University College of South Wales and Monmouth, which are taking place as we go to press. The basis of the agreement is that the unit system is to continue unchanged, but that the clinical curriculum of the students will be settled by a Board of Clinical Studies on which the infirmary staff will be adequately represented. It would serve no good purpose to recapitulate the events which led to the disruption of this school at the very moment when its status had been settled and its active development was to be anticipated. But confidence in the future of an institution which aspires to the dignity of a national medical school will only be restored if the conditions of the agreement include a substantial guarantee of stability. The success of any teaching school must ultimately depend on the goodwill of individual members of the hospital staff, and their willingness to coöperate in the educational side of the hospital's work must be assumed when they undertake the charge of patients within its walls. It is our sincere hope that any arrangements made for the reopening of a clinical school in Cardiff will be founded on a firm basis and that such provision will be made for the adjustment of future difficulties of organisation as will at least safeguard the interests of the students.

IN the General Election which is taking place as we go to press 37 medical candidates are submitting themselves for election. A candidate whose name has not yet been mentioned in our columns is Dr. John Fraser Orr, a general practitioner in Winchburgh, who is standing as a Liberal for Linlithgowshire.

Major-General H. B. Fawcus has been selected to succeed Lieut.-General Sir Matthew Fell, who is retiring at his own wish, in September next, from the post of Director-General, Army Medical Services. Colonel W. R. Blackwell, late Royal Army Medical Corps, will succeed Major-General Fawcus as Deputy Director-General, Army Medical Services.

Two important benefactions to medical schools have been announced this week. Lord Beaverbrook has undertaken to pay £63,000 to St. Mary's Hospital Medical School in seven annual instalments, while the Edinburgh University Court will receive £20,000 from the trustees of the late Sir William Dunn, and £35,000 from the Rockefeller Foundation towards the internal reconstruction of buildings at Teviot-place, Edinburgh.

GROSVENOR HOSPITAL FOR WOMEN.—The new nurses' home at this hospital in Vincent-square, Westminster, was opened recently by Princess Louise, Duchess of Arygle. Last year 524 patients were admitted. The annual report points to the average length of stay of 20·5 days as illustrating the serious nature of the operations, and it is recalled that the King's Fund statistics show that, in comparison with similar institutions, the Grosvenor Hospital is the lowest in cost per bed.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXXII.—PYELOGRAPHY.

WITH ILLUSTRATIVE PLATE (*Facing p. 1135*).

THE practice of filling hollow cavities—viscera, sinuses, &c.—with shadowgraph media and obtaining on an X ray plate a silhouette photograph, has constituted one of the most remarkable of modern advances. When employed to outline the renal pelvis it is termed pyelography and this form of examination has become one of the most valuable of the numerous diagnostic weapons now at the disposal of the urologist. It has actually been available for nearly 20 years, but the fact that until comparatively recently the recognised solutions have involved some element of risk to the kidney has restricted its employment to the most difficult cases. Safer media are now happily available and pyelography is freely undertaken in almost all types of renal disease and also, where symptoms are anomalous, for the purpose of excluding renal disease. Its use is to-day almost ubiquitous and indeed in the absence of facilities for pyelography the standards exacted by modern urology cannot be satisfied.

Technique.

A ureteric catheter is passed up one or both ureters as considered advisable. It is radiographically opaque so that it may be identified on the X ray plate and thereby show—

1. Its relationship to shadows seen in any previous radiogram.
2. How far it has been passed, and to what extent, if any, it has been responsible for the production of any displacements or kinks which may be seen in the ureter.
3. In the event of its having failed to reach the renal pelvis, whether this failure may result from kinks or other obstruction and whether it may account for any difficulty experienced in filling that structure.

Small catheters are selected as an additional precaution against over-distension of the kidney. They do not completely fill the ureter and therefore any excess of fluid can find a ready egress along the side of the catheter. On many plates peristaltic waves of this fluid may be observed passing down the outside of the instrument and thus producing a ureterogram.

A 13·5 per cent. solution of sodium iodide as recommended by D. F. Cameron is the most popular medium. It has good opacity, is non-irritating, non-viscid and, except in highly susceptible persons, is non-toxic. It is easily sterilised and has an osmotic pressure similar to that of the urine. I inject with a record syringe and this, if used with care and a knowledge that over-distension is to be avoided, is a perfectly safe method and has the great advantage of simplicity.

The operation is performed without anæsthesia in the female and under sacral anæsthesia in the male, a general anæsthetic being contra-indicated first, because the sensations of the patient are the best guide to when the danger point of distension has been reached, and secondly, because it is imperative that the patient shall hold his breath during the taking of the radiogram. Otherwise the picture will be blurred and a blurred image often leads to misinterpretation. The fluid is injected very slowly and the patient is asked to say if any abnormal sensation is experienced. In order to avoid apprehension on the part of the patient, one never refers to it as pain, and to eliminate suggestion the anticipated site is not indicated. Dilatation should be continued to the point of mild discomfort, but it must be remembered that the pain of pelvic distension (which is colicky in nature) has a long latent period so that if the injection is made too rapidly the correct point may be passed before the patient experiences any discomfort. When discomfort is acknowledged the patient is interrogated to discover if he recognises this as comparable in type or situation to that which he has previously experienced (if any).

Till recently I admitted most patients to the wards for pyelography, but now am more prone to save time and beds by undertaking it on the same occasion as the routine cystoscopy in the out-patient department and our patients have not thereby suffered any untoward experiences. After the bladder has been examined it must be decided whether the ureters shall be catheterised with large catheters for the purpose of separating the urines or with small ones for pyelography. The two operations should not be performed with the same catheters. If, however, the dye test will serve to estimate renal function it is well to employ it, and before the vesical medium is too discoloured a catheter is slipped into the ureter. In this way we combine the advantages of a dye test, which is usually sufficiently accurate, with those of a pyelogram.

The Normal Pelvis.

There are many variations of the normal pelvis but Fig. 1 is selected as particularly characteristic. Its trumpet-like contour and the calyces which adorn its outer margin are well seen. In the most usual type the triangular shape of the pelvis is well marked, and it receives above the upper calyx, below the lower, and at a point near its centre one or more shorter ones. The goblet-like shape of the calyces is here beautifully portrayed, notably in the upper member of the middle group. The primary or major calyces—i.e., the main stems adjacent to the pelvis proper—follow the common arrangement in being thicker in the upper and lower calyces and finer in the middle groups. The secondary or minor calyces are formed by the expanded extremities of the primary ones and are moulded over and receive the apices of the renal papillæ. In this instance they are multiple in the upper and lower groups whilst the middle ones are duplicated. This, however, is not constant as may be seen by examining other films.

Some calyces lie in the antero-posterior plane. They then appear end on, so that the major calyx, always actually short, vanishes entirely and the minor is seen as a circle. Such a minor calyx is shown in the lower pole of Fig. 1. If stereoscopic photos are obtained it can be ascertained whether these face forward or backward and the impression produced is that of looking into the depths of the chalice.

Emphasis has been laid by some writers on the regularity and shapeliness of the sweep made by the junction of the lowest calyx and the ureter, the so-called uretero-calycine curve. An examination of a series of normal pelves will show that this curve is variable and I personally attach little value to its appearance.

Dilatation.

It is convenient to discuss the results of renal distension before touching on congenital deformity. With a long narrow exit like the ureter it is not surprising that the outlet is prone to obstruction. If the obstruction is of more than fleeting duration an impress is left on the kidney which can be recognised pyelographically. Evidence of renal distension is extremely common when looked for by this examination. It results from intra- or extra-ureteric blockage and from plugging of the pelvic outlet however caused. The symptoms which it produces constitute the syndrome known as renal colic. When a patient complains of colic, stone is the explanation which jumps to the mind. It is the provisional diagnosis which usually accompanies him when he is referred to the surgeon for investigation. Yet it is actually one of the less frequent causes of colic, a fact which is insufficiently realised by the profession. Renal colic denotes renal distension and may be due to stone but is more probably due to some other cause, that cause being as a rule recognisable by pyelography. This was the province to which pyelography was first applied.

Figs. 2 and 3 show X rays of minor degrees of pyelectasis. The minor dilatations produce pain not less in severity than the greater ones, for behind them lies the full production of a kidney in nearly complete vigour, whilst behind the major ones is in many instances a mere shell of renal parenchyma. The latter can, moreover, be felt as tumours in the loin, whilst the former are too small to be palpated and can indeed be diagnosed by no other method than pyelography, for even at exploratory operation they are liable to be overlooked in so far as the distension occurs within the renal sinus and therefore out of sight. Pyelography thus assumes great importance in these early cases.

The effects of distension are well seen in Figs. 2 and 3. The former is from a movable kidney with pyelectasis. Note that the calycine extremities have become expanded, that the cupping has disappeared, and the concave outline has been replaced by a convex one (clubbing), whilst the major calyx has lost its customary slight waist. In this as in most other examples of early renal distension the incidence of pressure has shown itself to be most effective on the renal poles, the middle calcyes retaining their distinctive shape for a longer time. Fig. 3 was from a case in which infection played a part. When this happens dilatation may result from one or more of the following factors:—

(1) Simple mechanical dilatation from plugging of the outlet with inflammatory products.

(2) Ulcerative processes occurring at the apices of the papillæ.

(3) Abscesses originating in the parenchyma which on bursting into the pelvis retain some communication with that structure. This is best seen in the case of tuberculous disease (in which disease, however, I consider pyelography to be contra-indicated).

(4) Inflammatory weakening of the pelvic wall.

The effects of inflammatory dilatation are more polymorphic than those of simple dilatation and would be more difficult to interpret were it not for the fact that the clinical recognition of the renal infection assists in the interpretation of the pyelogram even more than is the case with other diseases.

Observe how the catheter has curled itself up in each pelvis. The diagnosis of a dilated kidney is often suggested by a catheter passing further than usual as occurred on the right side in this patient. The left kidney is a normal one but is not completely filled with solution.

Renal Stones.

The two following illustrations (Figs. 4 and 5) have been selected to show the advantages of pyelography in cases of renal stone. When a previous X ray has shown a shadow, its relationship to the urinary tract may be displayed by pyelography. If the shadow has a doubtful origin X rays in inspiration and expiration or stereoscopic plates may then decide its exact situation. Fig. 4 shows multiple renal stones on the right and a large hydronephrosis on the left side. Three renal stones had been diagnosed by a previous X ray. By overlaying the plates their position is identified and is dotted in on this plate. The right kidney pelvis is quite definitely distended as a result of being occupied by stones. At cystoscopy indigo-carmine was delayed to 7 minutes on the right side (3½ to 4½ minutes is the normal time before excretion) and was then feebly excreted, but on the left side no dye was observed during 15 minutes. Bilateral pyelography showed the relation of the three stones to the kidney pelvis. On the left side there is a very large hydronephrosis, the lower limit of which is identified by the transverse trickle of fluid opposite the bottom of the third lumbar vertebra. The rest of the solution has gravitated to the sump of the hydronephrosis where it has formed a pool. The size of the sac can be surmised. It has a vertical measurement of not less than 4 lumbar vertebræ. Only 7 c.cm. of sodium iodide solution were employed on the left side in making this film and no further distension was attempted as the diagnosis was thereby established. Had more fluid been used it might have had the effect of provoking an attack of retention in the hydronephrosis with undesirable consequences. An X ray taken three days after this one showed the sac to be clear of sodium iodide. Large sacs can generally be adequately recognised without fully distending them and it is better to avoid such distension. Fig. 5 shows a stone in a horse-shoe kidney. This discovery of the kidney deformity was invaluable as it forthwith became evident that the kidney could not be elevated on to the loin. The plate shows a low-lying, misshapen, dilated pelvis, situated abnormally close to the mid-line and showing calyces facing inwards. The ureter crosses the lowest calyx. These features are all characteristic of this deformity. Calyces lying to the inner side of the ureter always suggest a horseshoe kidney.

Duplication of the Ureter and Renal Pelvis.

Fig. 6 shows duplication of the ureter and renal pelvis. Catheters occupy each ureter. This pelvis is true to the invariable rule that the upper pelvis is smaller, often rudimentary, and has few calyces, whilst the lower is more complete, larger, and has better formed calyces. Congenitally ill-formed organs are quite common; they occur in about 3 per cent. of bodies. They are, however, found with undue frequency in urological practice as their abnormality appears to render them disproportionately susceptible to disease.

Renal Neoplasm.

In Fig. 7 a large renal neoplasm has developed in the upper pole of the kidney. The pelvis occupies a position opposite to the iliac crest, having been displaced downwards by the overlying growth. The upper and middle calyces and the upper part of the pelvis have been occupied by the neoplasm and are missing on the pyelogram. Deformity in renal growths varies according to the site of the growth, for instance, if the lower pole is involved it is the lower calyx which first disappears. The kidney then retains its normal position, but the ureter may be displaced inwards by the tumour.

Congenital Cystic Disease.

In congenital cystic disease (Fig. 8) the pyelographic deformity has much in common with that caused by renal growth and the two may easily be confounded. The former disease, however, is always bilateral, so that cases of difficulty may be resolved by a double pyelogram, as also by renal function tests. In this figure, as in Fig. 6, a great enlargement of the upper pole, this time by cyst formation, has depressed the pelvis to the level of the iliac crest. Note how it has been deformed by the encroachments of cysts on its cavity and that one limb stretches out beyond its recognised bounds to serve parenchyma which has been dislocated by the cysts.

Conclusion.

For years we have been able to study separate renal function by various excretion tests and to collect the urine from each individual kidney and examine its organic and inorganic content. It is odd that the anatomical study of the pelvis of the kidney should have lagged behind these physiological and pathological studies, but now by pyelography we have made good the defect. The renal function and chemical tests will tell that a kidney is wholly or in part out of action but may omit to say why. The latter not infrequently rectifies this omission. Renal function testing and pyelography are mutually interdependent; they are sister examinations and of these the younger bids fair to win a place not less important than that held honourably through many years by the elder.

J. B. MACALPINE, F.R.C.S. Eng.,
Honorary Surgeon, Salford Royal Hospital.

INTER-STATE POST-GRADUATE ASSEMBLY OF NORTH AMERICA.

VISIT TO LONDON, MAY 27TH–29TH, 1929.

INAUGURAL ADDRESS.

THE session on Monday, May 27th, was opened by Sir JOHN BLAND-SUTTON who gave a short address of welcome to the delegates at the house of the Royal Society of Medicine.

It is ordained, he said, that I should welcome the members of this Assembly. In the autumn of 1927 I was present at the meeting in Kansas City, took part in the proceedings, and realised the importance of this great organisation. There never was a time when it was so necessary for medical men in active practice to keep themselves informed of the progress in the arts and sciences ancillary to medicine. The proud position of surgery is a consequence of discoveries in chemistry which supplied the means for inducing anæsthesia—the conquest of pain, which was the starting-point of modern surgery. The conquest of sepsis followed and helped to raise surgery from a craft to a beneficent art.

Improvements in the microscope enabled men to see the minute organisms which provoke disease in plants and animals, and revealed the astonishing fact that germs of disease and death lie hid in the smallest of living things and are conveyed to plants and animals by unsuspected carriers. The invention of clever instruments laid the foundation of specialties. Two of them were invented by non-medical men: the laryngoscope by a singer, Manuel Garcia; and the ophthalmoscope by a physiologist, Helmholtz. It is recorded that when von Graefe saw the fundus of the living human eye with its optic disc and blood-vessels, he flushed with excitement and exclaimed "Helmholtz has unfolded for us a new world." I spent a session in Arlt's eye klinik at Vienna in 1881 to acquire facility in using the ophthalmoscope. I foresaw that it would render valuable aid in the diagnosis of disease elsewhere than in the eye.

The incandescent lamp is a most useful clinical instrument. Any hollow organ in man's body can be illuminated by it. When watching a colleague rescue some false teeth from a woman's gullet with the aid of an œsophagoscope I suggested to him that the instrument required to be used by a surgeon with the instinct of a sword swallower and the eye of a hawk! The incandescent lamp was followed by X rays which render living bodies diaphanous and transformed the methods of dealing with broken bones. No surgeon who values his reputation and the patient's welfare trusts to tactile impressions in the detection of fractures. An X ray picture reveals such injuries to patients, friends, and solicitors as well as to doctors!

Our debt to optical glass is very great; photography requires flawless lenses. The progress of radiography leads us to believe that it may become possible to make cell-elements visible in human bodies as in the familiar experiment of watching red corpuscles whirling through the capillaries in the web of a frog's foot. When I was a boy microscopists wrangled about the shape of these corpuscles. To-day clinical observers describe almost as many varieties of erythrocytes as there are races of men.

Metchnikoff, a Russian biologist, discovered the defensive powers of leucocytes. His wife has described the simple way in which this discovery was made. Metchnikoff was at Messina and had been watching the mobile cells in the body of transparent star-fish larva, and the idea occurred to him that such cells might serve in the defence of the organism against intruders. To test this idea he took some thorns from a rose tree and introduced them at night under the skin of some beautiful star-fish larvæ—these larvæ are as transparent as water. "In the morning the thorns were surrounded by mobile cells as is to be observed in a man who runs a splinter in his finger." This simple experiment laid the foundation of phagocytosis, a theory to the development of which Metchnikoff devoted 25 years of his life. His first paper on phagocytosis was written in Odessa in 1883. He propounded his theory to Claus and other colleagues at Vienna, and asked a Greek equivalent for devouring cells. The name phagocyte was suggested and adopted.

In 1886 at the Royal College of Surgeons of England I delivered a lecture on Inflammation as a Zoological Process, and in the light of Metchnikoff's discovery I ventured to describe the action of leucocytes in relation to bacteria as amœbic warfare. In this room a year ago Dr. Canti showed an astounding film, a combat between phagocytes and bacteria. We may hope some day, with the help of X rays and the microscope, to detect the exotic fauna of the blood in living patients and watch trypanosomes, spirochætes, filariæ, and the like disporting in the blood stream, jostling erythrocytes like minnows and tadpoles in a brook. Young guinea-worms have been detected migrating through the subcutaneous tissue like eels wriggling in the grass seeking a pond.

It is an advantage, Sir John concluded, to meet annually and hear masters of the craft expound their methods. Operative procedures change so rapidly that text-books on surgery become like railway time-tables, useful only for a season. The meeting of the Inter-State Assembly keeps its members in touch with the almost kaleidoscope changes in every department of practice.

Dr. **JAMES COLLIER** then gave an address on

EPILEPSY.

A number of conditions, such as rickets and cranial injury, might, he said, give rise to a lifelong epilepsy indistinguishable from true epilepsy and manifesting every known phenomenon of epilepsy proper. Not one of these causes, however, invariably produced these convulsions, so that there must be some other determining factor. This was connected with the chemical processes of the body; all epilepsy was a disease of metabolism. The metabolic error might exist in birds, in all mammals and in man. There were three classes of individuals: (1) those in whom no sort of aggravation would cause epileptic manifestations; (2) those who would develop them more or less readily from any of the known causes, the potentially epileptic; and (3) those who developed epileptic manifestations spontaneously. The error was most likely to develop in infancy and childhood and least likely at the zenith of life; it might be now present, now absent, and could be removed by the metabolism of a second individual, as when the epileptic woman had no seizures during her pregnancy. It was very difficult indeed to make an animal or man epileptic by injuring the brain unless the individual were potentially epileptic to begin with. Only 4-10 per cent. of severe cerebral injuries during the war had resulted in epilepsy. Recent experiments had shown that one-seventh of the dose of wormwood oil required to cause convulsions in normal cats was sufficient to produce them in cats whose brains had previously been damaged, and that a minimal dose would produce strictly localised convulsions corresponding with a cerebral injury. There had been six cases of pre-frontal tumour at the National Hospital, Queen-square, ending in status epilepticus as sole symptom.

The stability of the hydrogen-hydroxyl ratio varied in different people, and convulsions had long been known to result from alkalosis. Occasionally patients being treated with alkalis would pass suddenly into status epilepticus with very high blood-urea but with normal chloride content of the cerebro-spinal fluid, thus excluding uræmia. Severe tetany—which was closely allied to epilepsy—might also occur in the course of alkali treatment. Epilepsy therefore might be produced by alkalosis, and if alkalosis were artificially induced in a series of epileptics of all kinds by hyper-ventilation, 60–80 per cent. of them would in half a minute have a convulsion, probably a severe one. Thus even temporary alkalosis was a potent exciting cause. In the same way tetany could be provoked at will by hyper-ventilation in some subjects. At the moment of onset of the fit the brain became blanched, flushing again with the convulsion. This must mean a sudden drop in blood pressure followed by a rise. The initial drop might account for the swiftness of the onset. These facts being established, the convulsive element might be regarded as a response to the grave threat to the organism constituted by alkalosis and fall of blood pressure; it offered a powerful check to both, and if it failed it was repeated. If even status epilepticus was unavailing, Nature abandoned the struggle and the patient, though free from convulsions and perfectly conscious, slowly died with increasing pulse, temperature, and blood-urea.

Migraine was also very like and might alternate with epilepsy, and intermediate conditions occurred. Syncope was a most mysterious and interesting event; and there was a sudden or slow drop in blood pressure associated with a real convulsion, however small. The most valuable treatments, both for migraine and syncope, were those used in epilepsy. Dr Collier described a case he had recently seen which had convinced him that the epileptic attack might be initiated in other parts of the brain besides the cortex. Epileptic manifestations were nowadays regarded from the point of view of loss of function; the "gunpowder and match" theory was gone for ever. The best treatment was a perfectly normal life; education, work, and pleasure should never be stopped. The "epileptic diet" might do more harm than good. Extensive biochemical research was needed.

Mr. **VICTOR BONNEY** spoke on

GYNÆCOLOGY.

He advocated *myomectomy for fibroids*, emphasising the reasons why the uterus should be spared if possible. The number of fibroids did not matter at all, but those on the front were much easier to deal with than those on the posterior wall. It was essential that the incision should be single and anterior. Posterior fibroids could be removed through an anterior incision by sidetracking through the muscle or viâ the cavity. Often the capsule of a large posterior one could be pulled right over the fundus like a hood and sutured anteriorly. The reason for the anterior scar was the grave risk of adhesion to intestine. Oozing into the utero-vesical pouch did not matter. If a posterior wound was unavoidable, the risk might be lessened by stitching the colon or the mesosalpinx lightly to the wound. No two cases were exactly the same and each called for ingenuity. The great danger of the past—hæmorrhage—had been obviated by the special clamp he had devised to encircle both urine arteries above the broad ligaments.

In speaking of *carcinoma of the cervix*, Mr. Bonney referred to the report of his paper published in THE LANCET last week (p. 1090), and emphasised the fact that more lives would be saved by surgery combined with radium than by radium alone, provided the operation were properly performed. It was a specialist operation, but any surgeon could learn to do it.

When investigating *sterility*, he said, he never inflated tubes in the consulting-room, partly because of the possibility of error when the patient was conscious and restless, and partly because he thought a woman should not be told she had closed tubes unless something could be done about it. He was not sufficiently convinced that inflation alone would promote conception. He demonstrated the apparatus he used, which had never failed him. If one squeeze of the bulb failed to pass air through the tubes he packed the tube in the cervix with gauze and opened the abdomen. A nurse then squeezed the bulb and he watched how far the air went. Air could also be blown through the abdominal ostium, and if it [illegible] down into the uterus the manometer on the cervical tube would record it even if it were inaudible. Retroversion only caused sterility through kinking the tubes; kinks might be very hard to find. If the abdominal ostium only were closed he slit it up, avoiding ligatures if possible. If the uterine ostium were blocked he cut the tube right off, snipped away until air would pass through, and then split the uterus across its fundus and sewed the tube in. It was not possible to pass anything into the uterus from the abdominal ostium and be sure of avoiding a false channel.

For *salpingitis* he advocated immediate operation and had never lost an acute case. Delay might mean involvement of the ovaries and an indefinite period of illness, as well as the danger of delaying an acute appendix or carcinoma through mistaken diagnosis. An acute appendix was operated upon immediately, why not a tube? He found that the people who opposed operation had never tried it. If the tube were knotty with blobs of pus on it, it should be removed; if soft and oozing a little pus only it should be drained and perhaps the ostium slit up. Only a small proportion of uteri gave subsequent trouble, and it was time enough to do a hysterectomy when the need arose. The less that was done in the acute stage the better. He disapproved of a purely vaginal operation, and thought a vaginal drain in addition to an abdominal one was superfluous.

Dr. H. C. SEMON spoke on

SOME PATHS OF PROGRESS IN DERMATOLOGY.

The jungle of eczema, he said, had undergone considerable clearance. The exogenous type was usually weeping; the superficial epidermal cells only were activated. When the irritant was endogenous every element in the cutaneous structure became a battlefield between the antigen and the specific cutaneous antibodies, and all the appendages of the skin might be involved. The difficulty usually lay in localising the septic focus. In erythema multiforme and nodosum it was usually a hæmolytic streptococcus in the buccal cavity, and apical abscesses associated with intestinal stasis were the most common cause of acne varioliformis and chronic furunculosis. X rays—especially negative reports—should not be trusted too much in suspected dental abscess. The possibilities of the tonsil, sinuses, and intestines should not be forgotten. Urticaria usually arose from an altered bacterial content of the intestine, and might be a symptom of grave metabolic disturbance, as might also pruritus.

X rays as a form of treatment were a two-edged sword, only to be used by a skilled technician under the constant observation of the dermatologist. The results of over-dosage were grave. While the indications were still somewhat vague, the contra-indications were now fairly definite. X rays should never be used in lupus, psoriasis, or hypertrichosis, and with the greatest caution only in pruritus of the genitals. There was no individual idiosyncrasy to X rays. In sunlight and its artificial substitutes we had an aid which had no real dangers except for the possibility of lighting up a hidden tuberculous focus—and in which the patient was the best judge of overdosage. Lupus vulgaris melted like the proverbial snow before proper heliotherapy in the Swiss Alps, but even the lamp substitutes available in this country had excellent results in all kinds of tuberculides, many septic lesions, including acne, boils, and carbuncles, and in chronic intractable sycosis. Vaccines were disappointing, and non-specific protein therapy, especially milk preparations, were just as useful as streptococcal vaccines or sera and were quite harmless. Chronic urticaria and dermatitis herpetiformis responded particularly well to autohæmotherapy, which was also useful for boils, pruritus, and obstinate eczema. For resistant cases more violent shock therapy in the from of TAB vaccine could be tried. Septic or allergising foci should always be removed before vaccines were used. Intravenous sanocrysin or other gold salts had proved a valuable new weapon for lupus erythematosus; the patient should be watched for toxic effects. In psoriasis there had been no advance since the days of Hebra, and Dr. Semon, after trying all the treatments advocated, had returned to inunctions of chrysarobin. Psoriasis was the most formidable problem and most outstanding reproach of modern dermatology. For extensive seborrhœic eruptions, psoriasis, and eczema, for which no cause could be found, the elimination treatment was useful, especially for stout middle-aged men who were fond of their port. Dermatology was tending more and more to return to the fold of general medicine.

On May 28th the chair was taken by Sir JOHN BROADBENT, and Mr. J. E. H. ROBERTS spoke on

INTRATHORACIC SURGERY.

Collapse of the lung in bronchiectasis and pulmonary tuberculosis, he said, could be procured in two stages: 1. By division of the phrenic nerve in the neck. This was always done before a thoracoplasty as it improved the patient's condition and gave an idea of what the effects of collapse would be. The diaphragm rose about two and a half inches and compressed the lower lobe very considerably. 2. By extrapleural paravertebral thoracoplasty, in which the ribs should be removed from the tip of the transverse processes. Partial thoracoplasty had been given up. Collapse was produced in three ways: the anterior part of the ribs was pushed back when the posterior part was removed, the anterior ends of the upper ribs dropped and the lowered ribs buckled down. Local anæsthesia was not advisable, for injecting the nerves caused rather than prevented post-operative pain, and shock could be obviated by attention to hæmostasis, careful preparation (including administration of salines, glucose, and morphine), and above all by careful handling. There was no need to hurry the operation under nitrous oxide and oxygen; 25 minutes was an average time. Mr. Roberts showed a series of X rays and photographs of illustrative cases, many of them showing how mistaken diagnoses might be made, and the importance of a preliminary bronchoscopy to make sure that the lung was not bound down by granulation tissue. Bronchoscopy, creosote chamber, and inversion make all palliatives and should always be tried before collapse therapy.

In Mr. Roberts's view collapse therapy was used too little and too late. The phrenic nerve should be divided as soon as bronchiectasis was diagnosed in one lobe. Abdominal surgery had reached its high standard of results because the surgeon operated in the early stages.

Intrathoracic tumours often went undiagnosed. An accurate history was the first essential, followed by thorough physical examination, including search for glands and for the effects of pressure on nerves. The next process was radiography in antero-posterior, true lateral, and oblique positions, with screen examination. Sputum tests came fourth and blood tests fifth in importance. The hydatid skin reaction and bronchoscopy followed, and when an artificial pneumothorax had been induced thoracoscopy might teach a good deal. Biopsy and exploratory operation completed the list. Mr. Roberts then showed slides illustrating these points. X rays, he pointed out, by no means always gave the correct diagnosis. Fibrotic calcified breasts, subpleural tuberculous abscess, hæmatoma, and tumours of the ribs projecting inwards might all simulate intrathoracic tumour under X rays. Fibromas consisted of fibrous tissue and a little unstriped muscle; they caused death by pressure and were removable. Dermoids might be mistaken for tuberculosis; their usual position was in the anterior or middle mediastinum. Mr. Roberts had had five cases of traumatic inclusion dermoid—pieces of metal or bone driven into the lung by war wounds had been enclosed in a capsule lined by squamous epithelium. In the diagnosis of hydatid cyst eosinophilia was unreliable; tests for a specific antigen were helpful but uncertain. Fifty per cent. of aneurysms did not pulsate when watched on the screen. The operative chances in intrathoracic malignant growths were very poor; the future lay with radium therapy.

Sir WILLIAM WILLCOX spoke on

CHRONIC RHEUMATISM AND THE TOXÆMIC FACTOR.

It was generally admitted, he said, that most forms of rheumatism were caused by toxæmia. Physicians were constantly dealing with diseases of which the cause was still to seek, and he had been trying to find the toxæmic cause of several common conditions. "Focal sepsis" was not a satisfactory term, because the infection might be more widespread than a focus; it was often a "surface sepsis" of an entire mucous membrane. He attached great importance to sepsis and believed in starting treatment with a clean slate. Every patient should be systematically searched. The mouth should be X rayed, as an unerupted tooth might be septic. He showed a series of photographs illustrating the various conditions that might affect the teeth and jaws. An expert should investigate the tonsils, glands, and sinuses. The frequency of infection of nasal sinuses in patients with no localising symptoms was only just becoming recognised. An X ray was essential, since transillumination sometimes failed to reveal the disorder. In doubtful cases puncture could be performed without any risk. Infected antra were particularly common in diabetics. The bowel, gall-bladder, appendix, and urogenital tract should also be investigated bacteriologically and radiologically in obscure cases. The treatment of disease was really a problem in immunity which was a very delicate balance. Removal of a focus of infection did not produce immediate cure because the infection had usually spread beyond it. Symbiosis played an important part, especially in recurrent boils. If a patient with phthisis had septic teeth his phthisis was not likely to improve. Sir William Willcox then recounted some cases showing how systematic search for infection repaid the physician in difficult cases. A para-enteric infection (i.e., by one of the less common organisms of the typhoid group) was not uncommon in arthritis. In early cases of diabetes removal of the sepsis caused remarkable improvement and the patients could go back to practically normal diet; in long-standing cases there would be only an improvement in the carbohydrate tolerance.

In the course of the morning Dr. R. G. CANTI showed his cinematograph film.

MEDICINE AND THE LAW.

Patient in Public Ward: Successful Claim for Operation Fee.

IF a patient occupies a bed in the public ward of a hospital, can the honorary physician to the hospital claim a fee for performing an operation on the patient? His honour Judge Crawford, before whom the question came on May 13th in the Watford County Court, answered it in the affirmative in the following circumstances. Dr. John Alexander McKinnon, of Park-drive, Wembley, sued Mr. Thomas Cox for 25 guineas for professional services rendered. Dr. McKinnon stated in evidence that he had been called in by Dr. Elizabeth Jenkins to give his opinion on the condition of Mrs. Cox who was suffering from an internal complaint; he found an operation to be necessary; the patient was taken to the Wembley Cottage Hospital, and the operation—a matter of life and death—was entirely successful. Dr. McKinnon explained that, owing to the existence of a septic case in the private ward, it was necessary to place Mrs. Cox in the public ward; he gave his services gratuitously to the sick poor in the public ward, but he did not regard Mrs. Cox as a person needing charity. He added that when he discussed the question of fees with Mr. Cox, the latter said that, although not a rich man, he did not want charity. Mr. Cox, the defendant, said he was a railway employee and a member of the railway hospital fund, which entitled his wife and himself to free hospital treatment. He denied that he ever engaged the services of Dr. McKinnon, or that he had ever seen him before. The Secretary of the Wembley Hospital gave evidence that Mrs. Cox was throughout regarded as a public patient, and that the hospital received two guineas a week in respect of her treatment. Dr. R. H. Martin, chairman of the medical committee of the hospital, said that the rule of the hospital provided that a patient in the public ward should receive free treatment. The judge had presumably to address himself to the question of contract. Had Mr. Cox employed Dr. McKinnon? If so, was there any reason to exclude the ordinary principle of law that a professional man exercises his skill for reasonable reward? His honour, accepting (it would seem) the plaintiff's rather than the defendant's evidence on the question of employment, decided that Mr. Cox had employed Dr. McKinnon. Judgment was given accordingly for the plaintiff for the amount claimed and costs. The judge observed that he thought Dr. McKinnon had broken the hospital rules by charging a fee, but this was a matter for the hospital authorities to settle.

"Neurasthenic" in Poor-law Infirmary.

A Coroner's jury at the Steyning Union Poor-law institution, on May 24th, in recording its verdict of suicide while temporarily insane, expressed the opinion that the union infirmary was not a suitable place for a typical neurasthenic case where constant observation was necessary. The jury had been called by the coroner, Mr. F. W. Butler, because he thought the circumstances rather unusual. A man, aged 25, a market garden labourer, of Sompting, was taken to the infirmary in June of last year, suffering from neurasthenia. Unhappy with his surroundings he went home after ten days, and was afterwards more or less an invalid. In February this year he was repeatedly asking his mother to end his life, and as he became beyond control it was proposed to again take him to the infirmary. He declared he would never go there, and taking a clothes-line, barricaded himself in his bedroom. The police were telephoned for, and when the young man saw them approaching the cottage he jumped out of the window with the end of the rope attached to his neck. The police cut him down, and he was charged at Worthing police-court with attempted suicide, and was bound over on condition that he entered the Steyning Union infirmary. He was readmitted to the institution on May 1st and for a time had a special day and night attendant. He soon became normal, and was allowed in the general ward. On May 21st he died from injuries caused by falling from a balcony. Dr. G. F. L. Mitcheson said the man was neurasthenic, but in order to certify him he would have had to be able to put down queer things he had seen or done that he (Dr. Mitcheson) had himself witnessed. It was not sufficient for him to be told anything. The coroner: "You did not feel you could certify him as insane?" Dr. Mitcheson: "The Commissioners would not accept it." Dr. Mitcheson said in his opinion the infirmary was not a fit and proper place to send a case of this description. It was often done, but the conditions were not ideal at all. Acute medical cases should not be mixed up with neurasthenics. Dr. Mitcheson agreed that it would have been better to have sent the man to Portsmouth on remand, and to have asked the prison doctor to keep him under observation. The coroner said it always seemed to him that if a man attempted his life once and was still ill, he might do so again. It was very questionable if an institution, such as a poor-law infirmary, which was not a lunatic asylum—although he believed they had a considerable number of mental defectives there—was a suitable place for the care of such a case as they had been inquiring into, where they had not the means, in fact, to take care and look after such cases.

uterus the manometer on the cervical tube would record it even if it were inaudible. Retroversion only caused sterility through kinking the tubes; kinks might be very hard to find. If the abdominal ostium only were closed he slit it up, avoiding ligatures if possible. If the uterine ostium were blocked he cut the tube right off, snipped away until air would pass through, and then split the uterus across its fundus and sewed the tube in. It was not possible to pass anything into the uterus from the abdominal ostium and be sure of avoiding a false channel.

For *salpingitis* he advocated immediate operation and had never lost an acute case. Delay might mean involvement of the ovaries and an indefinite period of illness, as well as the danger of delaying an acute appendix or carcinoma through mistaken diagnosis. An acute appendix was operated upon immediately, why not a tube? He found that the people who opposed operation had never tried it. If the tube were knotty with blobs of pus on it, it should be removed; if soft and oozing a little pus only it should be drained and perhaps the ostium slit up. Only a small proportion of uteri gave subsequent trouble, and it was time enough to do a hysterectomy when the need arose. The less that was done in the acute stage the better. He disapproved of a purely vaginal operation, and thought a vaginal drain in addition to an abdominal one was superfluous.

Dr. H. C. SEMON spoke on

SOME PATHS OF PROGRESS IN DERMATOLOGY.

The jungle of eczema, he said, had undergone considerable clearance. The exogenous type was usually weeping; the superficial epidermal cells only were activated. When the irritant was endogenous every element in the cutaneous structure became a battlefield between the antigen and the specific cutaneous antibodies, and all the appendages of the skin might be involved. The difficulty usually lay in localising the septic focus. In erythema multiforme and nodosum it was usually a hæmolytic streptococcus in the buccal cavity, and apical abscesses associated with intestinal stasis were the most common cause of acne varioliformis and chronic furunculosis. X rays—especially negative reports—should not be trusted too much in suspected dental abscess. The possibilities of the tonsil, sinuses, and intestines should not be forgotten. Urticaria usually arose from an altered bacterial content of the intestine, and might be a symptom of grave metabolic disturbance, as might also pruritus.

X rays as a form of treatment were a two-edged sword, only to be used by a skilled technician under the constant observation of the dermatologist. The results of over-dosage were grave. While the indications were still somewhat vague, the contra-indications were now fairly definite. X rays should never be used in lupus, psoriasis, or hypertrichosis, and with the greatest caution only in pruritus of the genitals. There was no individual idiosyncrasy to X rays. In sunlight and its artificial substitutes we had an aid which had no real dangers except for the possibility of lighting up a hidden tuberculous focus—and in which the patient was the best judge of overdosage. Lupus vulgaris melted like the proverbial snow before proper heliotherapy in the Swiss Alps, but even the lamp substitutes available in this country had excellent results in all kinds of tuberculides, many septic lesions, including acne, boils, and carbuncles, and in chronic intractable sycosis. Vaccines were disappointing, and non-specific protein therapy, especially milk preparations, were just as useful as streptococcal vaccines or sera and were quite harmless. Chronic urticaria and dermatitis herpetiformis responded particularly well to autohæmotherapy, which was also useful for boils, pruritus, and obstinate eczema. For resistant cases more violent shock therapy in the from of TAB vaccine could be tried. Septic or allergising foci should always be removed before vaccines were used. Intravenous sanocrysin or other gold salts had proved a valuable new weapon for lupus erythematosus; the patient should be watched for toxic effects. In psoriasis there had been no advance since the days of Hebra, and Dr. Semon, after trying all the treatments advocated, had returned to inunctions of chrysarobin. Psoriasis was the most formidable problem and most outstanding reproach of modern dermatology. For extensive seborrhœic eruptions, psoriasis, and eczema, for which no cause could be found, the elimination treatment was useful, especially for stout middle-aged men who were fond of their port. Dermatology was tending more and more to return to the fold of general medicine.

On May 28th the chair was taken by Sir JOHN BROADBENT, and Mr. J. E. H. ROBERTS spoke on

INTRATHORACIC SURGERY.

Collapse of the lung in bronchiectasis and pulmonary tuberculosis, he said, could be procured in two stages: 1. By division of the phrenic nerve in the neck. This was always done before a thoracoplasty as it improved the patient's condition and gave an idea of what the effects of collapse would be. The diaphragm rose about two and a half inches and compressed the lower lobe very considerably. 2. By extrapleural paravertebral thoracoplasty, in which the ribs should be removed from the tip of the transverse processes. Partial thoracoplasty had been given up. Collapse was produced in three ways: the anterior part of the ribs was pushed back when the posterior part was removed, the anterior ends of the upper ribs dropped and the lowered ribs buckled down. Local anæsthesia was not advisable, for injecting the nerves caused rather than prevented post-operative pain, and shock could be obviated by attention to hæmostasis, careful preparation (including administration of salines, glucose, and morphine), and above all by careful handling. There was no need to hurry the operation under nitrous oxide and oxygen; 25 minutes was an average time. Mr. Roberts showed a series of X rays and photographs of illustrative cases, many of them showing how mistaken diagnoses might be made, and the importance of a preliminary bronchoscopy to make sure that the lung was not bound down by granulation tissue. Bronchoscopy, creosote chamber, and inversion make all palliatives and should always be tried before collapse therapy.

In Mr. Roberts's view collapse therapy was used too little and too late, The phrenic nerve should be divided as soon as bronchiectasis was diagnosed in one lobe. Abdominal surgery had reached its high standard of results because the surgeon operated in the early stages.

Intrathoracic tumours often went undiagnosed. An accurate history was the first essential, followed by thorough physical examination, including search for glands and for the effects of pressure on nerves. The next process was radiography in antero-posterior, true lateral, and oblique positions, with screen examination. Sputum tests came fourth and blood tests fifth in importance. The hydatid skin reaction and bronchoscopy followed, and when an artificial pneumothorax had been induced thoracoscopy might teach a good deal. Biopsy and exploratory operation completed the list. Mr. Roberts then showed slides illustrating these points. X rays, he pointed out, by no means always gave the correct diagnosis. Fibrotic calcified breasts, subpleural tuberculous abscess, hæmatoma, and tumours of the ribs projecting inwards might all simulate intrathoracic tumour under X rays. Fibromas consisted of fibrous tissue and a little unstriped muscle; they caused death by pressure and were removable. Dermoids might be mistaken for tuberculosis; their usual position was in the anterior or middle mediastinum. Mr. Roberts had had five cases of traumatic inclusion dermoid—pieces of metal or bone driven into the lung by war wounds had been enclosed in a capsule lined by squamous epithelium. In the diagnosis of hydatid cyst eosinophilia was unreliable; tests for a specific antigen were helpful but uncertain. Fifty per cent. of aneurysms did not pulsate when watched on the screen. The operative chances in

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Hospital Policy in Dublin.

A DISCUSSION has been going on for the past few weeks in the Dublin press, and in speeches delivered at annual meetings of hospitals, concerning the policy of amalgamation of some of the smaller Dublin hospitals. The first contribution came from Sir William Taylor, who, in an interview given to an evening paper, was reported as having said that by failure to agree to an amalgamation scheme a few years ago Dublin hospitals had lost a grant of a million and a quarter sterling from the Rockefeller Foundation. Sir William Taylor assigned to religious differences the failure to come to an agreement, quoting an official of the Rockefeller Foundation as his authority. (On a previous occasion, it may be remarked, the difficulties arising out of the question of the Medical Register were assigned as the cause of the reluctance of the Rockefeller Foundation to assist medical education in Dublin.) Sir William Taylor went on to deplore the relative position of Dublin in medical education to-day. "In the realm of medical science," he said, "the Irish capital is practically unknown to-day." Belfast was miles ahead of Dublin; they had the hospitals, the equipment, and the means to facilitate study—all these were lacking in Dublin.

Both divisions of Sir William Taylor's interview have roused criticism. It is generally thought that if there is any documentary evidence or correspondence about the reasons why the Rockefeller Foundation did not accede to the request made a few years ago, it should be made public. If there is not such evidence it would be better to refrain from offering hypothetical explanations of a nature likely to give offence. In his comparison of the Dublin with the Belfast School Sir William Taylor drew at once a protest from his colleague, Dr. T. G. Moorhead, the Regius Professor of Physic in Dublin University, in a speech delivered at the annual meeting of the Royal Victoria Eye and Ear Hospital. While declaring himself a convinced supporter of amalgamation of hospitals, Prof. Moorhead denied that Dublin had no place in modern medical science. Dublin, while unable to compete with such centres as London and New York, continued to make contributions to current scientific thought in proportion to its resources and population. Dublin suffered, perhaps, from the antiquity of some of its hospital buildings, but it had also ancient traditions and culture which formed the best basis for a modern outlook. In his opinion, as a teaching centre and as a school Dublin held as high a position as ever it did. Some days later Sir William Wheeler returned to the hospital question in a newspaper interview. He gave reasons for holding that the hospital question in Dublin required serious study, and also for his opinion that amalgamation was desirable. He suggested that a tribunal of business men and medical men should be set up by the Government to inquire into the whole question of hospital service in Dublin.

In a speech delivered at the Coombe Hospital Mr. W. Doolin made a spirited defence of the present system of small hospitals. He argued that the system not only had grown up to fit local conditions, but was, in fact, best suited to Irish needs. He claimed that each year the small hospitals of Dublin, by virtue of their intimacy and their number, turned out practically trained practitioners of higher average value to the national community than any other medical centre within his knowledge. The Irish dispensary doctor was a better equipped practitioner than his fellows in either Germany or France. He did not think that as good practical training could be given in a large hospital, and he believed that from the point of view of the patient, the care given in the small Dublin hospital was more effective than that given in the infirmary institutions of Paris, Berlin, or Vienna. The conservative arguments of a surgeon of so progressive a mind as Mr. Doolin should receive due weight, but it might be suggested that the disadvantages he foresees in large hospitals are incidental rather than essential, and are not unavoidable. He does public service, however, in drawing attention to them.

The Risk of Infection by Imported Clothing.

In the Dáil last week Dr. Ward drew attention to the risk of introducing disease, particularly small-pox, to the Irish Free State, by infected second-hand clothing. In reply, on behalf of the Minister for Local Government and Public Health, reference was made in the Small-pox (Importation of Clothing, &c.), Temporary Regulations, 1927. Under these Regulations which came into effect on Sept. 1st, 1927, and are still in operation, second-hand clothing, used bedding, and rags may only be imported into the Free State from Great Britain and Northern Ireland through the ports of Dublin, Cork, Waterford, or Galway, where it becomes the duty of the Port Sanitary Authority to undertake the disinfection of the articles and return them to the custody of the Customs and Excise Authorities. Exception is made in the case of (1) articles transmitted by the postal service or forming part of passengers' luggage; (2) goods in course of transit through the Free State to an outside destination, if suitably packed; (3) articles accompanied by a certificate of the medical officer of health of the place of origin in Great Britain or Northern Ireland or of the port of arrival in Ireland, that they have been efficiently disinfected; (4) articles accompanied by a certificate from a medical officer of health in Northern Ireland that they have not been imported from Great Britain.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Disaster at the Cleveland Clinic.

ON the morrow of the disaster at the Crile Clinic in Cleveland 124 deaths are reported and some twenty others are hardly expected to recover from the effects of the gas. The plumber who was investigating a leak in a steam pipe in the vault where X ray films were stored when the first explosion occurred is among the survivors. He was actually blown through the open door of the vault. The clinic building was considered a model of fire-proofing. In the *Modern Hospital* for January, 1925, are to be found side by side two articles, one in praise of the new Cleveland clinic building and the other urging the importance of fire-proof precautions in hospitals. At the time of writing it appears that two explosions occurred in the vault without the closure of the automatic door. It is probable that these explosions took place at a temperature below that which is necessary to melt the fusible iron and so release the mechanism.

The cause of poisoning is still uncertain, but analyses of the victims' blood have all shown hydrocyanic acid and bromine. The brownish gas observed by onlookers is thought by chemists to have been nitrogen dioxide. This would indicate that some at least of the films were made of cellulose nitrate. According to officials of the Eastman Kodak Company, films made of cellulose acetate are not more inflammable than paper, and would not have caused the explosions.

Eight doctors, including six staff physicians at the institution, lost their lives, the last being Dr. John Phillips, one of the founders of the clinic. He was in the building when the catastrophe occurred, but walked home, believing he had not been affected by the gas. He was taken ill towards evening and rushed to a hospital, where a blood transfusion was done by Dr. Crile. The men and women who were in the building at the time of the explosion, in addition to the doctors and nurses, were there for examination. The building is one of a group of three and is known as the examination building. Patients seldom are kept at this building for more than a day. After diagnosis they are assigned rooms in the Clinic Hospital, dismissed or removed to hospitals of their own choosing.

Many tales of heroism are told. The telephone operator remained at her post warning occupants of the building until she was overcome by the gas. She was removed to a hospital but died soon afterwards. Dr. Crile himself is reported to have worked for 29 hours without rest. "We must carry on," he says, in a statement issued on behalf of the board of directors of the foundation. "The clinic has its work to do and must go forward. The staff is prepared to carry on." A committee of prominent citizens has already given assurance that the material damage will be immediately repaired.

Physical Measurements of School-children.

Of the many authropometrical studies of school children made hitherto in this country, none has been confined to a single race. The Public Health Service have now commenced a survey which is to be classified according to nationality, and the first results are published for 30,000 children of white stock who classify as "old American" under Dr. Hordlicka's standard, that is—both parents and all four grandparents were born in this country. Since samples were taken from widely separated districts the results form a first standard of the size of young America. The results in weight, standing height, and sitting height (Dreyer method) are tabulated according to the age on the nearest birthday. A comparison of the rate of growth between boys and girls shows that the latter start to overtake the former at about ten years of age, and by the thirteenth year have surpassed them in weight, height, and chest circumference, though in vital capacity and in transverse chest diameter the boys maintain at all ages a supremacy. After 13, with the onset of male puberty, the boys gain rapidly and soon recover a lead in all measurements except weight.

Mortality in 1928.

Although the mortality-rates for the year have not yet been calculated by the Bureau of Census, provisional figures are available from the summing of monthly returns made by certain States to the Public Health Service. The death-rate from all causes (12·3) is higher than in 1927, but lower than in any of the four years 1923–1926. Tuberculosis (all forms) continued its uninterrupted decline from 80·4 in 1927 to 76·9 last year. On the other hand the death-rate from heart-diseases (228·4) is the highest yet recorded. This figure includes items 87–90 in the International List. Cancer also reached a new maximum at 104·8. The influenza death-rate is given as 37·5. This compares with 19·7 in 1927 and 35·9 in 1926. It is true that the influenza epidemic was still at its height when the year came to a close. However, the Metropolitan Life Insurance Company has a complete study of the epidemic for its policyholders, from which it concludes that "the recent outbreak was far less serious than the great pandemic, and that, as far as it is possible to judge, in no city did the 1928–1929 death-rate exceed 40 per cent. of that recorded in 1918–1919." The indications of the first quarter's returns in the present year are that the death-rate from alcoholism will reach a new high point this year. The Metropolitan's death-rate for the quarter is 3·8 as compared with 3·2 last year.

Venereal Disease in West Virginia.

The Venereal Disease Bureau of the West Virginia State Department of Health has completed a study of 13,000 patients at present receiving treatment in the 12 clinics which are connected with the Bureau. The mean age of infection for single females is found to be 17 years, and for single males 22 years. A special effort is being made, through the routine examination of school-children, to discover and place under treatment children suffering from hereditary syphilis.

Malaria in the Canal Zone.

The completeness of the triumph of medical science in the Panama Canal Zone is emphasised by a recent report from the health officer. In 1906 the malaria admission-rate among 26,547 employees of the Panama Canal was 821 per 1000, and the death-rate 7·45. There has not been a death from malaria since 1920, except for two deaths in 1924. Last year the admission-rate was only 14·2 per 1000. The average rate for the last three years has been 13 per 1,000 in a force having a mean strength of 13,517.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments are notified: Surg.-Comdr. L. W. Gemmell to *President*, for Medical Dept. Surg. Lt.-Comdrs. S. G. Rainsford to *President;* J. L. Edwards to H.M.H.S. *Maine;* and D. C. Eglington to *Pembroke.* Surg. Lt. (D.) A. W. Wallace to *Tiger.*

ARMY MEDICAL SERVICE.

Maj.-Gen. H. B. Fawcus, C.B., C.M.G., D.S.O., K.H.P., has been selected for the appointment of Director-General, A.M.S., on the retirement of Lt.-Gen. Sir Matthew H. G. Fell, K.C.B., C.M.G., K.H.P., in September next at his own wish. Col. W. R. Blackwell, C.M.G., will succeed Maj.-Gen. Fawcus as D.D.G.A.M.S.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Lts. (on prob.) are confirmed in their rank: F. Welsh, H. Daukes, D. C. Ettles, and J. A. Timoney.

Lt. (on prob.) E. M. Hennessy from the secd. list is restd. to the estabt.

ARMY RESERVE OF OFFICERS (DENTAL CORPS).

J. W. Cooper, late Lt., 6th Bn. Welch R., to be Lt.

TERRITORIAL FORCE.

Maj. R. D. Cran, having attained the age limit, relinquishes his commn.

Capt. D. F. Dobson to be Maj.

B. M. Dick to be Lt.

INDIAN MEDICAL SERVICE.

Col. R. F. Baird retires.

The undermentioned officers relinquish their temp. commns.: Temp. Capts. Ram Mansoor, Ardeshir Ratanji Wadia, Mangharam Rochiram Lalvani, Bala Prasad, and Des Raj Kajuria.

DEATHS IN THE SERVICES.

Major-General Charles Edward Pollock, late R.A.M.C., who died on May 18th at his residence, Northwood, Middlesex, at the age of 61, was the son of Mr. Alexander Pollock, of Paisley, and received his early education at Wellington College. He afterwards entered at Guy's Hospital as a medical student and qualified with the conjoint diploma in 1891. He received his first commission in the Royal Army Medical Service two years later, and was promoted to captain in 1896, in which rank he served on the North-West Frontier of India in 1897–98, and was with the Tirah Expeditionary Force (medal and two clasps). In 1902 he served in the South African War, taking part in the operations in Orange River Colony and in Cape Colony (Queen's medal and two clasps). In 1904 he was promoted major, and when the late war broke out he was appointed A.D.M.S. of the 15th Division and D.D.M.S. of the IV. and VI. Corps. He was awarded the D.S.O. in 1917, created C.B.E. in 1919, and C.B. in 1921. After the war he was appointed a member of the British Military Mission to Berlin, and was afterwards A.D.M.S. in the Eastern Command and D.D.G.A.M.S. He retired in 1926. Major-General Pollock married Winifred, daughter of the late C. E. H. Jay, by whom he had a son and two daughters.

GERMAN RONTGEN SOCIETY.

CONGRESS IN AUSTRIA.

(FROM OUR VIENNA CORRESPONDENT.)

FOR the first time in its existence the Deutsche Röntgen-Gesellschaft held its biannual meeting in Vienna, and the 800 medical men who attended from April 20th–23rd comprised not only representatives from Germany, Austria, Czecho-Slovakia, Switzerland, and Hungary, but also a few from France and Italy. More than 200 papers were read, and there were also a large number of minor demonstrations, whilst a post-graduate course, lasting four days, was held at the close of the official meeting. The first paper was read by Prof. Berven (Stockholm) on the radiological treatment of tumours of the oral cavity. He emphasised the necessity of combining the use of X rays and radium in dealing with growths in this region. By this combination, he said, the energy of growth was markedly diminished, and the reactive powers of the organism could be strengthened. In Stockholm, where they have five grammes of pure radium-bromide, they got 66 per cent. of cures in tumours of the lips and 47 per cent. in tumours of the tongue, the criterion of cure being freedom from recurrence for at least five years.

Prof. Döderlein (Munich) maintained that radiological treatment in cancer of the uterus is at least as successful as surgical treatment, having the advantage of being free from danger whereas surgical treatment has high mortality. He has been working with X rays and radium in gynæcology since 1913, and already he can point to 10 per cent. of cures in desperate cases which surgeons have declared inoperable. In Munich 2000 women have so far been irradiated, with over 35 per cent. of cures lasting more than five years. Prof. Wintz (Erlangen) also combines X rays with radium treatment in cancer of the uterus and of the breast. As a preliminary he uses injection of copper salts and his results show permanent cure in 34 per cent. of cases. Prof. Lacassagne (Paris), who read a paper on the biology of irradiated cancer cells, also referred to the beneficial effect of radiotherapy in cancer of the uterus, and was seconded by Prof. Lahm (Chemnitz).

The methods used in Berlin and Kiel by Prof. Stockel were described by Dr. Mikulicz. They consist chiefly in applying an intensive dose of radium before the radical operation is performed; then at the end of the operation radium needles are inserted into the tissues and after full convalescence intensive X ray treatment is given. This method is rather tedious and very tiring both to patient and surgeon, but gives excellent results. In Würzburg, where Prof. Jauss and Dr. Neeff are working, they take great care to find out what *dose* of the rays is required for each individual case, this dose being soon found by Dr. Neeff's method. Dr. Bardackzi and Dr. Epstein (Prague) uttered a caution against too intensive irradiation of tumours, and Prof. Schwarz (Vienna) pointed out that experimental animal cancer behaves differently from human cancer, in that the latter shows no local immunisation after application of X rays. Schwarz suggests that the prophylactic and post-operative irradiations should be of the same dose as the main treatment, and holds that the earliest stages of cancer should not be treated by the radiologist, but by the surgeon.

The relations of radiology to dermatology were discussed by Prof. Freund (Vienna)—called the father of radiological treatment—and by Dr. Reisner (Frankfurt). Dr. Pordes (Vienna) applies X rays in acute inflammations of the subcutaneous tissues, with excellent results; Dr. Eisler has found them very useful in pruritus and prurigo, especially in elderly persons, and Dr. Wieser has obtained good results in therapy of post-influenzal affections of the brain.

The diagnostic value of X rays was discussed on the second day. The possibility of controlling the progress of improvement in tuberculosis of the lungs was demonstrated by Dr. Fleischner; the pathology of the thymus was dealt with by Dr. Lenk (Vienna), and Dr. David discussed radiological methods in aortic disease. The examination of the gastro-intestinal canal was the subject of a large number of papers presented to the congress. "The micro-method" (using small quantities of barium) for the intestinal canal, as demonstrated by Dr. Berg (Berlin), is especially designed for the diagnosis of changes in the mucous membranes; it shows the finer folds of the membrane. Dr. Grebe (Berlin) explained how to examine the gall-bladder by giving tetra-iodine-phenol-phthalein, and Dr. Roseno (Cologne) said he used the same substance to obtain radiograms of the uropoietic system, even better results being obtained with iodine-urethane, given intravenously. He claimed that this method allows photography of both kidneys simultaneously, radiograms being also obtainable in infective disease of the lower parts of the urinary system.

The third day began with a cinematographic demonstration of X ray stereography by Prof. Gottheimer (Berlin). He demonstrated in a surprisingly clear way the movements of the heart, the respiratory changes of the lungs, the rise and fall of the diaphragm, and the peristaltic movements of the œsophagus. Dr. Hintze (Berlin) showed distinct pictures of the diminished speed of healing after exposure to X rays, and was able to demonstrate, by cinematograph, the progress of healing of a facial cancer, the film showing a process which really lasted 400 days, in the course of 100 seconds.

Great interest was evoked by the papers of Dr. Pordes and Dr. Freund, of Vienna, who, in coöperation with the Japanese surgeon, Fukase, have observed the beneficial effect of prophylactic and therapeutic use of X rays in inflammation of various tissues. Dr. Hausmann showed the effect of the kathode rays upon the red blood corpuscules, and Dr. Kisch discussed the effect of X rays and electric-light combination in tuberculous affections, whilst Dr. Pincherle (Trieste) demonstrated his method of examining the brain and its blood-vessels. X rays are now used extensively in the teaching of anatomy in Vienna, and close attention was paid to Dr. Goldhammer's paper on this subject.

An exhibition of instruments, apparatus, and implements used in radiology and heliotherapy was held coincidently with the meeting. It gave an excellent opportunity of inspecting and studying the ideal equipment of the most up-to-date laboratory, and every visitor certainly got the impression that the outfit of a Rontgen institute is a very expensive affair.

RAILWAYMEN'S PAYMENT TO HOSPITALS.—The London, Midland, and Scottish Railway Hospital Fund disbursed £100,000 during last year to hospitals where railwaymen and their families receive free medical treatment. Over 1000 hospitals received grants, ranging in amount from £2000 to three guineas. When the fund was started 50 years ago the railwaymen contributed half a day's pay per annum. Now they contribute threepence a week, and the railway company contributes one penny per member. Last year's income amounted to £160,000.

JOINT TUBERCULOSIS COUNCIL.—At a meeting of the Council held at the House of the Society of Medical Officers of Health on May 18th the secretary for post-graduate study reported that 16 members of the tuberculosis service were now attending the arranged course in Paris. There were prospects of a course at Alton in July, and one on the interpretation of skiagrams in November. Consideration was given to a memorandum on the notification of tuberculosis and a proposal from Dr. Lissant Cox to have a single notification form so worded that it could be used for all purposes. It was decided to suggest an alteration in the present wording of the Tuberculosis Regulations so as to read: "Provided that a medical practitioner shall not notify a case of tuberculosis under this Article if he has reasonable grounds for believing that the case has already been notified, either under this order or under the previous Regulations or otherwise, *to the medical officer of health for the district within which the place of residence of the person is situate.*"

authorities, as to the prophylactic and curative values of irradiated milk in the treatment of rickets. If rickets can be controlled, the bearing of this on obstetric work and on child welfare and infantile health and mortality is profound and far-reaching. For some months past I have been investigating this subject with the coöperation of Dr. T. Y. Finlay, of the Child Welfare Department, Edinburgh, and Dr. J. B. King, of the Radiological Department of the Royal Infirmary, and the results of this inquiry, which will shortly be published, amply confirms the claims made by German authorities. The manner in which the use of irradiated milk controls the disorderly manner of growth of the cells characteristic of rickets is very striking, and opens up a vista of possibilities of far-reaching interest and importance.

If full advantage is to be taken of the possibilities of the moment, it seems advisable that a very broad and comprehensive view of the possibilities of radium and radiation be taken, not only in relation to cancer, but in relation to normal and abnormal nutrition and diseases arising therefrom. The admirable report of the Radium Sub-Committee deals with radium only, and is essentially restricted to cancer. This view is probably too restricted. The sum of £250,000 obtained as a radium fund is small in relation to the real needs of the situation. Assuming that one-eighth of this was available for Scotland, this sum, added to present available supplies, is certainly far short of what is required. It is also doubtless far short of what would be provided by the public for a comprehensive well-considered business-like scheme. The basis for any successful scheme is the recognition of the need for much thorough clinical research to be carried out primarily by experts, with the coöperation of clinicians. A question I would like to ask is, whether the experts have said their last word on the subject. What are their recommendations? Taking Scotland as a unit, is it not possible to devise a scheme, in which the four University teaching centres would coöperate, their scheme being allied to and part of a larger scheme?

Unless action is taken on some broad comprehensive lines there is reason to fear that only a fraction of the possible benefits to private and public health will accrue from the present movement.

I am, Sir, yours faithfully,

Edinburgh, May 26th, 1929. CHALMERS WATSON, M.D.

PATHOLOGICAL POSTURES.

To the Editor of THE LANCET.

SIR,—Dr. Walshe's confidence in the support of the decerebrate sloth is entirely misplaced. His point was that this animal's pathological posture had occurred "in response to the mode of life of the sloth itself and not in relation to its phylogenetic associations." (This, of course, does not logically exclude such an origin for pathological postures in other animals.) But he omitted to state the essence of my argument concerning the flexed upper limb in hemiplegia. I pointed out that this posture arose in monkeys and anthropoid apes in response to their adoption of an erect sitting attitude and was perpetuated in man as he developed and perfected the erect attitude for standing and walking. I concluded that the association of the flexed upper with the extended lower limb in hemiplegia was "the primitive human standing attitude." In other words, it was "the response to the mode of life of" man himself. Dr. Walshe has arrived on physiological grounds at the conclusion that the flexed upper limb in hemiplegia is a postural modification brought about by "the assumption of the erect posture." He regards his conception as "in accord with physiological principles" and mine as a "figment" and an "allegory." I do not think that unprejudiced critics will consider that there is much difference between them.

I am, Sir, yours faithfully,

Harley-street, W., May 20th, 1929. W. RUSSELL BRAIN.

CANCER OF THE COLON.

To the Editor of THE LANCET.

SIR,—The general excellence of the address given by Prof. Grey Turner on the above subject and reported in THE LANCET (May 18th and 25th) is, I am sure, obvious to all who have read it, and I hope he will not think my criticisms are made in anything but a fair and friendly spirit. I want to comment on three points which arise in his address—the incision, the blood-supply of the colon, and Paul's operation.

1. *The incision.*—Mr. Grey Turner says he strongly recommends direct exposure over the situation of the growth, using the oblique or transverse muscle-cutting incision of Rutherford Morison, as he finds adherent growths in the ascending or descending segments of the colon cannot be satisfactorily dealt with by the paramedian incision. This is not my experience; however adherent the growth may be it is quite easy to mobilise it from a paramedian incision made to the right or left according to the site of the growth. Perhaps in Leeds we are prejudiced in favour of this incision, because I believe Lord Moynihan is responsible for its introduction, as Mr. Grey Turner may be influenced by his association with Mr. Rutherford Morison. If there is no advantage to be gained by direct incision, as I maintain, then I think there can be no doubt as to which is the better one, as with the paramedian incision there is the minimum risk of a post-operative hernia, and the ensuing scar is much more satisfactory in every way. The only consideration which would make me use the direct approach would be an intimate blending of the growth with the anterior abdominal wall, where a large segment of this might need removing; this is only rarely encountered.

2. *Danger of insufficient blood-supply at the anastomosis.*—Contrary to the view expressed by Mr. Grey Turner, I believe that if sepsis occurs after an anastomosis is made in the colon it is almost invariably due to the spread of infection at the time of operation, and not to lack of blood-supply and consequent necrosis at the suture line. It is, in my opinion, almost impossible to deprive the colon of an efficient blood-supply, and I do not believe that the critical point of Sudek exists. If necrosis follows an anastomosis it is not due to the precarious supply of blood, but to the suture line being under tension, and as it is always possible to bring one or other side of the colon, or both, to the anastomosis quite free of tension by adequate mobilisation, necrosis should never be seen.

3. *Paul's operation.*—I am surprised Mr. Grey Turner should only make a passing reference to this operation in the treatment of carcinoma of the colon. The growth and glands are mobilised through a paramedian incision and delivered through a small separate opening such as one makes for a colostomy, the first incision being completely closed after the afferent and efferent loops have been stitched together on the mesial and lateral aspects. The two loops are clamped across at the level of the skin, and the parts containing the growth and glands removed with a cautery. The result is that the two loops come to the surface like the barrels of a shot-gun, and in a few days the septum is destroyed by crushing, and finally the lumen of the gut restored by suture. The chief virtue of this operation is its amazing safety. I became intimate with the technique from Lord Moynihan when I was his private assistant. He informs me he has never had a death from this operation, and I have only had one in something over 30 cases—the fatal case was one in which a loop of small intestine had also to be removed owing to extension of the growth. This operation has not acquired the popularity it deserves and chiefly, I believe, because it has been asserted that the glands cannot be effectively dealt with owing to interference with the vascular supply of the parts which are left. I believe this is quite wrong, as on one occasion I deliberately tied the superior hæmorroidal vessels and no appreciable sloughing ensued in the lower loop.

"Audi alteram partem."

THE INITIAL LESION OF SLEEPING SICKNESS.

To the Editor of THE LANCET.

SIR,—With regard to your annotation in THE LANCET of May 25th, on the initial lesion of sleeping sickness, will you permit me to record that the illustrious Manson had pointed out, before 1910, the occurrence of this very lesion in some of his European cases of African trypanosomiasis? Sir Patrick concluded, and taught, that the indurated inflammatory lesion (carefully and almost unavoidably noted by the patient), which developed at the exact site of, and surrounding, the tsetse bite, and sometimes persisted for many weeks, signified an *infective* bite, and that its recognition was very important in that thereby the sufferer could, and should, be brought quickly under treatment before the development of constitutional symptoms and severer lesions. In fact, early in 1910, when I had the happy privilege of being his house physician at the old and distinctive London School of Tropical Medicine founded by him at the Seamen's Hospital, Royal Albert Dock, he demonstrated to his class just such an initial (infective bite) lesion—an indurated inflamed circular node, on the leg of a case of Rhodesian trypanosomiasis in a white man. The patient, a professional hunter, had often been bitten by tsetses, but was quite positive that that particular bite on the shin had been the only one to develop into an inflammatory lesion and to be followed by fever.

In spite of Manson's teaching, reference to this initial lesion is absent from text-books on tropical diseases. To Dr. Graf therefore belongs the credit of its renewed and independent discovery, of demonstrating trypanosomes in the blood from the lesion, and of recognising and acting on its clear call for immediate antitrypanosome treatment.

I am, Sir, yours faithfully,

H. M. HANSCHELL.

Weymouth-street, W., May 25th, 1929.

To the Editor of THE LANCET.

SIR,—Your annotation would suggest that Dr. Graf was the first to observe what might be regarded as the infective bite and the particular reaction of the tissues to the same in cases of trypanosomiasis. This is not so. Sir Patrick Manson had noted and taught, certainly earlier than the year 1910, that patients the subject of trypanosomiasis frequently described one particular bite occurring a short time before they became ill and which had caused a very marked degree of induration and prolonged pain. He believed this to be the infective bite, and I well remember seeing with him one or two cases of the disease in which a clear-cut history of such a particular bite was elicited.

During the war, whilst I was in East Africa, I came across two cases of the disease in white soldiers, who gave a graphic account of a particular bite they had good cause to remember and which shortly preceded the onset of symptoms. These cases are described in an article I wrote on Trypanosomiasis in the East African campaign, and published in the *Journal* of the Royal Army Medical Corps in 1919.

Undoubtedly to Manson must be ascribed priority in describing what would appear to be the infective bite.

I am, Sir, yours faithfully,

H. B. NEWHAM, M.D., M.R.C.P., D.P.H.,

London School of Hygiene and Tropical Medicine,
Torrington-square, W.C., May 27th, 1929.

LEPROUS LESIONS OF THE SCALP.

To the Editor of THE LANCET.

SIR,—Dr. A. R. Davison's article on this subject in your issue of April 6th (p.717) is of extreme interest. Since I have seen this condition fairly frequently in Japan, I shall be glad if you will publish the following additional notes. Leprosy of the scalp, while not uncommon in India, seems to be comparatively common in Japan. In fact, Dr. Mitsuda, of the Government Hospital outside Tokio, claims that it is one of the commonest lesions found in leprosy. It seems to occur in two forms.

(*a*) A patchy alopecia, quite unlike that of syphilis, and is associated with and generally follows certain of the larger nerves of the scalp, e.g. the great occipital, superficial, temporal. Prior to complete alopecia in these areas one finds a thinning of the hair and then baldness. Not infrequently this is associated with anæsthesia of the scalp. The micobacterium of leprosy can be demonstrated in properly stained sections.

(*b*) The second type of lesion seen is complete alopecia of the whole head, associated with actual nodule formation. These occur chiefly over the front of the vertex.

During tours in the Far East of practically all the countries where leprosy is prevalent, it is only in Japan that I have seen leprosy affecting the head. Recently, however, I came across two cases in the Leper Farm at Nicosia, Cyprus. The disease in Japan is of a very severe type, and this is probably the reason why leprosy affects the head. Nowhere in the world have I seen such extensive nodular cases, and I am not surprised that the scalp should be affected. All the predisposing factors that Dr. Davison mentioned, except the short frizzly hair, occur in India as well as Africa. Therefore I feel that it is the type of disease rather than the individual which is the causative factor in determining whether this area of the body is invaded or not.

I trust Dr. Davison's article will stimulate others to look carefully for scalp lesions in leprosy.

I am, Sir, yours faithfully,

ROBERT G. COCHRANE, M.D.,
M.R.C.P., D.T.M. & H.

British Empire Leprosy Relief Association,
Cavendish-square, W., May 27th, 1929.

THE NEW IMPORTANCE OF RADIUM.

To the Editor of THE LANCET.

SIR,—In regard to the therapeutic use of radium for cancer and other conditions, and the treatment of disease by irradiation generally, there would appear to be two great dangers to real progress at the present time. First, a danger of uncontrolled enthusiasm, to be followed by the disappointment to which Mr. Victor Bonney referred in the recent discussion published in your issue of May 25th. Secondly, a risk that the opportunity is not taken by the medical profession at the present time to promote the most effective organisation for taking fullest advantage of the wide and sympathetic interest of the public in this important branch of medical work. There are, doubtless, many medical readers who are less concerned with the relative merits of operation versus radium in the treatment of any particular local condition, cancerous or otherwise, than with the fundamental proved fact that radium possesses real value in the treatment of cancer and possibly other conditions; that largely owing to shortage of supplies the study of this subject has been relatively neglected in this country; and that, in addition to shortage of supplies, there is a shortage in the number of the necessary trained investigators, whose services are essential for placing our knowledge of the subject on a true level.

It is probably true to say that radium and treatment by radiation has found one of its chief spheres of influence in gynæcological surgery, in the treatment of cancer of the cervix and uterine fibroids. In the allied field of obstetrics there is much hope for the future, in the results claimed by numerous German authorities, as to the prophylactic and curative values of irradiated milk in the treatment of rickets. If rickets can be controlled, the bearing of this on obstetric work and on child welfare and infantile health and mortality is profound and far-reaching. For some months past I have been investigating this subject with the coöperation of Dr. T. Y. Finlay, of the Child Welfare Department, Edinburgh, and Dr. J. B. King, of the Radiological Department of the Royal Infirmary, and the results of this inquiry, which will shortly be published, amply confirms the claims made by German authorities. The manner in which the use of irradiated milk controls the disorderly manner of growth of the cells characteristic of rickets is very striking, and opens up a vista of possibilities of far-reaching interest and importance.

If full advantage is to be taken of the possibilities of the moment, it seems advisable that a very broad and comprehensive view of the possibilities of radium and radiation be taken, not only in relation to cancer, but in relation to normal and abnormal nutrition and diseases arising therefrom. The admirable report of the Radium Sub-Committee deals with radium only, and is essentially restricted to cancer. This view is probably too restricted. The sum of £250,000 obtained as a radium fund is small in relation to the real needs of the situation. Assuming that one-eighth of this was available for Scotland, this sum, added to present available supplies, is certainly far short of what is required. It is also doubtless far short of what would be provided by the public for a comprehensive well-considered business-like scheme. The basis for any successful scheme is the recognition of the need for much thorough clinical research to be carried out primarily by experts, with the coöperation of clinicians. A question I would like to ask is, whether the experts have said their last word on the subject. What are their recommendations? Taking Scotland as a unit, is it not possible to devise a scheme, in which the four University teaching centres would coöperate, their scheme being allied to and part of a larger scheme?

Unless action is taken on some broad comprehensive lines there is reason to fear that only a fraction of the possible benefits to private and public health will accrue from the present movement.

CANCER OF THE COLON.

To the Editor of THE LANCET.

SIR,—The general excellence of the address given by Prof. Grey Turner on the above subject and reported in THE LANCET (May 18th and 25th) is, I am sure, obvious to all who have read it, and I hope he will not think my criticisms are made in anything but a fair and friendly spirit. I want to comment on three points which arise in his address—the incision, the blood-supply of the colon, and Paul's operation.

1. *The incision.*—Mr. Grey Turner says he strongly recommends direct exposure over the situation of the growth, using the oblique or transverse muscle-cutting incision of Rutherford Morison, as he finds adherent growths in the ascending or descending segments of the colon cannot be satisfactorily dealt with by the paramedian incision. This is not my experience; however adherent the growth may be it is quite easy to mobilise it from a paramedian incision made to the right or left according to the site of the growth. Perhaps in Leeds we are prejudiced in favour of this incision, because I believe Lord Moynihan is responsible for its introduction, as Mr. Grey Turner may be influenced by his association with Mr. Rutherford Morison. *If there is no advantage to be gained by* direct incision, as I maintain, then I think there can be no doubt as to which is the better one, as with the paramedian incision there is the minimum risk of a post-operative hernia, and the ensuing scar is much more satisfactory in every way. The only consideration which would make me use the direct approach would be an intimate blending of the growth with the anterior abdominal wall, where a large segment of this might need removing; this is only rarely encountered.

2. *Danger of insufficient blood-supply at the anastomosis.*—Contrary to the view expressed by Mr. Grey Turner, I believe that if sepsis occurs after an anastomosis is made in the colon it is almost invariably due to the spread of infection at the time of operation, and not to lack of blood-supply and consequent necrosis at the suture line. It is, in my opinion, almost impossible to deprive the colon of an efficient blood-supply, and I do not believe that the critical point of Sudek exists. If necrosis follows an anastomosis it is not due to the precarious supply of blood, but to the suture line being under tension, and as it is always possible to bring one or other side of the colon, or both, to the anastomosis quite free of tension by adequate mobilisation, necrosis should never be seen.

3. *Paul's operation.*—I am surprised Mr. Grey Turner should only make a passing reference to this operation in the treatment of carcinoma of the colon. The growth and glands are mobilised through a paramedian incision and delivered through a small separate opening such as one makes for a colostomy, the first incision being completely closed after the afferent and efferent loops have been stitched together on the mesial and lateral aspects. The two loops are clamped across at the level of the skin, and the parts containing the growth and glands removed with a cautery. The result is that the two loops come to the surface like the barrels of a shot-gun, and in a few days the septum is destroyed by crushing, and finally the lumen of the gut restored by suture. The chief virtue of this operation is its amazing safety. I became intimate with the technique from Lord Moynihan when I was his private assistant. He informs me he has never had a death from this operation, and I have only had one in something over 30 cases—the fatal case was one in which a loop of small intestine had also to be removed owing to extension of the growth. This operation has not acquired the popularity it deserves and chiefly, I believe, because it has been asserted that the glands cannot be effectively dealt with owing to interference with the vascular supply of the parts which are left. I believe this is quite wrong, as on one occasion I deliberately tied the superior hæmorrhoidal vessels and no appreciable sloughing ensued in the lower loop.

This would seem to be an instance of what I have already said, that it is extremely difficult to deprive any part of the colon of a viable blood-supply.

I am, Sir, yours faithfully,

Leeds, May 28th, 1929. E. R. FLINT.

THE LONDON RHEUMATISM CLINIC AND THE PROFESSION OF MASSAGE.

To the Editor of THE LANCET.

SIR,—It is a little hard that you should say, in a leading article on the London Rheumatism Clinic that there is "no proper clinic for out-patient treatment of those *in the early stages of disease* (the italics are mine) who can remain at home, and no place where those who have had the benefit of institutional treatment can receive the continued observation and after-care which will alone ensure results." After all, the Red Cross Clinic at Kensington has been doing this work for seven years, and only this last week we have been in frequent correspondence with the authorities at one of the spas about our various patients.

You give a list of four remedial agencies, every one of which, with the solitary exception of the water treatment, has been provided at Kensington, and in many hospital out-patient departments, for years past. Many other forms of treatment not mentioned are also provided. The only innovation that the new clinic can claim, so far as I can see, is the addition of the treatment with water in its various forms—a treatment which, though of undoubted value in some cases, is certainly by no means the most important part of treatment in the vast majority of other cases, particularly those which can best be described as of the early ambulatory type.

But setting aside this contention for the moment, I must confess that the last two sentences of the first paragraph are calculated to excite alarm. These read, "Those who are able and willing to pay a reasonable fee for treatment will do so and there is every prospect that the industrial assurance societies, all of whom have coöperated, will contribute. In this way the Clinic itself should be self-supporting or something like it." Does this mean that there is to be no almoner at the new Clinic, to safeguard the interests of the professional masseur and masseuse in private practice? There are 1550 masseurs and masseuses practising in the London district. Many of them have staked everything they possess on making themselves proficient, and in acquiring the necessary qualifications to enable them to practise all the various forms of physical treatment which are to be provided at the London Rheumatism Clinic, with the solitary exception of the water treatment. If patients who can afford to pay for private treatment are to be taken at this Clinic for any form of physical treatment other than one of the recognised forms of bath treatment, an immense amount of hardship will be done to the private masseur and masseuse.

At our Clinic at Kensington, not only have we fixed a minimum fee, but we have fixed a maximum fee as well; anyone who, in the opinion of our trained almoner, can afford to pay more than the maximum of 5*s*. per treatment is handed over to the care of a masseuse in private practice and in this way the interests of these highly skilled, hard-working and, for the most part, generous members of a recognised profession are safeguarded. I know it is perfectly simple to say that any patient suffering from rheumatic symptoms would be benefited by the addition of some sort of bath treatment to the electric, massage, manipulative, and exercise treatment which is prescribed, but in the great majority of ambulatory patients, radiant heat, massage and ionisation, or diathermy, faradism, and skilful manipulation and graduated exercise form the main-stay of treatment. If patients for whom this treatment will be adequate, and who can afford to pay the customary fees of private physical treatment practice, are to be treated at the new Clinic, the private practice of the masseur and masseuse in London will disappear. If it were in the best interests of the patients that this should be so, then naturally there is no more to be said. I submit, however, that it is not so.

For the insured populace, of course, the new Clinic will be a godsend. We have frequently tried to induce the various insurance societies to make use of the Clinic for their members, and have not infrequently been successful in obtaining grants on their behalf. Undoubtedly there are a number of people whom regular bath-treatment would help more than other forms of physical treatment, but they form a comparatively small minority and the best possible treatment can usually be given without this adjunct in early ambulatory cases.

I am, Sir, yours faithfully,

JAMES MENNELL.

Park-crescent, Portland-place, W., May 20th, 1929.

CICATRISATION OF WOUNDS.

To the Editor of THE LANCET.

SIR,—In an annotation entitled the Cicatrisation of Wounds in your issue of May 11th (p. 989) it is stated that the optimum hydrogen-ion concentration of the tissue juice lies between 7·4 and 7·8. Sympathectomy, it is said, suppresses the acidity of wounds, and brings the pH back to the most favourable point. I would be glad to know if this is the generally accepted view. I had thought that the normal pH is round about 7·3–7·4, and should regard 7·8 as well over to the alkaline side with predominance of sympathetic. Removal of sympathetic action would, in my view, reduce the alkalinity of blood and increase the acidity, allowing of the acid vagus predominance. This fits in with recent writers who find that ammonium chloride increases the healing of wounds and with my own use of calcium chloride.

I am, Sir, yours faithfully,

Darlington, May 18th, 1929. R. CHALMERS.

VACCINATION INSERTIONS.

To the Editor of THE LANCET.

SIR,—The recent Commission on Vaccination recommended that not more than two insertions of lymph be made; but I understand that public vaccinators have received no fresh instructions, and are continuing to make four. In the case of re-vaccinations by a practitioner who is not a public vaccinator, can two insertions be relied on to give adequate protection?

I am, Sir, yours faithfully,

May 25th, 1929. H. S. S.

THE FINANCE OF VILLAGE SETTLEMENTS

To the Editor of THE LANCET.

SIR,—In a review of Dr. W. Bolton Tomson's book "Some Methods for the Prevention of Tuberculosis," reference is made (THE LANCET, May 18th, p. 1039) to his "defence" of tuberculosis village settlements, and to his courage in dealing with "the weak spots in village settlements—their finances." I would suggest that the word "support" would be better than "defence," for so far as I know village settlements have never been attacked with success. In face of their achievements, indeed, it would be impossible to do so. As to their "weak spots," our only weak financial spot is that we at Papworth have to house cases that come from all over England. Papworth has spent over £10,000 in housing London cases alone; and the London boroughs, who have thus been relieved of the cost of maintaining the families of these cases, have not contributed a penny towards this. This is a very weak spot, but it is no argument against village settlements. At a nett trading cost of less than

£3000 Papworth Industries have paid £112,000 in wages to normally unemployable persons suffering from clinical tuberculosis in a moderately advanced form. If this is not sufficient demonstration that finance, at any rate, is not the "weak spot" of village settlements, I can only say that there are none so blind as those who won't see. Village settlements cost money, of course, like railways and battleships; but as they save more than they cost, and limit the spread of infection into the bargain, they surely need no "defence" on the "weak spot" of finance.

I am, Sir, yours faithfully,
P. C. VARRIER-JONES,
Medical Director, Papworth Village Settlement.
Papworth Hall, Cambridge, May 27th, 1929.

⁂ Dr. Tomson is convinced that no better agent has been devised in this or any other country for combating tuberculosis than the village settlement, and we commended this claim with its financial implications to the serious consideration of our readers. A whole-hearted support of the settlement principle need not blind its advocates to the financial side of this as of all other antituberculosis measures.—ED. L.

Public Health Services.

SMALL-POX MILD AND SEVERE.

A Memorandum issued by the Ministry of Health last week is directed towards the misunderstanding here and in America as to the prevalence of small-pox in this country. It is pointed out that small-pox of mild degree has been more than usually prevalent in *England and Wales since 1922, the number of cases* having reached the peak of 14,787 in 1927, while the maximum number of 53 deaths occurred in 1928, being a percentage mortality of 0·43. These cases of small-pox of mild degree have been distributed chiefly in certain industrial areas where vaccination among adolescents and adults has been relatively neglected. The increased movement of the people, together with *the extreme mildness of degree of infection, has tended* to disseminate the malady. This mild small-pox, however, is now regarded as showing signs of abatement, and in England, at all events, we are no worse off than we have been for a quinquennium. Dealing with the *Tuscania* outbreak, it is stated that the number of severe cases which arose from this source amounted to 51 (out of 1554 passengers and crew); of these, 35 occurred in England and 16 in Scotland, 10 cases proving fatal. There has been no further infection from the *Tuscania* since April, and the outbreak, which was in any case narrowly restricted, has definitely terminated.

ADMINISTRATIVE ACTION AGAINST AN INSURED PERSON.

THERE is a well-founded grievance among insurance practitioners that the rules for the administration of medical benefit, printed on the medical cards of insured persons, are not loyally observed, while a strict watch is kept on infringement of any regulations for medical conduct. One of the rules on an insured person's card prohibits him from making unreasonable demands upon the professional services of the practitioner who attends him, and another lays it down in so many words that except in serious emergency the insured person shall not summon the practitioner to visit him after 9 at night or before 9 in the morning. A case has recently been dealt with by the Birmingham Insurance Committee in which a doctor lodged a complaint against an insured person on his list for a flagrant breach of this rule. It was stated without contradiction that, being summoned at midnight to attend a woman at her father's house, he found there a drunken brawl in progress, and the alleged patient suffering from no injury or illness. The Insurance Committee found the complaint as well based, and imposed a fine of half-a-crown, which, if inadequate in the particular case, may serve as a reminder to the great mass of inconsiderate insured persons, should it be feasible to bring the decision pointedly to their notice.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Reading.

THE estimated population of this county borough in 1928 was 96,183, the Registrar-General's figure not being available. Other statistics were: birth-rate, 15·5; death-rate (crude) 11·9, (standardised) 10·4; tuberculosis, 1·13; cancer, 1·33; respiratory diseases and influenza, 1·5; *and heart disease, 1·9. The rates per 1000 births were:* neonatal 28, infant 53·6, 1 to 5–year children 23, and maternal from childbirth 6·7.

Dr. H. J. Milligan mentioned in his last report that two cases of small-pox had occurred at Battle Infirmary in the early weeks of 1928; there were no further cases during the year. A notable feature of 1928 among the infectious diseases was the increased prevalence of diphtheria, including many cases of a severely toxic character. The notifications of diphtheria numbered 136 and the deaths 19, giving a case mortality-rate of 14 per cent. All of the fatal cases showed acute toxæmia. Tracheotomy was performed on five patients at the Park Hospital, of whom all but one recovered. The disease was widely distributed and schools did not appear to play an important part in its spread. There is no evidence in Reading of a decline in tuberculosis. The deaths from the pulmonary form have remained practically constant in the years since the war. In 1928 there was a considerable increase of non-pulmonary tuberculosis deaths. The proportion of tuberculous milk remains high. During 1928 44 samples were examined and five gave a positive result, equivalent to 12 per cent. The corresponding figures for the three preceding years were 7 per cent., 17 per cent., and 14 per cent. respectively.

The maternity and child welfare scheme has been extended in the following respects: consultants have been appointed for puerperal fever, complicated cases of labour, and ophthalmia neonatorum; an agreement has been made with the Royal Berkshire Hospital for the hospital treatment of complications of pregnancy and labour, and with the Queen Victoria Nursing Institute for the home nursing of such cases; and an agreement has been made for the admission of mothers and babies to Battle Infirmary in cases of severe ophthalmia neonatorum. The Dellwood Maternity Home had a successful year, and more than one-sixth of the confinements in the borough were conducted there.

The refuse of the borough is tipped at Manor Farm. The usual tip nuisances have arisen and measures are being taken to mitigate them by lowering the height of the tip and by covering it more efficiently with earth. There are 24 slaughter-houses in the borough, of which 14 are owned by the Corporation, and eight registered and two licensed are owned privately. The public slaughter houses are of old design and inconvenient and new premises are needed. There is still an urgent shortage of working-class houses. A review of the insanitary houses in the borough was made during the year, and indicates that there are 107 houses, mostly more than 100 years old, which cannot be made reasonably fit for human habitation. There is a second category of 391 houses without a separate water-supply or a separate water-closet, and many of these are also suitable only for demolition. The housing committee has resolved to allot a certain number of newly constructed flats to suitable tenants now occupying insanitary houses.

In his school report Dr. Milligan expresses his regret that nothing is being done during the pre-school age to prevent the occurrence of such defects as enlarged tonsils and adenoids, defective vision and carious teeth, and he urges the great importance of the teaching of hygiene and of habits of health and cleanliness at the earliest possible age. The answers to a questionaire addressed to the head teachers show that the teaching of practical hygiene is not by any means general. The report of the school dentist, Miss Marion S. Mackinnon, shows that the dental staff is quite insufficient to cope with the work. A new method of treating unhealthy nasal passages was begun in 1928, and consists in massaging the nasal passages with soft inflatable rubber bougies, the size of which is gradually increased. For this treatment the word "diastolisation" (a Greek equivalent for dilatation) has been quite unnecessarily coined. It is claimed that the treatment will restore the normal function of the nose. Sixty-eight cases were selected, 36 of nasal catarrh or obstruction, 18 of otorrhœa, and 14 of deafness. Sufficient time has not elapsed to enable any verdict to be given as to results.

Ilfracombe.

The population of this urban district is estimated at 9067 and reaches a maximum during the season of 35,000. The birth-rate for 1928 was 11·5 and the crude death-rate 12·3 (standardised 9·2). As regards other rates the figures on which they are based are small. Thus five infant deaths gave an infant mortality of 48 and one maternal death a child-birth rate of 9·6. The cancer and heart disease rates were high, 2·2 and 2·5 respectively, and the respiratory with influenza rate low—viz.: 1·2—as one would expect in a health resort. The tuberculosis rate was 0·99. The hours of bright sunshine were 1531·3 and the rainfall about 40 inches.

Dr. D. C. Adam reports that the water-supply is of the highest purity. It comes from moorland gathering grounds in the Forest of Exmoor. As it has a plumbo-solvent action at certain periods of the year the use of lead pipes in its distribution for domestic use is forbidden. There is a great shortage of houses suitable for the working classes and the closing of unfit houses cannot be enforced. No subsidy houses were erected during the year. There are 44 cowkeepers, but there is no producer of graded milk in the district. One dealer, however, has a licence, issued last June, to bottle and sell Grade A (T.T.) milk. There is one public slaughter-house situated conveniently away from the centre of the town. It requires to be extended in order that the three private slaughter-houses, situated undesirably near the centre of this health resort, may be closed.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 18TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 362 (last week 277); scarlet fever, 1978; diphtheria, 944; enteric fever, 40; pneumonia, 1475; puerperal fever, 57; puerperal pyrexia, 121; cerebro-spinal fever, 17; acute poliomyelitis, 1; acute polio-encephalitis, 1; encephalitis lethargica, 26; dysentery, 10; ophthalmia neonatorum, 96. No case of cholera, plague, or typhus fever was notified during the week.

The largest incidence of small-pox at the moment is in London (Bethnal Green 13 cases, Stepney 26), Chesterfield R.D. 11, West Ham 45, Ashton-under-Lyne 28, Stoke-on-Trent 41, Spenborough (Yorks) 22, and Ebbw Vale 13 cases.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on May 21st–22nd was as follows:—Small-pox, 332 under treatment, 12 under observation (last week 292 and 15 respectively); scarlet fever, 1447; diphtheria, 1582; enteric fever, 13; measles, 136; whooping-cough, 830; puerperal fever, 26 (plus 13 babies); encephalitis lethargica, 111; poliomyelitis, 1; "other diseases," 61. At St. Margaret's Hospital there were 14 babies (plus six mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 1 (0) from enteric fever, 81 (1) from measles, 5 (1) from scarlet fever, 63 (20) from whooping-cough, 23 (3) from diphtheria, 33 (9) from diarrhœa and enteritis under two years, and 81 (14) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to London (Woolwich Met. B.). Two cases in which small-pox was mentioned as the cause of death should (it is stated) have been reported in earlier returns. One of these has been provisionally assigned to Lincoln C.B. (week ended April 13th), and the other to Stoke-on-Trent C.B. (week ended April 20th). No great town reported more than three deaths from influenza except Manchester with 5, Bournemouth, Stoke-on-Trent, and Birmingham with 4 each. Liverpool reported 17 deaths from measles, Leeds 7, Birmingham and West Hartlepool 6 each. The mortality from whooping-cough continues to diminish; Manchester still has 4 deaths to report, Liverpool 3. No more than 2 deaths from diarrhœa occurred in any great town.

The number of stillbirths reported during the week was 301 (corresponding to a rate of 41 per 1000 births), including 51 in London.

Obituary.

HUGH LATHROP MURRAY, F.R.C.P. & S. EDIN.

Dr. Hugh Murray, who died at Melbourne on March 17th in his sixtieth year, had made his mark on the practice of medicine in the Commonwealth, for it was under his tutelage that the very fine department of physiotherapy at Melbourne Hospital attained its full development. He himself narrowly escaped being a martyr to his pioneer work, for he was suffering from exposure dermatitis before he gave up the personal direction of the X ray department.

The son of a commissioner of the Victorian Railway, Hugh Murray was born at Ararat, Victoria, in 1869, and was educated at Melbourne before entering on his medical curriculum at Edinburgh, where he qualified in 1892. In the following year he served as house physician to Dr. Andrew Smart at the Royal Infirmary, and continued to study for the higher qualifications of both Royal Colleges. Returning to Australia in 1895, he settled in a residential suburb of Melbourne, where he became a successful general practitioner long before his attention to physical agents brought him recognition in that special department of medicine. He lectured to and examined the Australian Massage Association, of which he was actually the founder, and it was his undaunted persistence which saw the Massage Registration Act through the Victorian Parliament, whereby an end was put to the unlicensed practice of medical electricians, physical culturists, and the like. In 1916 he served as regimental medical officer with several Australian battalions in Egypt, and in the following year he organised the department of medical electricity at No. 3 Australian Auxiliary Hospital in England. On his return to Melbourne he was put in charge of the physiotherapy department of No. 11 General Hospital, where he carried on his army work until 1921, with special attention to the muscle re-education required by many of the sufferers from war injuries.

The colleague to whom we owe many of these biographical details writes of Hugh Murray as a man of splendid physique, with the activity and grace of the all-round athlete. Already in his early student days he had won swimming and throwing championships, and had played lacrosse for Victoria against South Australia. At the age of 21 he beat the world's record for throwing the lacrosse ball, only to be beaten by his brother, the present holder, a few years later. He had a baritone voice of wide range, finely modulated and excellently controlled, which brought him in request in his Edinburgh days at public concerts and social functions. Unfortunately, his later years were clouded by illness, for he suffered from renal calculus, undergoing two operations for its relief, and developed angina pectoris; but in these troubles he maintained the fortitude and cheerfulness which were characteristic of him from his student days.

Dr. Murray was twice married. His first wife was the daughter of John Macinnes of Melbourne, and by this marriage he had two sons, of whom the elder qualified last year at University College, London, and the younger, an officer in the Royal Air Force, recently flew in a Moth aeroplane from Peshawar to Queensland. His second wife, who survives him, is the daughter of James Calvert of Kyabram, Victoria.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on May 24th the following degrees were conferred:—

M.D.—V. B. Wigglesworth and L. B. Winter.
M.B. & B.Chir.—J. R. H. Towers and H. W. Nicholson.

UNIVERSITY OF OXFORD.—Convocation has passed a decree thanking Mr. Gilbert Varley for the offer to transfer to the University the sum of £6000, subject to a life annuity, to be at the disposal of the University for the furtherance of medical research in accordance with the wishes of his brother, the late Richard Stanley Varley.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—Dr. R. Dods Brown will deliver the Morison lectures at the College at 5 P.M. on Monday, Wednesday, and Friday, June 3rd, 5th, and 7th, his title being Some Observations on the Treatment of Mental Diseases.

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL.—The *Duke of Connaught will distribute prizes in the Governor's* Hall of St. Thomas's Hospital at 3 P.M. on Tuesday, June 11th.

SOUTH LONDON HOSPITAL FOR WOMEN.—Princess Helena Victoria will open a garden party at this hospital on Clapham Common at 2.45 P.M. on Saturday, June 1st.

THE ROSS ARCHIVES.—The British Museum trustees have decided that the papers relating to Sir Ronald Ross's discovery that the anopheles mosquito is the vector of malaria, which were presented to the Museum last year by Lady Houston, shall be transferred to the Ross Institute at Putney.

LEBANON HOSPITAL FOR MENTAL DISEASES.—The thirtieth annual meeting of this hospital took place on May 21st at Friends House, London. Dr Fortescue Fox, who presided, said that a recent visit to Syria with the secretary had impressed him more than ever with the importance and magnitude of the task of caring for the insane in that country. The first hospitals to undertake the humane and curative treatment of mental disease in the Near East were founded a little more than 30 years ago: in Egypt, by Dr. Warnock; in Jerusalem, by a group of Jewish women, and at Asfuriyeh, in Syria. Whereas the number of beds for mental diseases per population in England and Wales was 1 in 270, in Egypt it was 1 in 4500, in Palestine 1 in 6000, and in Syria 1 in 16,300. Great extensions were in contemplation in Egypt under the guidance of Dr. Dudgeon, and in Palestine, in both cases under Government auspices. The need for additional beds in Syria was even more urgent. The Lebanon Hospital was entirely voluntary, and was a small but well-equipped unit (150 beds). It had remained open to all nationalities and religions, through famine and revolution, and enjoyed the entire confidence of the country and of the French authorities. As Sir George Newman had stated on a recent visit, it was seriously overcrowded. Happily the hospital had become to a great extent a self-supporting institution, but it still looked to the Central Committee in London and affiliated committees for all capital expenses for buildings and improvements, and for salaries and pensions. Dr. Fox *hoped that new helpers would come forward* to make an investment for these sufferers which would bring in sure dividends of health and happiness in that country.—Dr. E. W. G. Masterman (chairman of the London Committee) said that two new houses were needed (one for men and one for women), and mentioned the possibility of help from New Zealand in erecting a New Zealand memorial house with 50 beds.—*Dr. Doris Odlum referred to the large* number of indigent cases (110 in 1928) that were now sent by the local authorities in Syria, and to the large number of cures obtained.—Sir Wyndham Deedes said that of all the work done in that part of the world there was nothing that better commended the West to the East, both in its nature and in the manner in which it was done. After further speeches a letter was read from Dr. John Warnock, late of Cairo, warmly advocating the extension of the work.

The office of the hospital is at 139, Marylebone-road, London, N.W. 1.

EXTENSION OF INVERNESS NORTHERN INFIRMARY.—The Duke of York, who is Earl of Inverness, has opened a new children's ward, which the Duchess, who accompanied him, named "the Princess Elizabeth of York Ward."

CUMBERLAND INFIRMARY.—The governors have received £500 from Mrs. Glyn, of Dalston, for the endowment of a cot in the infirmary in memory of her husband and four sons. An anonymous donor has given £1000 towards the Radium Fund.

MEMORIAL TO A PHYSICIAN.—A window in memory of the late Dr. Landel R. Oswald, physician superintendent at the Glasgow Royal Mental Hospital at Gartnavel, was unveiled last week in the church of the institution. The window is the gift of his brother.

SOUTHEND GENERAL HOSPITAL.—The plans for *the new General Hospital at Southend-on-Sea* have been enlarged, and it is now proposed to provide 196 instead of 168 beds, at a cost of £136,000. There will be 26 beds for paying patients, a similar number for maternity cases, and eight for eye cases. Eventually the hospital will be extended to hold from 400 to 600 beds.

NEW TREASURER OF THE KING'S FUND.—The Prince of Wales, as President of King Edward's Hospital Fund for London, has appointed Mr. Edward Robert Peacock as chairman of the Finance Committee and treasurer of the Fund. Mr. Peacock, who succeeds the late Lord Revelstoke is a director of Baring Brothers and Co., and has been a director of the Bank of England.

HOPE UNION INFIRMARY.—Sanction has been given by the Ministry of Health to an extensive enlargement of the Hope Union Infirmary of the Salford Guardians at Pendleton. It is claimed that with the new portion the institution will be one of the largest separate hospital units in the world. There will be 1500 beds, and a further 500 for aged and infirm persons in adjoining buildings.

HOSPITAL COÖPERATION AT LIVERPOOL.—The Merseyside Hospitals Council have made an arrangement with the guardians of the West Derby Union whereby the guardians have agreed to treat any cases admitted to their *poor-law hospitals which, in the opinion of their medical* officer, would normally be admissible to a voluntary hospital. Payment will be made out of the Penny-in-the-Pound Fund without cost to the contributor.

A LIVERPOOL MOTOR AMBULANCE.—From the proceeds of their "Panto Day," the Liverpool University undergraduates have voted *£1500 to provide the Merseyside* Hospitals Council with a motor ambulance for the use of the out-patients' departments. It will accommodate ten sitting cases, will be warmed by hot water, and will be fitted with an arrangement for keeping lying-down patients, in a horizontal position when the ambulance is descending an incline.

ST. BARTHOLOMEW'S HOSPITAL, ROCHESTER.—This hospital, which was founded in 1078 by Bishop Gundulph and claims to be the oldest institution of its kind, is crippled for lack of space and money, and the Mayor of Rochester is appealing for help. Although there are only 126 beds last year there were 1858 in-patients. The Mayor, Coun*cillor F. C. A. Matthews, announces* his intention of "sitting outside the Guildhall" from 8 in the morning till 8 in the evening to-day (Saturday) to receive contributions.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Friday, June 7th.—10 A.M. LARYNGOLOGY: Summer Meeting. Papers by Mr. F. J. Cleminson, Mr. Musgrave Woodman, and Mr. W. S. Thacker Neville on Treatment of Carcinoma of the Œsophagus. Mr. Harold Barwell and Dr. J. A. Gibb: Inflammation in the Maxillary Antrum and Frontal Sinus. Also papers by Mr. W. S. Thacker Neville and Mr. O. Popper. 5 P.M.—Paper: Dr. W. Jobson Horne: Cancer of the Vocal Cords. Clinical Cases will be shown by Mr. Norman Patterson, Sir James Dundas-Grant, and Dr. A. L. MacLeod.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

Tuesday, June 4th.—5 P.M., Dr. H. H. Dale: Some Chemical Factors in the Control of the Circulation (First Croonian Lecture).

Thursday.—5 P.M., Dr. H. H. Dale: (Second Croonian Lecture).

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, June 3rd.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Ward Visit. 2 P.M., Mr. Bishop Harman: Eye Department.

Tuesday.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Wednesday.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

Friday.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, June 3rd.—2.30 to 5 P.M., Medical Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

Friday.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, June 3rd, to Saturday, June 8th.—MEDICAL SOCIETY, Lecture Room, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Course. Lectures on Tues. and Frids. at 8.30 P.M. Tues., Prof. Hugh MacLean: Nephritis with Special Reference to Cardiovascular Involvement. Frid., Prof. Hugh MacLean: Recent Views on Diabetes and Insulin. HOSPITAL FOR DISEASES OF THE SKIN, Blackfriars-road, S.E. Clinical demonstrations by Dr. Willmott Evans, at 3.30 P.M., on Thurs. (No fee for attendance.) ROYAL NORTHERN HOSPITAL, Holloway-road, N. Clinical demonstration (fractures) by Mr. F. D. Saner, at 10.30 A.M., on Sat. (No fee for attendance.) ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, Holborn, W.C. Special afternoon course continuing for three weeks.—THE INFANTS HOSPITAL, Vincent-square, S.W. Second week of afternoon course.—Further particulars from the Fellowship of Medicine.

ST. THOMAS'S HOSPITAL, Albert Embankment, Westminster Bridge, S.E.

Thursday, June 6th.—5 P.M., Prof. S. J. Cowell: Dietetics. (Last of six lectures.)

UNIVERSITY COLLEGE, Gower-street, London.

Thursday, June 6th.—5 P.M., Mr. R. J. Lythgoe: Special Sense Physiology. (Last of six lectures.)

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

Monday, June 3rd.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Mr. Leslie Paton: Papillœdema (2).

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Mr. Donald Armour: Cranio-cerebral Topography.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Gordon Holmes: Lesions involving the Optic Chiasma (2).

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Neurosyphilis (3).

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmorland-street, W.

Thursday, June 6th.—5 P.M., Dr. R. O. Moon: Some Observations on Diseases of the Myocardium. (St. Cyres Lecture.)

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

Friday, June 7th.—3.30 P.M., Mr. Ferguson: Changes in the Eye in General Diseases.

Appointments.

Durie, Doris L., L.R.C.P. Lond., M.R.C.S., D.P.H., has been appointed Assistant Medical Officer of Health, Southend.

Horne, H. F., M.D., B.Chir. Camb., Medical Referee under the Workmen's Compensation Act for Barnsley County Court.

Quastel, J. H., D.Sc., Ph.D., Bio-Chemist, Cardiff City Mental Hospital.

Schofield, J. E., M.B., Ch.B. Sheff., F.R.C.S. Eng., Deputy Medical Superintendent, Hackney Hospital.

Vacancies.

For further information refer to the advertisement columns.

Accrington, Victoria Hospital.—H.S. £150.
Albert Dock Hospital, Connaught-road, E.—Res. M.O. at rate of £110.
Barking Urban District Council.—Asst. M.O. and Asst. School M.O. £500.
Birkenhead County Borough.—Res. Asst. M.O. £150.
Birkenhead General Hospital.—Hon. Dermatologist.
Birmingham, City Hospital for Infectious Diseases, Little Bromwich.—4th Asst. M.O. £300.
Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.
Birmingham and Midland Homœopathic Hospital and Dispensary. H.S. £150.
Cambridge, Addenbrooke's Hospital.—Res. Anæsthetist. Also H.P. At rate of £180 and £130 respectively.
Carshalton, Surrey, Queen Mary's Hospital for Children.—Jun. Asst. M.O. £500.
Carshalton U.D.C. Maternity and Child Welfare Services.—M.O. of Clinics. Rochester Road Clinic, £100 per annum. Stanley Road Clinic, 30s. for each attendance.
Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100.
Chester Royal Infirmary.—H.S. £120.
Chesterfield and North Derbyshire Royal Hospital.—Cas. O. and H.S. to Ear, Nose and Throat Dept. At rate of £200.
City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. At rate of £100. Also Laryngologist.
City of London Maternity Hospital, City-road, E.C.—Registrar. £100.
Derby, Derbyshire Hospital for Children.—H.S. £150.
Dover, Royal Victoria Hospital.—H.S. £180.
Dreadnought Hospital, Greenwich, S.E.—H.P. and H.S. Each at rate of £110.
East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. Also Res. H.P. and Cas. O. At rate of £150 and £100 respectively.
East London Hospital for Women, &c., Shadwell, E.—Pathologist. £400.
Essex Administrative County.—Asst. M.O.H. £600.
Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Res. Surg. O. At rate of £175.
Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S. Also H.P. Each at rate of £100.
Hertford County Hospital.—H.P. At rate of £150. Also Hon. Surg.
Hong-Kong.—Asst. Clinical Pathologist. £720.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100. Also Res. M.O. for Country Branch, Tadworth, Surrey. At rate of £250. Also Surg. Reg. £300.
Hove, Lady Chichester Hospital.—H.P. At rate of £100.
Hull Royal Infirmary.—Cas. H.S. At rate of £130.
Ilford Emergency Hospital.—Hon. P.'s also Hon. S's.
Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150. Also 2 H.S.'s. Each at rate of £120.
Kensington, Fulham and Chelsea General Hospital, 194, Finborough-road, Earl's Court, S.W.—Res. Cas. M.O. At rate of £100.
King Edward Memorial Hospital, Mattock-lane, Ealing, W.—Consulting Ophth. S.
Lancashire County Council.—Asst. County M.O. £800.

Lancs. County Council, High Carley Sanatorium, Ulverston.—Asst. Tuber. M.O. £450.
Lancaster, Royal Albert Institution for the Feeble-minded.—Jun. Asst. M.O. 8 gns. a week.
Liverpool, Bootle Borough Hospital, Derby-road.—Anæsthetist. £50.
L.C.C. Mental Hospital Service.—8th Asst. M.O. £300.
London Jewish Hospital, Stepney Green, E.—Cas. O. At rate of £150.
Lowestoft and North Suffolk Hospital.—H.S. £120.
Male Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.
Manchester, Ancoats Hospital.—Assist. Pathologist. £150.
Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Sen. Res M.O. At rate of £125.
Manchester, Salford Royal Hospital.—H.P. Also Three H.S.'s to special departments. Each at rate of £125.
M.A.B., Infectious Hospitals Service.—Jun. Asst. M.O.'s. Each £300.
M.A.B. Mental Hospitals Service.—Jun. Asst. M.O. £500.
M.A.B., Sutton, Surrey, Antitoxin Establishment, Belmont Laboratories.—Bacteriologist. £700.
Miller General Hospital, Greenwich Road, S.E.—Out-Patient Officer. At rate of £150.
Montrose Royal Asylum.—Jun. Asst. M.O. £325.
Northampton Mental Hospital, Berrywood.—Locum Tenens M.O. 7 gns. a week.
Northamptonshire County Council.—Tuberculosis Officer. £750.
Nottingham, Harlow Wood Orthopædic Hospital, near Mansfield.—Res. Surg. O. ; £250.
Norwich, Norfolk and Norwich Hospital.—H.S. £120.
Plymouth, South Devon and East Cornwall Hospital.—Res. Surg. O. At rate of £150. Also H.S. At rate of £100.
Portsmouth Royal Hospital.—H.P. At rate of £130.
Portsmouth, St. Mary's Hospital, Institution, &c.—3rd Asst. Res. M.O. £250.
Preston, Biddulph Grange Orthopædic Hospital.—Jun. H.S. At rate of £150.
Princess Louise Kensington Hospital for Children, N. Kensington.—Hon. Assist. Surgeon to Ear, Nose and Throat Dept.
Queen Mary's Hospital for the East End, Stratford, E.—Res. M.O. £200. H.P. and Cas. O. £150. Also H.P., Two H.S.'s and Obstet. H.S. Each £120.
Queen's Hospital for Children, Hackney-road, E.—H.P. £100.
Rochdale Infirmary and Dispensary. Jun. H.S. £175.
Romford, Oldchurch Hospital.—3rd Asst. Res. M.O. £250.
Royal London Ophthalmic Hospital, City-road, E.C.—Surgeon to Ear, Nose and Throat Dept.
Royal Northern Hospital, Holloway, N.—H.S. Also Res. Med. Cas. O. and Anæsthetist. Each at rate of £70.
Ryde, Royal Isle of Wight County Hospital. Res. H.S. £130.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C. Clin. Assts.
Salop County Council.—Asst. M.O. £600.
Sheffield Royal Hospital.—Residents. At rate of £80.
Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £150. H.S. for Ophthalmic and Aural Departments. £150. Also Asst. H.P. £125.
Sudan Government Medical Dept.—Two M.O.'s, LE720.
Sudan Medical Service.—M.O. LE720.
Sydney University.—Chair of Physiology. £1100.
Taunton and Somerset Hospital.—Sen. and Jun. House M.O.'s. At rate of £150 and £100 respectively.
Torquay, Torbay Hospital.—Hon. Surgeon.
University of London.—External Examinerships.
Warrington Infirmary and Dispensary.—H.P. At rate of £150.
Watford Peace Memorial Hospital.—Locum Tenens H.S.
West London Hospital, Hammersmith-road, W.—H.P., H.S., Aural S., and Ophth. H.S. Each at rate of £100.
York County Hospital.—H.P. and H.S. Each £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Brampton (Cumberland); Lesmahagow (Lanark); Newport (I. of W.); and at Muirkirk (Ayr).

Births, Marriages, and Deaths.

BIRTHS.

RODGER.—On May 25th, at West Lodge, Bicton Heath, Shrewsbury, the wife of Dr. Kenneth M. Rodger, of a son.

MARRIAGES.

ARTHUR—ROBSON.—On May 25th, at Chelsea, Arthur Samuel Arthur, Lieut.-Colonel, R.A.M.C., to Mrs. Ellen Seymour Robson.

BAILEY—MEADE.—On May 15th, at Epsom Parish Church, Basil Noel Victor Bailey, M.B., Ch.B. Edin., D.T.M. and H. Eng., of Georgetown, British Guiana, to Ena Elizabeth Meade, of Woodbury, Reigate-road, Ewell.

CAMAC WILKINSON—FRY.—On May 23rd, at St. Marylebone Church, London, W. Camac Wilkinson, M.D., F.R.C.P., to Dulcie Dea, daughter of Mr. and Mrs. Walter R. Fry, of Sydney.

DEATHS.

GIMSON.—On May 21st, at Springfield House, Chelmsford, William Douglas Gimson, M.R.C.S., L.R.C.P., aged 61.

HUXTABLE.—On May 25th, Richard Rossiter Huxtable, L.R.C.P., M.R.C.S., late of Sutton Ely.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

PROTOPLASMIC BUBBLES.

ARCELLA is a testaceous protozoan about 0·1 mm. in diameter. The shell is shaped like a bun and on the lower flat side is a large hole through which the pseudopodia are extruded when the animal is active. It has been known for a long time that the various species of the genus had the remarkable capacity of producing bubbles of gas in the protoplasm and of afterwards absorbing them. The meaning and mechanism of this procedure is obviously of great interest, and the last number of the *Quarterly Journal of Microscopical Science* is entirely occupied with a beautifully illustrated account of the researches into the subject which occupied the late Dr. E. J. Bles, of Cambridge, for many years chequered with serious ill-health and ending with his death in 1926. Shortage of oxygen stimulates the production of the gas vacuoles with the useful result that the animal is floated to the surface of the water where oxygen may be had. But bubbles are also formed if Arcella is rolled over on to its back. Engelmann (using another species) studied this reaction and thought that the animal was ingenious enough to adjust the size and position of the bubbles so that it got it right side up. Dr. Bles, working with *A. discoides*, could not confirm this in all details; the actual righting of the animal is, according to his observations, achieved by a pseudopodium reaching over and getting a grip of something firm; the bubbles merely reduce the specific gravity and make the reversal much easier. When the animal has regained its natural position the gas is quickly absorbed and the vacuoles disappear. The gas produced to form the bubbles is oxygen and apparently pure or nearly pure oxygen. Among the various proofs of this are some elegant experiments with methylene blue. An Arcella in a dilute solution of this dye remains unstained. If it is then taken out into clean water (and even kept till next day) and then rolled on to its back the cytoplasm in spots near the periphery turns blue and bubbles appear in blue areas which fade away as the bubbles are afterwards reabsorbed. Evidently the dye is absorbed by the animals, but reduced to the leuco compound; it does not become manifest until oxygen is produced in response to some external stimulus. A large part of the paper is occupied with an intricate argument about the mechanism by which free oxygen is generated. The sum of it is that it arises from an oxidase system, working presumably on hydrogen peroxide as an intermediate metabolite. It is here that some commentary by Sir Gowland Hopkins and Dr. D. Keilin (who have edited the paper for publication) would have been useful; recent years have seen great advances in our knowledge of oxidases of which Dr. Bles was hardly aware. But the whole forms an unusually interesting chapter of cellular physiology which has a far wider significance than the motions of Arcella.

MUSEUM TECHNIQUE.

Dr. Maude Abbott is to be congratulated on the latest of the occasional publications[1] of the Association of Medical Museums of which she has always been the moving spirit. The contents are as varied as the daily work of a morbid anatomist and museum curator, and all are of interest. There are a number of obituaries of deceased members of the Association, including a curious portrait (p. 265) which we should hardly have suspected to be Adami; another on the frontispiece is easily recognisable. Another notable feature is a full account by Prof. P. Masson, lately migrated from Strasbourg to Montreal, of his methods of cutting sections and fixing them to slides with gelatin and of his various staining methods which, for all their æsthetic drawbacks, are becoming well-established in pathological laboratories. Articles on celloidin corrosion, mounting calculi, silver staining, and a number of other practical topics are all useful. The journal also deals with results as well as methods; teratology occupies a considerable section of which, as one might expect, malformed hearts have the greater share. Several pages give queries from puzzled members, some of which are answered, and there is an exchange department for pathological material. We should be glad to know if this really works usefully in practice. The whole is lively reading for any working pathologist. Our only criticism is that the book is sewn so tightly that it will not lie open.

---

TRAFFIC ACCIDENTS IN DENMARK.

In a paper by Dr. T. G. Knudtzon, of the Medico-Legal Institute of the University of Copenhagen, published in *Nordisk Medisinsk Tidsskrift* for May 4th, with the title the Doctor's Medico-Legal Duties in Cases of Traffic Accidents, a table is published which shows at a glance how enormous is the increase in the burden thrown by modern vehicular traffic on the medico-legal expert. The figures in column II. refer to the number of official post-mortem examinations on persons dying as a result of traffic accidents in Copenhagen and the Danish islands. Those in column III. refer to the total number of official post-mortem examinations made in the same period and area. The figures in column IV. indicate the number of motor vehicles in Denmark from time to time, whilst those in column V. show the total population of Denmark in certain years in the period under review.

NEW PREPARATIONS.

Acécoline (Laboratories Chevretin-Lematte, Rue La Bruyère, Paris).—In THE LANCET of March 9th (p. 493) we published an article on the Therapeutic Application of Acetylcholine by Prof. Maurice Villaret, physician to the Hôtel-Dieu, Paris, and Dr. L. Justin-Besançon, Director of the Laboratory of the Faculty of Medicine of Paris, in which the authors summarise their research into the properties of this new vaso-dilating preparation. In view of this article the Anglo-French Drug Co., Ltd., of 238A, Gray's Inn-road, London, W.C., point out that they hold a stock of acetylcholine-hydrochloride which they are marketing under the name of acécoline.

Johnson's Allsoy Biscuits.—From the Johnson's Cereal Food Company, 2, Bridge-road, Willesden, N.W.10, we have received a sample of Allsoy biscuits, which are made of soya flour, nut butter, and saccharine, the analysis supplied with the sample showing moisture 2·70 per cent., starch 0·70 per cent., fat 39·45 per cent., protein 32·81 per cent., nitrogen-free extract 18·93 per cent., fibre 1·55 per cent., mineral salts 3·86 per cent.—from which it will be seen that the biscuits contain no sugar, while starch is less than 1 per cent. The biscuits are quite palatable, and have been found a suitable and digestible adjunct to diet in patients suffering from eczema and eruptive cutaneous disorders associated sometimes with high blood pressure. It is pointed out by the manufacturers that in severe cases of diabetes their use is less obvious and may be deleterious.

THE FUTURE OF MEDICAL PRACTICE.

To the Editor of THE LANCET.

SIR,—Many of those who read the letter by "Forward" in THE LANCET of April 27th will no doubt appreciate how it strikes a note to the effect that the future of medicine is merely one of the side issues of commerce. In a nation of shopkeepers it is well that the physician be merely a "dagone" salesman. When all the doctors will "hold a stated amount of stock," so that "they may have a financial interest and stake in the success of their hospitals," the next step will be somewhat to pursue the patient even after death in demanding a bonus from the undertaker, a notion which contains exactly 200 cents to the dollar. In concluding, "Forward" says, "Also we could control both the number and type of students entering the different medical schools, and gradually build up a profession of which the medical men and the nation generally could be justly proud." From which it seems there is no cause for present elation. And yet one cannot help reflecting that the English seats of learning have always sent forth just that type of cultured and highly skilled gentlemen who made the profession what used to be considered an honourable one. These universities have ever eschewed the donating of M.A.s of the soda fountain and Sc.D.s in hot air. As to the selection of students the present standard of written examination in Latin, Greek, mathematics, &c., has everything to commend it. Many, to the credit of all concerned, proceed to degrees in arts, science, modern languages, philosophy, and so on before taking up the study of medicine proper, and thus still further carry a real culture to all environments; a poor training certainly in the catch-as-catch-can of the industrial market. There are, however, reasons for everything, and it will be well to investigate the causes whereby such suggestions as those of "Forward" should discover themselves. If the situation is inevitable it were well either to burn our bridges or prepare for the worst.

I am, Sir, yours faithfully,

California, U.S.A., May 9th, 1929. EN AVANT.

GOGARBURN INSTITUTION.

THE details of the new institution for the feeble-minded at Gogarburn were given on p. 1114 of our last issue. The memorial stones were laid by the Duke and Duchess of York on May 22nd, when there was a large assemblage representing both the city of Edinburgh and the south-eastern counties. "The day was ideal," writes our Edinburgh correspondent. "The beauty of the old estate, varied by the new buildings, itself symbolised the beneficent purpose of the new colony. In the afternoon sun, the grey-brown of the old mansion house against the delicate summer green of the beech trees, all toned by the glimpse of the Pentlands to the south, made a very beautiful picture. For its new purpose, the site is as fitting as for its old. It is one more example of the adaptive developments of a democratic civilisation."

DONATIONS AND BEQUESTS.

Mr. W. Lewis Morris, of Wallasey and Liverpool, left about £30,000 to charities. Subject to a life interest, he gave £5000 to the Liverpool Hospital for Cancer and Skin Disease; £3000 to the Wallasey Victoria Central Hospital, Liscard; £2000 to the Wallasey Cottage Hospital, and the ultimate residue for charitable institutions or objects as the executors may think proper.—Sir Harry Branston, of Crewe Hill, Farndon, Cheshire, left the balance of £1000 war stock invested by him out of the moneys received as salary as an M.P. as to two-thirds to the Chester Royal Infirmary, and one-third to the Nantwich Cottage Hospital.—Mrs. Victoria Gildea Grimond, of Barbazon Lodge, Sunningdale, Berks, left £2000 to the Dundee Infirmary for the endowment of two beds.—Mr. Montague Goodall, of Hampstead, left £1000 to University College Hospital; £500 each to the Hampstead General Hospital and Dr. Barnardo's Homes; and £250 each to the Royal London Ophthalmic Hospital and the National Lifeboat Institution.—Mr. Charles Arthur Wells, of Epping, left £1000 each to the Queen's Hospital for Children, Hackney-road, the City of London Hospital for Diseases of the Heart, Victoria Park, and to the London Hospital.—Mr. John Braidwood Gray, of 16, Kensington Gore, London, left, besides other bequests, £2500 to King Edward VII. Hospital Fund for London, and £500 each to St. Mary's Hospital, St. George's Hospital, Victoria Hospital for Sick Children, London, and the Surgical Aid Society.—Mr. Hermann Edward Frederick Bonner, of Villa Gloirette, Monte Carlo, Monaco, left £5000 to the Hospital for Sick Children, Great Ormond-street, London, W., and £2000 to the German Hospital, Dalston.

THE COMPOSITION OF CELLULOSE.

A CORRESPONDENT, referring to our leader last week on the Lessons of the Cleveland Disaster, writes to point out that gelatin is not a constituent of celluloid as is there implied. We regret the phrasing of the statement, which should, of course, have read "a gelatinised product of" nitrocellulose and camphor.

Vasotomy in the Treatment of Early Urethritis.—Mr. J. F. Peart writes that the statement attributed to him (THE LANCET, May 25th, p. 1095) that he "had done vasotomy only twice" is misleading. It should have been clear from the heading and context that the allusion was to vasotomy *in early urethritis* which has never been advocated, nor so far as he can ascertain, practised before he did it in April, 1927.

Primogeniture.—Dr. M. T. Macklin asks us to state that the full text of her paper on Primogeniture as a Factor in the Production of Developmental Anomalies, an abridged version of which appeared in THE LANCET of May 11th (p. 971), will be published with the bibliography in an early number of *Human Biology*. The paper was read before the Royal Society of Canada in Winnipeg.

Croonian Lectures

ON

SOME CHEMICAL FACTORS IN THE CONTROL OF THE CIRCULATION.

Delivered before the Royal College of Physicians of London

BY H. H. DALE, M.D. CAMB., F.R.C.P. LOND., F.R.S.,
DIRECTOR OF THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH.

LECTURE I.

(Delivered on June 4th.)

INTRODUCTION.—VASOMOTOR HORMONES.

SIX years ago I had the honour of giving here the Oliver-Sharpey lectures,[1] and chose as my subject the Activity of the Capillary Blood-vessels. My aim in those lectures was to bring together the evidence, much of it then of recent date, on the independent contractile activity of these minute vessels and its bearing on certain problems of physiology and pathology. Among the investigations which had provided this evidence were some in which I had myself taken part; and these had been largely concerned with the vascular effects of certain intensely active chemical principles. One of these, adrenaline, had long been known as a natural hormone, and as the first of the hormones to be chemically isolated, structurally identified, and prepared by artificial synthesis. Two other bases, rivalling adrenaline in the intensity and evanescence of their activity on the tone of the small blood-vessels, were also mentioned—histamine and acetyl-choline. There was then no evidence, however, which seemed to me adequate to justify the supposition that either of these substances was a normal constituent of the animal body. Their actions afforded a means of reproducing with certainty, and in graded intensity, changes in the tone of blood-vessels closely similar to those occurring in certain physiological and pathological responses. For the closer study and analysis of such responses, their use, and especially that of histamine, had been convenient and helpful. There was a certain amount of evidence suggesting that substances having what, for brevity, we called a "histamine-like" action might be liberated from injured or irritated tissues and play a part in the associated vascular reactions; but mere similarity of action on the blood-vessels did not afford evidence of identity or even of similarity in chemical structure. We were at that time concerned not so much with the chemistry of the agent, which we regarded as possibly inaccessible to investigation, as with the physiology of the reaction; and the results obtained by studying the effects of these known bases were applied only by way of analogy.

In the intervening six years evidence from a number of sources has produced a great change in the situation. In 1926 Sir Thomas Lewis gave his Croonian lectures on the Blood-vessels of the Human Skin, and in the following year published, in the remarkable book bearing the same title,[2] a systematic review of the investigations, mainly carried out by himself and his co-workers, on which the lectures had been based. A point of central interest in these researches was the recurrent evidence of liberation from injured or irritated cells of a chemical substance, closely resembling histamine in its action, and responsible for the vasodilatation and wheal-formation in the immediate neighbourhood of the lesion. In place of a plausible speculation we were thus presented with a fact, established by an impressive array of convergent and cumulative evidence. Meanwhile my own associates had been making progress, far beyond expectation, in the isolation in pure form from extracts of normal tissues, and the chemical identification, of substances producing the actions on peripheral blood-vessels with which we were concerned. From an entirely different direction evidence has appeared indicating that those changes in the automatic rhythm of the heart which are produced by stimulation of the vagus on the one hand, and of the sympathetic nerve-supply on the other, are not the results of the direct passage of nerve impulses to the heart muscle, but are mediated by the liberation, in close relation to its fibres, of chemical principles having inhibitory and excitatory actions. Again, a literature of recent growth and impressive volume has been devoted to the properties and significance of a substance which can be extracted from the heart, and particularly from the region of the sino-auricular node, and which has a stimulating effect on the rhythm. To this substance has been attributed the function of providing the natural stimulus to the heart's normal activity. From several different directions, therefore, evidence is accumulating of chemical factors in the control of the circulation, reinforcing and supplementing the long-recognised mechanisms of nervous control, and even intervening in the production of their effects. Moreover, between those chemical principles which appear to be concerned in the control of the function of the heart and those which are concerned with the variation of vascular tone, we have not merely a functional link, in that all are involved, in different ways, in regulating the circulation of the blood; in more than one instance there are grounds for suspecting that we may be dealing with the same chemical principle, exhibiting its activity in different forms on different organs. It has accordingly appeared to me that I might appropriately use this opportunity for a survey of the evidence concerning some of these chemical factors in the control of the circulation. I shall not attempt an inclusive review, but devote attention primarily to those factors concerned, in one direction or another, with the maintenance or modification of vascular tone. So far as evidence dealing with actions on the heart, or on other organs, is brought into the discussion, it will be on account of its bearing on my main theme. My choice of this limitation is determined partly by the direction of the investigations in which I have personally participated, and partly by the consideration that the evidence dealing with the agents concerned in vascular reactions is, as yet, more definite and detailed, especially on the chemical side, than any we have as to principles to which an exclusive effect on the heart's activity is attributed.

I shall of necessity touch on certain vascular phenomena with which I dealt, from another point of view, in the Oliver-Sharpey lectures, and on those which provided the rich evidential material of Sir Thomas Lewis's more recent Croonian lectures. My concern, however, will be primarily with the nature, distribution, and properties of the principles providing the chemical stimuli for such reactions; and the evidence which now makes it possible to speak with some assurance as to their chemical nature is largely a product of the past three years.

In order to give completeness to the conception which I wish to present to you, it will be desirable, in the first place, to pass in rapid survey over some familiar ground, and to consider the parts played in the control of the circulation by the long known substances which have claims to be regarded as circulatory hormones in the true sense—epinephrine or adrenaline, and the vasoconstrictor principle of the pituitary body. When I speak of these as "hormones in the true sense," it is necessary to make my meaning more explicit. When Bayliss and Starling introduced the word "hormone," they intended it to apply to an active principle formed in one organ and carried by the blood to others, in which it produces its specific stimulating or pharmacodynamic effect. Their discovery of secretin had suggested the need for a short term to indicate such chemical carriers of physiological stimuli by way of the blood stream. It appears to me to be very desirable, in the interests of clear thinking, to restrict the use of such a word to the meaning originally applied to it. In that original sense adrenaline might be taken as the perfect type of the hormones; and the pituitary vasoconstrictor principle, which, in view of its recent physiological separation, we may now refer to as "vasopressin," has at least a presumptive claim to be included in the list. In the larger part of these lectures, however, I shall be dealing with substances of a similarly intense physiological activity, restricted in its normal incidence to the immediate neighbourhood of their liberation. The distinction between the function of such a locally acting chemical stimulant and that of a true hormone, carried everywhere by the circulation, seems to me to be a real one, and one having a special significance for our present purpose.

ADRENALINE AND VASOPRESSIN.

Adrenaline and vasopressin have the characteristic of true hormones, that each is formed locally in an organ having the specific function of its production, and is distributed by the blood to all parts of the body, affecting all blood-vessels which are specifically sensitive to its stimulus. In neither case have we any evidence that the blood-vessels of the producing gland are sensitive to the hormone formed in immediate relation to them. On the contrary, we may regard it as practically certain that they are not so; in the presence of relatively high concentrations of a vasoconstrictor so potent as either of these, the small vessels of the gland, if showing the sensitiveness of those in other organs, would be constricted to obliteration; the circulation through the endocrine tissue, essential to the hormone function, would be rendered impossible. The fact that both these general circulatory hormones are predominantly vasoconstrictor in their action, is worthy of note by itself. Apart from these general similarities the two differ widely, in what we know of their chemical nature, of their detailed modes of action, and of the conditions under which they are secreted into the blood and exhibit their actions on distant organs.

Adrenaline (Epinephrine).

It is probable that our knowledge of adrenaline, of the conditions governing its secretion into the blood, and of the details of the method of its action, is more complete than of any other hormone. A relatively simple basic derivative of catechol, it was successfully produced by synthesis many years ago. It is readily destroyed by oxidation at the reaction of the body fluids, and quickly disappears from blood circulating through organs which react to its stimulus, so that its action, when applied through the circulation, is a very evanescent one, unless it is injected in quantities altogether above the physiological range. Accordingly it is admirably fitted for the temporary reinforcement, in response to some sudden emergency, of the effects of true sympathetic nerves on almost all organs supplied by them. The fidelity with which it reproduces such true sympathetic effects, augmenting or inhibiting the functions of different contractile or secreting cells in close accordance with their response to sympathetic impulses, was made clear many years ago, particularly by the work of Elliott.[3] It is further known, as hitherto in the case of no other hormone, that the output of adrenaline from the suprarenal medulla is under nervous control, responding to impulses in the splanchnic nerve-fibres running to the gland. The gush of adrenaline into the venous blood accompanying a sudden emotion, and the adaptation of its effects, especially on the circulation, to the physiological needs of the emergency, have been emphasised by Cannon.[4]

As regards the circulatory mechanism, we must suppose that adrenaline is carried in almost equal concentration to all parts of it, reproducing the sympathetic accelerator and augmentor effects on the heart-beat, and affecting the blood-vessels in the sense of their response to sympathetic impulses. The variations of this response, in intensity and even in direction, produce large variations in the relations between the vascular tone in different systems. The vessels of the gastro-intestinal canal are apparently in all animals more sensitive to the vasoconstrictor effect than those of the skeletal muscles, so that a small dose of adrenaline entering the general circulation will tend to produce a redistribution of the blood-supply, in favour of the muscles and at the expense of the alimentary canal. In some species—the cat and the dog—minute intravenous doses of adrenaline, given under the ordinary conditions of experimental anæsthesia, cause a relaxation of the minute vessels, particularly of the skeletal muscles, which often so predominates over the slight vasoconstriction produced by such doses in other tissues, as to give, on balance, a definite fall of arterial pressure. The meaning of this depressor, vasodilator action of small doses of adrenaline has been the subject of a number of investigations in quite recent years. Macdonald and Schlapp [5] have pointed out the pronounced accentuation of the phenomenon by administration of ether. In the decerebrate preparation the balance of the effect may change from depressor to pressor action, according as ether is given or withdrawn; and it has been suggested that the vasodilator action may not occur in the normal animal, but only under the artificial conditions imposed by ether. On the other hand, Richards and I were able to detect it on several occasions in the action of extremely minute doses of adrenaline on the vessels of the surviving, artificially perfused hind limb of the cat. On the whole, it seems to me probable that this dilator effect of minute doses of adrenaline, particularly on the small vessels of the skeletal muscles, is a truly physiological effect, occurring in the normal animal, and that ether assists its predominance, in the general effect on the arterial blood pressure, by a relative depression of the vasoconstrictor effects in other tissues.

The question as to whether this action is due to a true, sympathomimetic effect of adrenaline itself, or to the secondary liberation of a directly dilator principle, has also been raised. Richards and I [6] some years ago indicated the many points of resemblance between this special, weak vasodilator effect of adrenaline, as seen in the cat's limb, and the much more powerful dilator effect of histamine. The same changes of conditions, affecting the tone and response of the vessels, seemed always to accentuate or depress the two effects together. We were led to locate the action of both on the same type of minute vessels; and the resemblance was so suggestive as later to raise the question whether this effect of adrenaline might be due to a reactive liberation of histamine, just as a small dose of histamine, injected into a normal cat certainly causes the suprarenal gland to respond by a small gush of adrenaline (Kellaway and Cowell).[7] Burn and I [8] thought we had detected such a mechanism in the lung, but later experiments with Richards [9] revealed an error in our technique. On the evidence yet before us we must regard this vasodilator effect, as seen typically in the cat and the dog, as probably a true effect of adrenaline itself. Whatever the mechanism of its production, I think we must regard it as an important factor, in those species in which it occurs, in the redistribution of the blood-supply, in favour of the skeletal muscles and at the expense of the digestive viscera, which is occasioned by a natural acceleration of the output of adrenaline from the suprarenal medulla. We may think of it, therefore, as an item in the more general series of changes emphasised by Cannon, replacing the physiological conditions favourable to contemplative digestion by those which fit the animal for combat or flight, when adrenaline gushes into the vena cava at the call of anger or fear.

Another effect of adrenaline, almost certainly concerned in such a redistribution of the blood-supply in accordance with functional need, recently came to light in some experiments, as yet unpublished, which I carried out last year with Dr. Walter Bauer and Dr. Dickinson Richards, American guests in my laboratory. It concerns the control of the blood flow through the liver of the dog, and depends on a mechanism which has not yet been found in other species. The branches of the efferent, hepatic veins in the dog are furnished with stout coats of plain muscle (Simonds).[10] This muscle, as Mautner and Pick [11] first showed, is very sensitive to the effect of histamine, which throws it into powerful contraction, damming back the blood in the capillary spaces of the liver, and causing a pronounced congestion of the whole organ. It can hardly be doubted that, during the process of digestion, small quantities of histamine absorbed from the contents of the bowel, in which they are certainly produced, will keep up some degree of such resistance to the venous outflow from the liver, with a resulting collection of a relatively large fraction of the total blood, firstly in the liver itself, and probably to some extent also in all the viscera drained by the portal vein. In the isolated dog's liver, artificially perfused both from the portal vein and the hepatic artery, by the use of a double perfusion scheme, we found it very easy to demonstrate this action of the hepatic veins, narrowing like a veritable sluice-gate in response to traces of histamine. Under these experimental conditions, however, we were able to recognise an antagonistic effect produced by stimulating the sympathetic nerves to the liver or adding small doses of adrenaline to the perfusing blood. We could observe the well-known constrictor effects of such stimuli on the branches of the hepatic artery, and, in weaker degree, on those of the portal vein; but even more striking than either of these, when the liver had become congested by resistance to the venous outflow, was the opening of the hepatic sluice, so that the turgid liver emptied its blood rapidly into the reservoir receiving the blood from the vena cava. Again I think we can hardly miss the physiological significance of such a mechanism. At a sudden call for vigorous activity of the voluntary muscles, under the stimulus of sympathetic impulses assisted by a gush of their chemical understudy, adrenaline, the veins would open widely and release, for the needs of the whole organism, blood which, during digestion, had been filling the capacious capillary bed of the liver. Anatomical studies may reveal the presence of such a mechanism in other species; by physiological methods we regularly obtained evidence of its function in the dog's liver, but failed to detect it in that of the cat.

While effects of adrenaline on the tone of the larger arterial branches to the lungs and to the brain cannot be excluded, it seems safe to say that functionally important effects on the small vessels, such as adrenaline shows in other organs, are not produced by it in these. Here again its action, or lack thereof, is closely parallel to that of the sympathetic nerves. Finally, the clearest exception to the predominantly vasoconstrictor action of adrenaline is provided by its dilator effect, again corresponding to an exceptional dilator action of sympathetic nerves, on the arteries supplying the heart. The reality and functional significance of this effect has been established by the recent work of Anrep and his co-workers, which, by an ingenious application of refined physical methods to the exact and continuous record of the coronary blood flow, has clearly differentiated effects on vascular tone from those due to the contraction of the heart muscle.

Vasopressin.

The pituitary vasomotor principle presents in many respects a contrast to adrenaline. Though its existence was recognised by Oliver and Schafer[12] only a year after their discovery of the action of suprarenal extracts, our knowledge of its chemistry is still relatively meagre. An important step has recently been taken, however, towards its separation in a state of physiological purity. For some years past opinion had been sharply divided as to whether one or several active principles were responsible for the pressor, uterine stimulant and antidiuretic effects produced by extracts of the pituitary posterior lobe. My colleague Dr. Dudley and I had supported by evidence and argument the view that two at least, and probably more, were concerned; Prof. Abel of Baltimore and his co-workers had strongly defended the view that all the actions were due to one principle, which they believed that they had obtained in approximately pure condition. During the past year the matter has been settled, as it seems to me beyond further dispute, by Kamm, Aldrich, Grote, Rowe, and Bugbee,[13] who have made almost complete the separation which Dudley had partially effected, obtaining a powerfully vasoconstrictor fraction, which they term "vasopressin," with but slight action on the uterus, and another fraction which they term "oxytocin," powerfully stimulating the muscle of the uterus, but almost inactive on the blood-vessels. The action of the whole extract on the plain muscle of the uterus, and on the vascular tone are, therefore, certainly due to different principles. It is not yet possible to give an equally certain answer to the question whether the third therapeutically important action of the extract, the antidiuretic action, is due to yet another active substance, or represents a different aspect of the activity of the pressor principle. Specimens of vasopressin hitherto available have certainly shown antidiuretic activity; but it remains to be proved whether they possess it in the same relative potency, in comparison with the pressor action, as do complete extracts of the fresh gland. It would lead me too far from my present subject to discuss the evidence in detail, but there are indications that the two kinds of activity may vary independently in different commercial extracts, and that some samples of oxytocin, at least, may show antidiuretic without pressor activity. The available information leads me to expect that the antidiuretic action will prove to be due to another distinct principle.

However that may be, our immediate concern is with vasopressin and its function in regard to the circulation. Of its chemistry we know little. We can be certain that it is not a simple base like adrenaline or histamine. It is moderately stable when boiled in acid solution, but easily destroyed by alkali, resistant to peptic but destroyed rapidly by tryptic digestion. It is obviously either itself a relatively simple peptide, or closely associated with a body of that type and unable to exist in active form apart from it. The other pituitary principles have closely similar properties, but such evidence as we have suggests that vasopressin is rather more complex than oxytocin. Injected into the circulation it is not, like adrenaline, rapidly destroyed. Its action is, accordingly, long persistent, and even after its subsidence the vessels long remain relatively insensitive to further injections, suggesting that the principle is still present after its obvious effects have largely disappeared. When large doses have been injected, a substance having a similar pressor action, and very probably the unaltered vasopressin, can be recovered from the urine.

For its true hormone function, and the manner in which it comes into action, the evidence is again remarkably incomplete and indirect. The same is true of the other active principles found in this lobe of the pituitary body. It is difficult, indeed, to believe that a substance so potently active on artificial injection should be concentrated in a structure without other known function, with no provision for its carriage by the blood to the tissue in which its intense activity becomes effective. There appeared to be more direct evidence of the hormone function of the antidiuretic principle, in the artificial *diabetes insipidus* produced by removal or injury of the lobe, and the control of a pathological *diabetes insipidus* by injecting the extract. Even here, however, opinion is still divided between loss of the hormone and injury of the hypothalamic region of the brain, as the cause of the morbid diuresis. According to recent evidence, however, the evanescence of the diabetes following lobe removal, and its renewal on injuring the hypothalamus, may be due to the fact that the latter acquires, vicariously, the function of forming and storing the hormones normally found only in the pituitary posterior lobe.

In the case of vasopressin the evidence seems to be even less direct or convincing. Cushing and Goetsch[14] long ago put forward evidence in favour of its passage from the lobe into the cerebro-spinal fluid, and similar evidence has been given by Dixon and Marshall[15] with regard to oxytocin, the secretion of which they found to be influenced by the functional state of the ovary. It has never been clear, however, that the whole of the principle leaving the gland passes by this route; the gland and its posterior lobe are well supplied with blood-vessels, and it is difficult to suppose that the blood passing through a tissue so highly charged with these diffusible principles could fail to carry its share. In any case, to reach the sites of their known actions they must eventually enter the blood stream; but there is no evidence of any nervous or other influence, by which the rate of the direct or indirect entry of vasopressin into the circulation is caused to vary. On the other hand, the fact that the posterior lobe of a given species, such as the ox, contains a remarkably constant proportion of vasopressin, at all times of the year and apparently under all physiological conditions, suggests a steady flow into the circulation, rather than a fluctuating output adjusted to the call of physiological emergencies, such as the evidence indicates in the case of adrenaline.

So far as its action has yet been analysed, vasopressin appears to produce its effects on the circulation by increasing the tone of the minute vessels without any discrimination corresponding to their nerve-supply. Earlier experiments, made with the crude extracts, had shown a stimulant action on the tone of isolated segments of large arteries. The effects, however, appear to have been due to non-specific impurities, and it is stated that vasopressin, when free from these, is without such action. Several observers (Sacks,[16] Lawrence and Hewlett[17]) have observed the ghastly, corpse-like pallor of the skin, especially of the face, produced in a normal man by a moderate dose of the pituitary extract injected intravenously. The effect is associated with a relatively trivial rise of the general arterial pressure, and occasions little subjective sensation. It can only be attributed, as Lewis points out, to constriction of the minute skin vessels, which in some areas seem to have a peculiar sensitiveness to vasopressin.

The effects of such artificial injections of an extract of the pituitary posterior lobe, or of its vasopressin fraction, on the blood-vessels of the human patient or of the anæthetised or spinal mammal, are indeed sufficiently impressive. There still remain, however, the questions of the degree of our certainty that the active principle does steadily enter the blood stream by a normal, physiological process, and of the function which it exercises, or physiological need which it satisfies, under such natural conditions.

In my Oliver-Sharpey lectures I dealt with Krogh's evidence,[18] derived from observations on the blood-vessels of the frog, which led him to the conclusion that the pituitary vasoconstrictor has the function of maintaining the normal tone of the capillaries, and therewith the normal restricted permeability of their walls. He found a substance, apparently diffusible, in mammalian serum, having properties compatible with the supposition that it was the normally circulating pituitary hormone. On the other hand, removal of the pituitary body in the frog had been observed to be followed by general œdema. Further observations published since that date, and a consideration of the evidence from animals other than the frog, have not strengthened the force of Krogh's evidence. Drinker,[19] working with Krogh, could not confirm the suggestion that the pituitary principle could reproduce all the effects of serum in preventing œdema of the perfused limb. Again, I know of no evidence that a recognisable loss of capillary tone follows removal of the pituitary posterior lobe in the mammal; the results of such an operation, except on the diuretic function, appear from the records, indeed, to be remarkably small.

We are still left, therefore, with evidence only incomplete and indirect of the passage of vasopressin from the pituitary body into the blood stream by natural secretion, and of its functional significance when thus distributed through the vascular system. I think it must be frankly admitted that the strongest evidence in favour of its function as a true hormone is still its occurrence in such quantity, in a tissue in which no local function can be imagined for it, and which yields it so readily to simple extraction with water.

NORMAL FUNCTION OF THE VASOMOTOR HORMONES.

Assuming, as I think we must, that vasopressin is always being secreted, at however slow a rate, into the circulating blood, we are still without data which would enable us to appraise the importance of its presence for the maintenance of a normal vascular tone. The same is true, indeed, of the adrenaline which, in the absence of any special stimulus, trickles slowly from the suprarenal gland into the *vena cava*. Destruction of the medulla of both suprarenal glands is not only compatible with indefinite survival, but is also without any definite effect on the general vascular tone or the arterial blood pressure of the resting animal.

Such absence of obvious change in the efficiency of the normal circulation, when the supply of one or another of these hormones is cut off at the source, appears less surprising when we consider them as items in the multiple provision for the maintenance of the vascular tone. We have, in the first place, the vasomotor centres acting through the sympathetic nerves. At the call of emergency their action is reinforced by accelerated output of adrenaline. It may be that the function of the pituitary hormone is to provide yet another safeguard against circulatory collapse, by a general and undiscriminating maintenance of tone in the small blood-vessels when sympathetic impulses and adrenaline alike begin to fail, under the stress of a prolonged and excessive demand for their action. Such a conception of its function would at least render intelligible the otherwise curious discrepancy between the trivial effects, on the arterial pressure and the general circulation, which its injection produces in the normal individual, and the remarkable restorative action which it exhibits on vascular tone, and therewith on the efficiency of the circulation, in the victim of primary surgical shock or vasomotor collapse.

If we accept the suggestion that the normal, slow secretion of these hormones has little effect on the tone of the vessels, while this is upheld by an efficient vasomotor centre, it is natural to inquire whether their presence in the blood can be detected by an action on vessels in an area deprived of its vasomotor supply, in an animal otherwise normal. It is, indeed, the fact, that vessels of which the vasomotor nerves have been cut, after an initial loss of tone, rapidly acquire a new one, which must be due to some constituent of the blood, and which often becomes greater than that shown by the corresponding, normally innervated vessels. This "automatic" or chemically stimulated tone, as Richards and I pointed out, affects chiefly the minute vessels, and especially the capillaries, on which histamine produces its characteristic vasodilator effects. Finding that these vessels rapidly lost their tone, and their power of responding to histamine, under conditions of artificial perfusion, and that these normal properties could be restored by a trace of adrenaline, we were inclined to attribute the recovery of tone after denervation to the circulation of traces of this substance. One difficulty in the way of such a supposition was that the denervated limb vessels, in natural circulation, showed a conspicuous dilator response to a very small dose of adrenaline itself, artificially injected. In more recent experiments Burn and I[8] have found that a small quantity of pituitary extract will similarly restore tone to these minute vessels in the perfused organ. It may be that both hormones are concerned in the recovery of vascular tone after denervation; and this is a possibility which could be tested by observing whether such recovery occurred in an animal from which the pituitary posterior lobe and the suprarenal medulla had both been extirpated.

The antagonism between the vasoconstrictor effects of these hormones and the dilator effects of histamine may give another and more direct hint as to their functional importance. In my Oliver-Sharpey lectures I mentioned the then recent observations of Kellaway and Cowell, showing the prompt acceleration of adrenaline output in the normal cat when a small dose of histamine was injected intravenously, and the slight and evanescent effects which resulted from the balanced antagonism, as compared with the enormously enhanced and prolonged depressor effects of the same small dose of histamine in a cat deprived of the suprarenal medulla. As I shall show later, these observations gain greatly in direct significance from our new chemical evidence on the occurrence and distribution of histamine in the body. At this stage we may note that observations are lacking as to the effects, on the reaction of the animal to histamine, of *extirpating the pituitary posterior lobe*, either alone or in addition to the suprarenal medulla. But, while the evidence is far from complete, I think it is already sufficient to suggest a probability that a really important function of these hormones in relation to the normal circulation may be found in their power to check, and to restrict within physiological limits, the depressor effects of substances dilating the small vessels, when these escape into the general circulation.

CENTRAL NERVOUS CONTROL OF VASOMOTOR TONE.

We have dealt so far with substances which, being secreted into the general circulation, and affecting the whole vascular system simultaneously, have an action which, with certain local exceptions and qualifications, is to increase or to uphold the tone of the small vessels. In this respect their action broadly resembles, and probably supplements, the effects of the nerve-centres controlling the tone of the vessels through their nerve-supply. There is evidence, indeed, of variation of the vascular tone by reflexes through the nerve-centres, causing unequal distribution of the blood-supply in favour of a particular organ. In the well-known Loven reflex, central stimulation of a sensory nerve from a limb causes general reflex vasoconstriction, accompanied by dilatation of the vessels in that limb, so that the circulation through it is increased. Bradford [21] observed a similar reflex dilatation of the kidney vessels, leading to increased blood flow through that organ, on stimulating centrally a neighbouring sensory root. The late Sir William Bayliss made a series of investigations on the centres involved in these vascular reflexes, and came to the conclusion that, in addition to the well-known vasomotor centres in the bulb and the cord, the action of which can be stimulated or inhibited, with resulting general increase or decrease of the vascular tone which they control, there are other centres which, when called into activity by sensory stimuli, cause active vasodilatation. There is no doubt at all of the reflex activation, through vasodilator centres, of such specifically vasodilator parasympathetic nerves such as the *chorda tympani* and the *nervi erigentes*, causing relaxation of the arterioles in particular localised areas. Bayliss held that, in addition to these local effects, vasodilator centres could cause more general arterial relaxation by impulses passing antidromically down sensory fibres.

Looking at the function as a whole, however, of the nerve centres controlling vascular tone, it is almost a commonplace to say that, like that of the hormones which receive a general distribution through the blood, it is predominantly tonic and vasoconstrictor. And this control, whether by the nerve centres or the true hormones, may be regarded as adapted to the maintenance of the average vascular tone needed for an efficient circulation, to its adjustment in relation to the pressure created in the large arteries by the heart's activity, and to mass variations in the distribution of blood-supply as between one system and another, or as between one organ and the rest of the body.

LOCAL VASODILATOR MECHANISMS.

A large proportion of the vascular reactions of the body, however, are of quite a different type from these, and are fitted to effect a much finer adjustment of the blood-supply to more closely localised requirements. Into this class come all reactions, most accessible to observation in the skin and superficial mucous membranes, but occurring in almost all organs, in which a localised stimulus, irritation, or injury causes a local, vasodilator reaction. Sir Thomas Lewis devoted his Croonian lectures a few years ago to a detailed experimental analysis of these local vascular reactions in the human skin. He found that, whatever the nature of the provocative stimulus or injury—mechanical, thermal, electrical, chemical, or photochemical—the reaction presented a characteristic threefold complex. This consisted of the local red reaction due to dilatation of the minute vessels, a wheal succeeding and coincident with this, and a surrounding irregular "flare" due to dilatation of stronger arterioles. The two former were independent of nerve-supply, while the latter involved the integrity of the terminal axon-branchings of the sensory nerve-fibres, and was obviously due to a local axon reflex. The immediate stimulus, however, to the whole reaction was, according to Lewis, a chemical one. Some substance was liberated from the injured cells which directly dilated the minute vessels and rendered their walls abnormally permeable, and, by its irritation of sensory endings, acted also as the primary stimulus to the reflex flare. He had thus proved that, in these local vasodilator reactions, a chemical agent took part, not merely as a reinforcement or alternative to a nervous mechanism, but as the sole primary stimulus to the whole series of reactions. He had no evidence as to the chemical nature of this agent; but among known pure substances he found that one reproduced this complex with detailed fidelity when introduced in minute dosage into the epidermis. This was the base histamine, the dilator effect of which on minute vessels, together with its constrictor effect on larger vessels and on the plain muscle of certain organs, had been studied by Laidlaw, Richards, and myself. Sollmann and Pilcher[20] had also observed that this substance, introduced by a special technique into the superficial layers of the human epidermis, caused local redness and wheal formation in much higher dilutions than any of a large number of substances which they tested by the same method. Lewis, using it at every stage of his systematic investigation of the reaction of skin vessels, produced a highly impressive series of analogies between its action and that of the substance naturally liberated from injured cells.

The similarity of action, however, gave at that time no warrant for assuming identity, or even similarity, of chemical nature. In my next lecture I shall endeavour to make clear the nature of the more recent evidence, which seems to me to have changed that situation, so that we can now regard it as highly probable that the substance recognised by Lewis, as liberated from irritated or injured cells of the human skin, and as evoking the vasodilator complex in their neighbourhood, is either histamine itself or some loose combination owing its action to histamine.

Ingleby Lectures
ON
SOME TYPES OF SEPTIC INFECTION IN THE NEWLY-BORN.

Delivered in the University of Birmingham on May 23rd and 30th, 1929,

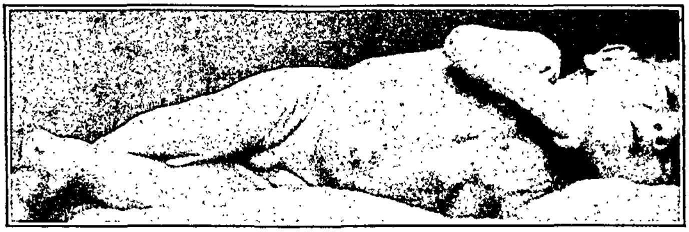
BY HECTOR CHARLES CAMERON, M.D., F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE DEPARTMENT FOR DISEASES OF CHILDREN, GUY'S HOSPITAL.

LECTURE II.*—TRISMUS NEONATORUM AS A MANIFESTATION OF SEPSIS NEONATORUM.

Its Confusion with Tetanus.

IN some cases of sepsis neonatorum it has been mentioned that after death there is disclosed the evidence of a widely spread cerebro-spinal irritation with œdema and hyperæmia of the pia mater, an exudation of serous or sero-sanguineous fluid and multiple small hæmorrhages. It has indeed been debated whether these post-mortem findings are the cause or the result of the striking clinical disorder known as trismus neonatorum. It has been said that they may be produced by the state of asphyxia and circulatory failure which precedes death, when the whole body is held in rigid spasm, and is liable to repeated and violent convulsive seizures. That they are the cause and not the results of trismus neonatorum seems to me proved by a careful consideration of all the circumstances. It has added to the difficulties that these cases have for long and persistently been confused with idiopathic tetanus. It may be that cases of idiopathic tetanus do occasionally occur in neonatal life. I know no way to disprove the possibility. But it is clear, I think, that trismus neonatorum is in general a manifestation, not of tetanus proper, but of sepsis, and that the assumption which has very usually been made that trismus neonatorum and tetanus are identical, has no justification whatever. It is perhaps of interest to notice that, if we exclude this neonatal disorder, tetanus is almost unknown, as Gowers[1] has emphasised, before the age of five.

FIG. 2.



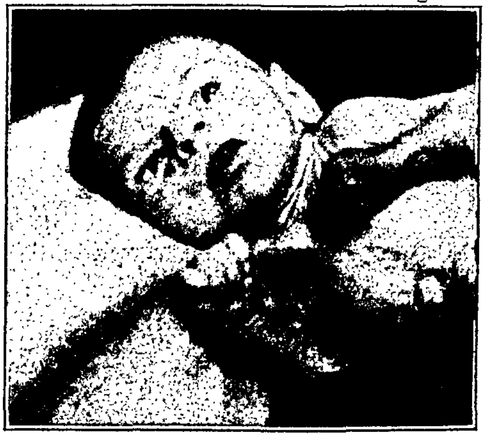
A case showing well the extreme rigidity of the whole body with a greater degree of trismus.

But even among adults we occasionally encounter this confusion clinically between tetanus and meningitis. Thus Batty Shaw,[2] in recording a case of streptococcal meningitis which during life was thought to be tetanus, writes as follows :—

> It is clear that meningitis may provoke spasm of the facial muscles, producing risus sardonicus, of the muscles of the neck and of the abdominal wall, that the spasm may be constant, lasting for hours or even for days, and that the spasm may be increased by irritation, such as is produced by nasal feeding, &c., the patient remaining conscious throughout the illness. Such features have been held in the past to constitute a clinical picture of undoubted tetanus. This view must be abandoned. It appears to us that no reliance can be placed upon an exclusive clinical picture of tetanus, because the disease may be accurately imitated by meningitis.

Batty Shaw further states that a search in text-books produced only one reference to the possibility of confusion (Allbutt and Rolleston[3]). I can, however, myself recall at least two cases of meningitis upon which I conducted post-mortem examinations on which a diagnosis of tetanus had been made during life. In the second case, as has happened in others, it was suggested that the meningitis had followed the injection of antitetanic serum insufficiently sterilised. The other case had had no serum. The possibility of confusion was certainly well known to the older physicians and, as I should have expected, is referred to in two separate places by Fagge and Pye-Smith[4] in their text-book. At a still earlier date the records of post-mortem examinations carried out upon cases which were regarded and described as tetanus include many in which the evidence of meningitis is described. A century ago, inflammatory appearances of the brain and spinal cord were confidently described as characteristic of tetanus, but tetanus, at that date, meant no more than muscular spasm.

FIG. 1.



A comparatively mild case, showing spasmodic contraction of the hands, rigidity of the facial musculature, and a mild degree of trismus.

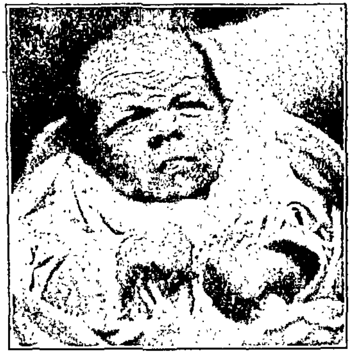
In almost all cases of sepsis neonatorum there will be found some evidence of excessive rigidity of the muscles. The face is apt to be stiff and lined, with a haunted, startled expression well shown in Fig. 1. The arms are flexed at the elbows. The hands are held pronated, clenched, and with the thumbs adducted, a characteristic position quite unlike that of the "accoucheur's hand" of tetany.

In that variety of sepsis neonatorum which we are now considering this rigidity of the muscles is the most characteristic feature and is developed to a remarkable extent. It is combined with restlessness or partial coma, convulsions, twitching of the muscles, some degree of opisthotonos, and finally with trismus. The rigidity of the jaw, unlike what is found in true tetanus, is not an early development, nor is there any tendency for the jaw muscles to be involved with special severity. The rigidity of the jaw is in keeping with the rigidity of all the muscles. As I have been at some pains to emphasise the infant functions solely as a suction apparatus and, characteristically, it is this peculiarity of the infant that has focused the attention of observers upon this particular group of muscles and led to the confusion with tetanus. In cases which recover the spasm of the jaw in trismus disappears comparatively early, while the spasm in the hands and feet may remain for many weeks longer, a feature very unlike what we find in tetanus.

---

* Lecture I. appeared last week.

FIG. 3.



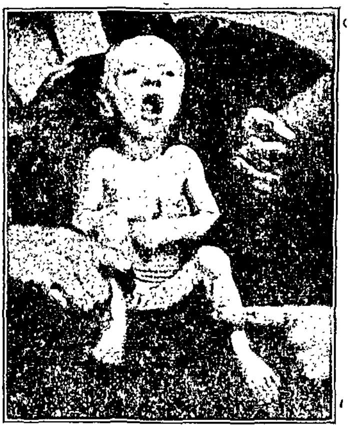
A severe case, showing complete "risus sardonicus" and spasm of the hands.

The accompanying photographs illustrate cases of trismus neonatorum which from time to time have been under my care. All were admitted to hospital in the first ten days of life. Two had septic exfoliative dermatitis of a mild sort, one had a septic umbilicus, one had a large sloughing ulcer on the palate (Bednar's aphtha), in a fifth no focus of infection was obvious, but the mother was admitted to hospital with puerperal symptoms. Fig. 1 shows a mild case which recovered in about three weeks. The face was stiff and lined, and there was generalised rigidity of all the muscles, and a slight degree of opisthotonos. The infant was unable to suck, and a finger introduced into the mouth was held firmly by the clenched jaws. Another case (Fig. 2) illustrates well the extreme rigidity of the whole body. Fig. 3 shows the condition in a third child, in which the severity was much greater, so that the simulation of tetanus was complete. Here we have the final picture of risus sardonicus. Death took place from gastro-intestinal disturbance a fortnight later, at a time when the spasm had to a great extent disappeared. Post-mortem examination showed great hyperæmia and congestion of the brain and spinal cord, with œdema of the pia mater. The study of the cerebro-spinal fluid in this case, removed during life, at the height of the spasm, showed clear evidence of cerebro-spinal infection or irritation. The cells numbered 250 per c.mm., and the protein content was raised to 0·12 per cent.—six times *the normal. Fig. 4, a photograph taken when the* infant was 3 weeks old, shows a case of special importance for my present argument. For many weeks the jaw was rigidly fixed, but with the mouth held widely open and not closed, a position recalling that characteristic of the progressive lenticular degeneration of Wilson.[5] The spasm of the hands and feet lasted for months. Indeed, it gave rise to a persistent deformity of the fingers, shown in Fig. 5. As we watched, there gradually developed a peculiar shortening of the tissues on the flexor aspects of the clenched fingers, so that ultimately, after all spasm had ceased, there remained an inability to extend the fingers because of this shortening. So far as I could judge, this infant, with a septic umbilicus, showed a condition identical with that of trismus neonatorum, save for the position of the jaw. The child, except for the persistent deformity of the fingers, made a good recovery, regaining the power to suck after about 16 days, but died when 2 years old from broncho-pneumonia.

The Disease of St. Kilda.—I believe that in these and other infants from poor homes in the south of London, I am witnessing the degenerate descendant of the awful *trismus nascentium, or eight days' sickness,* which was formerly so rife in this and all countries, which survived until recently in the remote Hebridean island of St. Kilda, which persists to-day among the negroes of the West Indies and the Southern States of America, and which appears to retain all its virulence and all its frequency among the natives of India, attracting only an occasional official comment in a Government statistical survey.

Formerly in this country new-born infants died in great numbers from a disease, characterised especially by trismus, which was called sometimes, from the day of its usual appearance, the "eighth day sickness" or the "nine days' fits," and sometimes indifferently trismus and tetanus neonatorum or nascentum. Colles,[6] at the beginning of last century, was apparently the first to identify the disorder with traumatic tetanus and to find the focus of infection in an "unhealthy or unkindly form of inflammation or ulceration of the umbilicus." But to Colles the word tetanus implied merely spasm, however produced.

FIG. 4.



A case in which the jaw was rigidly fixed in the open position with extreme spasm of the extremities.

In the 25 years ending 1782, of 17,650 infants born in the Rotunda Hospital in Dublin, 2944 died of trismus. Following improvements in ventilation and hygiene, the number fell rapidly from 17 per cent. in the above figures to 0·2 per cent. between 1826 and 1833. The decline elsewhere in these islands seems to have been steady, if especially in rural Scotland, more gradual until, by the second half of the last century, it lingered, like belief in witchcraft and the evil eye, only among the most remote and primitive communities. The story of St. Kilda is known to all. In 1860, of 125 children born to the 14 married couples in the island, 80 had lost their lives within 14 days, almost all of trismus. Up to 1890 the scourge continued unabated, when it ceased under the administrations of Nurse Chisnall, a Gaelic-speaking nurse, who consented to be marooned on the island for the winter, taking with her a plan of action worked out by Dr. W. L. Reid of Glasgow, a knowledge of the importance of cleanliness, and a plentiful supply of iodoform for the cord.[7]

Elsewhere on the edge of civilisation the disease continued its ravages, especially among the black population in the West Indies, in the Southern States of America, in the Balkans, and in India. In parts of India to-day it is still appallingly common. Thus the annual reports[8] of the Sanitary Commissioner with the Government of India for 1919 state that the deaths from tetanus in some towns and districts are over 50 per cent. of the total infant mortality, which itself stands at a figure of from 20 to 30 per cent. of live births.

A mortality so vast and so continuous among any population so long as it is ignorant of precautions against sepsis, and so easily controlled by the introduction of such precautions, seems more likely to be the direct result of septic infection of the newly-born than to be due to the accidental contamination of the umbilical wound with the bacillus in each and every case. In general the search for the bacillus proves quite in vain. For an account of numerous post-mortem examinations carried out at a time and in a district when the disease was still very common, I may refer to a description by Hartigan,[9] published a month or two before the discovery of the tetanus bacillus. From the descriptions of the older observers in all countries one point only emerges, that the spinal cord and meninges were very vascular. In many there were noted "extravasations of blood," "deposits of fibrin," or "extravasations of lymph." Hartigan, besides analysing the results of previous post-mortem examinations, himself conducted 23 autopsies in most of which extravasation of blood-stained lymph was found around the spinal cord. He gives a good microphotograph of the histological appearances, showing lymph around the cord. That same year the tetanus bacillus was discovered by Nicolaier. Since then it has been tacitly assumed that trismus and tetanus are identical. This assumption, and the increasing rarity of the severe and fatal forms of the disease, has made the post-mortem records of recent years few and unsatisfactory. In the post-mortem reports of my own hospital, at Guy's, I can find notes of only two recent post-mortem examinations. In one the notes and apparently, the examination, are too scanty to be of any value. The other was very fully examined by Prof. Laidlaw, and it is significant that this infant died with infective endocarditis on the tenth day of life. Numerous vegetations were found on the valves of the heart. The umbilicus was unhealthy, but the condition of the brain and cord is not stated.

Trismus neonatorum, then, I believe to be no more than a manifestation of sepsis neonatorum. In some few cases the muscular spasm is so prominent a symptom as to dominate the clinical picture, but in a high proportion of all cases of sepsis some degree of muscular rigidity, and some definite interference with the art of suction, is present. My own experience convinces me that the minor degrees of trismus in sepsis are not uncommonly met with even to-day. In infancy, the accidental importance of the act of suction, the one powerful coördinated muscular action of which the child is capable, has focused attention upon the jaw muscles and has led to the confusion with tetanus.

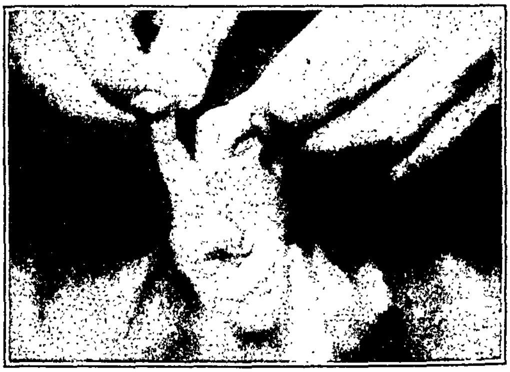
PREVENTION OF SEPSIS NEONATORUM.

To prevent sepsis neonatorum we must keep three objects in view: (1) We must remove all sources of infection. (2) We must protect, so far as is possible, all portals of entry, especially the skin, the umbilicus, and the mouth, from irritation, excoriation, and infection. (3) We must strengthen in every way possible the child's power of resistance to infection.

Let me consider each of these three points in turn.

1. The chief risk to the newly-born is from the person of the attendant. Especially dangerous is any septic sore or abrasion upon the skin of her hands. Not infrequently an epidemic of pemphigus or dermatitis exfoliativa among the newly-born in a district has been traced to such a septic point on the hand of a particular midwife. Impetigo among the older children in the family is also responsible for many cases. Pyorrhœa alveolaris in a midwife who constantly wets her fingers in saliva, and purulent nasal or bronchial secretions is another source of danger. One of the worst cases which I have encountered in a comparatively well-to-do family was caused by a nurse with a sore place, quite small but very unhealthy, at the angle of her mouth, which had been present some days before the birth and which, as she spoke to me, she touched more than once. The increasing attention paid to such matters is probably the explanation of the remarkable decline in the incidence of sepsis neonatorum. It is interesting to note that, for the same reason, osteomyelitis has become a comparatively rare disease because the percentage of children going about their ordinary life and exposed to trauma, while suffering from local pyogenic skin infections, has so greatly diminished. There is reason to believe that a century ago such skin infections were almost universal and too little infections were almost universal and little regarded.

FIG. 5.



The hand of Case 4 photographed some months later, showing permanent deformity of the fingers. The middle finger is being extended to the utmost of which it is capable.

2. In very many cases infection takes place through the skin. The skin of the newly-born is peculiarly ill-fitted to stand contact with infection. The epithelium is very thin and, especially the protective horny layer, is little developed. In all cases, but in very varying degree in different infants, there is visible desquamation of the most superficial layers in the first days of life. In the papillæ, which are also poorly developed, there is a well-marked network of vessels, which is situated so superficially that its presence goes far to explain the great tendency to exudative and serous processes, as for example, urticaria, pemphigus, and so forth. While the sweat glands are poorly developed, the seborrhœic glands are large and numerous, as we might expect from the frequency of seborrhœic disturbances. The study of the microscopic structure of the skin of the newly-born shows perhaps better than in any other way the danger to the infant of friction in removing the vernix caseosa, or in drying, of reflex scratching, and generally of irritation from contact with urine and fæces.

Pemphigus and Dermatitis Exfoliativa.—In the skin of the newly-born, with its peculiar structure, impetiginous infection shows itself in two characteristic forms of rash—i.e., the discrete form, pemphigus, and the confluent, dermatitis exfoliativa. In pemphigus a number of large superficial bullæ rapidly form, filled with serous, later with turbid, contents. The bulla soon ruptures, discharging fluid, and leaving a circular area, moist and bright red, outlined by a ring of the separated epithelium which still remains adherent. In the diffuse or confluent forms known as dermatitis exfoliativa, large areas of the deeper layers of the skin are exposed, while the remains of the superficial epithelium hang adherent here and there in shreds and patches like pieces of soaked tissue paper. The appearance may be so like that of a scald that I have known this diagnosis made despite the protests of the mother that no scalding had taken place. These profuse and rapidly spreading rashes, repeating at each point the same appearance, should be readily distinguished from syphilitic eruptions, with which they are nevertheless often confused. It is well to bear this in mind, because almost always the suggestion that the rash is syphilitic has been made by some irresponsible person. In the past the mortality has been high. The older writers (Corrigan, 1834) spoke of a 90 per cent. mortality. In my own experience the mortality has not been high. Probably the fatal cases are those in which a generalised infection is added with cerebro-spinal involvement—trismus and convulsions—and these have grown rare with the decline of severity in this type of skin infection. The umbilicus is always infected secondarily in pemphigus and dermatitis exfoliativa, and as a primary source of infection it plays a considerable part. The danger is especially great when the cord has been very thick and has remained adherent for an unusually long time. In such cases the desiccation of the cord does not proceed satisfactorily, and a moist gangrenous process is apt to be substituted for a dry.

Sometimes it is clear that infection of the skin has taken place by contact with fæces and fæcal organisms. A deeply eroding pustular eruption of the buttocks, spreading from the anus, to which the name echthyma gangrenosa varicelliforme has been given, may in turn give rise to a generalised infection. Trauma, to the delicate mucous membrane of the mouth, is apt to result from any attempt to cleanse the cavity by friction, however gentle. The utmost cleanliness and the greatest gentleness in handling the infant is very necessary.

3. Breast-nursing—a great gain for the healthy baby—becomes all-important for the baby with septic infection. In trismus, nasal or œsophageal feeding with milk expressed from the mother's breast is the best plan. Blood transfusion, if quickly and dexterously carried out, no easy task in a young infant, may save life.

THE CLINICAL SIGNIFICANCE OF HYPERBILIRUBINÆMIA.

BY H. G. MOGENA, M.D.

(From the Medical Clinic of the General Hospital, Madrid).

THE clinical significance of the estimation of the various bodies that are found normally or pathologically in the blood becomes steadily greater. To obtain these estimations in everyday practice simple methods are essential; these have been perfected for the estimation of urea, glucose, chlorides, calcium, and creatine. Bilirubin-determinations have revealed latent jaundice in obstruction of the bile-ducts, early hepatic cirrhosis, after treatment with the arsenobenzols, in secondary carcinoma of the liver, and in hepatic insufficiency. On the other hand, they prove the absence of jaundice in subjects tinted with other pigments such as carotin, or in patients whose straw colour might suggest subjaundice. If, as modern theories state, bilirubin is formed in the endothelial tissue and the hepatic cell is only a filter through which it passes, variations in its amount in the blood would be expected in diseases of that tissue, or when the hepatic cell does not allow circulation of the bile, or whenever elimination of the bile through its ducts is totally or partially obstructed.

Several methods of estimating bilirubin have been proposed: (1) comparison of different dilutions of the serum with a standard solution of potassium bichromate (Meulengracht, Gram, Berhardt and Mans, Erst and Förster); (2) transformation of bilirubin into biliverdin by oxidation (Gilbert and Herscher and Herzfeld); (3) combination of bilirubin with the diazo-reagent and estimation by a standard solution (H. van den Bergh). The first method, though quite simple, is useless for small quantities and has the disadvantage of requiring comparison of intensities but not of colourations. The van den Bergh method, much used recently, depends on the reddish colouration that bilirubin shows in a neutral medium when mixed with Ehrlich's diazo-reagent; in an acid medium the colour becomes bluish-purple. This reaction is very sensitive; the estimation is made by comparison with a standard solution. Bilirubin was first employed by the author, but on account of the difficulty of obtaining and preserving it he substituted an ethereal solution of iron sulphocyanide. Haselhort uses a mixture of Bordeaux red and methyl-blue, and Thannhäuser and Andersen a solution of bilirubin in an acid medium. The diazo-reaction does not take place with biliverdin, and this is often inconvenient if the examination is delayed. The presence of a substance that is not bilirubin renders the procedure uncertain. Herzfeld criticises the van den Bergh method on the ground that the amount of bilirubin in the alcoholic extract may vary with different quantities of bile and also with the alkalinity of the blood. By increasing this alkalinity with sodium bicarbonate they extracted with the alcohol large amounts of bilirubin. Furthermore, van den Bergh believed that only bilirubin gave a red colouration in an acid medium; but Herzfeld has seen indol and pyrrol produce the same effect, the test being 200 times as sensitive to the latter as to bilirubin or indol. Indol in the blood comes from the hæmoglobin and gives rise to a series of pyrrolic bodies.

Technique of Herzfeld's Method.

The method founded on the transformation of bilirubin into biliverdin is quite simple and very exact, and we have used it in many cases.

Into a series of test-tubes we put 1 c.cm. of water, except that the first tube has 1 c.cm. of undiluted serum. To the water in the second tube we add 1 c.cm. of serum and from this mixture of serum and water we take 1 c.cm. and put it into the third tube and so on with the rest, repeating the dilution until a colourless mixture is obtained. Then to every tube is added a few drops of freshly prepared Hammarster's reagent, the limit where light green colouration appears being noted against a white background. The Hammarster's reagent is prepared by mixing one volume of 25 per cent. nitric acid with 19 volumes of 25 per cent. hydrochloric acid; we let it stand 24 hours before use and keep it for one year. At the time of use we mix one volume with four of alcohol. The colouration of these tubes is compared with others that contain a known dilution of bilirubin. Frigyer, in order to get greater accuracy, made a 1 in 10 dilution with the last tube.

The advantage of this procedure, besides its simplicity, is that the comparison is made with a similar solution of bilirubin. Van den Bergh believes it possible to differentiate the types of jaundice according to the behaviour of the serum with the diazo reagent. He noticed that the serum of patients suffering from obstructive jaundice gave the reaction with Ehrlich's reagent without the addition of alcohol, while in the serum of patients suffering from hæmolytic jaundice or pernicious anæmia the combination does not occur at all or occurs only after a certain time and incompletely; these serums gave the reaction quickly and normally if alcohol was added. The first reaction is called "direct," the second "immediate indirect" if it appears in a few seconds and completely, after the addition of alcohol, and the third "delayed indirect" if it takes place more than half a minute after the addition of alcohol and partially. Feigl has applied the term "diphasic reaction" to a slight change appearing at once and then ceasing. The different reactions of jaundice serums, van den Bergh thinks, may be due to a slight difference in the chemical composition of the bilirubin molecule or, more probably, to a binding of the molecule of bilirubin with albuminoid bodies in the serums giving delayed reaction, this union being broken before the reaction can be produced. Adler and Strauss, after numerous experiments, believe that it corresponds with physico-chemical modifications of the serum and that both the direct and indirect reaction in the serum of icteric subjects or of those with some blood disease differ essentially in their colloidal reaction.

As a result of our investigation we cannot admit that the van den Bergh reaction is useful in distinguishing the different kinds of jaundice. We often find an immediate direct reaction when the serum is rich in bilirubin, and when the proportion of bilirubin is small a delayed or indirect reaction is sometimes shown. The different reactions of the serum with Ehrlich's reagent depends, according to us, more on the quantity of bilirubin than on the way this has been formed. Friedmann and Strauss found in some cases that, while the indirect reaction is positive only at the beginning of jaundice, later the direct reaction occurs immediately and distinctly. Barchi also has observed that the rapidity with which the direct reaction appears depends on the concentration of bilirubin in the blood; it is therefore useless as a criterion by which to distinguish the nature of jaundice; dynamic jaundice responds to the diazo-reaction in the same way as the so-called static jaundice does.

Bilirubin in the Normal State.

The amount of bilirubin in the blood varies according to different authors and their estimates depend perhaps on the method used. According to van den Bergh it varies between 0·2 and 0·6 units, which corresponds with 0·1 to 0·3 mg. per cent. Jenndrasik and Czirke, using a modification of the former's technique, found higher amounts, and if the determinations are carried out on the plasma instead of the serum the quantity is still greater. Haselhort, Scherk, and Cowen give 0·5 mg. as an average quantity. In Wiener's opinion the normal amount is 0·8, a figure also found by Botzian. Förster and Förstener think that 1 mg. per cent. is the limit. Herzfeld, using his own technique, found in normal subjects from 1·6 to 6·25 mg. per cent., a figure 20 times as high as those obtained with the van den Bergh technique. Our observations with Herzfeld's technique have shown that bilirubin does not normally exceed 6·25 mg. per cent.; higher figures are a sign of functional disorder of the liver or of obstruction to the flow of bile. Schiff has cited figures a little higher for men than for women; Ernst and Förster found a greater quantity of bilirubin in normal persons when fasting than after meals, the variations fluctuating from 0·1 to 0·2 mg.; Brown and his assistants found some greater differences. According to Förster and Förstener this increase is probably due to the elimination of bilirubin from the blood during the digestive phase. Hooper and Whipple have observed that after the ingestion of carbohydrates the serum-bilirubin transitorily increases because, they think, the starch stimulates the elimination of the pigments already formed. Meyer and Knüpffer noted a decrease of bilirubin between the second and third hour after meals in normal subjects, this diminution being greater in the fifth hour but disappearing after eight hours, when the bilirubin begins to increase. They also found an increase when the subject fasted all day or when milk or rice or barium sulphate was administered. On the other hand, the ingestion of a litre of water did not bring about any alteration.

While many people with hepatic trouble show a normal amount, others have a hyperbilirubinæmia after food ingestion that might be explained by reabsorption of bilirubin through the intestine and its passage to the disordered liver. Perkin has noted a relation between the quantity of bilirubin and the skin pigmentation, the bilirubin being greater in swarthy subjects than in fair ones. H. van den Bergh calls a slight increase of pigment, which might correspond either to Gilbert's "familial colæmia," or to the "bilious temperament" of other authors, a "physiological hyperbilirubinæmia." We regard this increase of bilirubin as invariably pathological, a sign of latent jaundice.

Bilirubin in Pathological States.

The course of a jaundice is empirically estimated by the colouration of the tissues and urine; this depends not only on the quantity of pigment present but also on the dilution—i.e., the amount of urine eliminated. Both procedures are rough enough and can only be relied on to reveal gross variations of pigmentation that need several days to produce. Bilirubin has been regarded as an echelon body, like glucose for instance, so that the pigment only begins to be eliminated through the urine when it reaches a certain concentration in the blood. For the subicteric tinge to be perceptible the blood-pigment must reach 50 mg. by Herzfeld's method which, as we have stated, gives us figures 20 times as high as van den Bergh's. The majority of authors have found with this method or any similar one that from 2·5 to 3 mg. per cent. of bilirubin must be present in the blood to give visible jaundice. The evolution of jaundice can be rapidly and certainly followed by examining the serum bilirubin quantitatively, and there is no need to emphasise the diagnostic and prognostic importance of exacerbations or remissions of jaundice, especially after surgery of the biliary passages. The determination of pigment in the blood is of great advantage for the diagnosis of cholecystitis, both in its quiescent stages and in acute attacks. While diagnosis of hepatic colic is usually easy, it may at times cause confusion. When the bile obstruction is complete and lasts a certain time, the presence of bile-pigments in the urine or commencing jaundice will be valuable data; but if the obstruction is partial or of short duration, then the bile retention will not have been enough to dye the tissues or to appear in the urine, even though there is hyperbilirubinæmia. In these doubtful cases blood should be tested from 12 to 24 hours after the commencement of the attack. If there is a disorder of the biliary passages, there will be an increase of bilirubin in this specimen over that taken when the patient was quite well; the differences, of course, are not great or there would be obvious jaundice. In this way it is possible to distinguish the hepatic colics from those arising from other sources such as kidneys, appendix, intestine, stomach, or urethra.

Takats recently saw an increase of bilirubin in 15 cases of hepatic colic without jaundice; he examined the blood every four hours and believes that the increase of pigment after the colic is due to a rapid increase of tension in the bile-ducts. The hyperbilirubinæmia lasted one or two days; when atropine was administered there was a decrease, which might be explained by muscular relaxation and better passage of bile through the excretory ducts.

In cases of cholecystitis, even in the intervals of the attacks, we can detect pigment increase, a sign of latent jaundice. Friedmann and Strauss find increase of pigment in 93 per cent. of cases during the attack and 63 per cent. in the intervals; they account for it either by the greater reabsorption of pigment through the walls of the inflamed gall-bladder or by an expansion of the inflammatory process, or of the bile-duct obstruction. According to William Bloom, ligature of the cystic duct of dogs does not produce an increase of bilirubin in the blood, which would explain the lesser degree of hyperbilirubinæmia that Friedmann and Strauss found in the intervals of the attacks.

Kehr states that 51 per cent. of patients suffering from cholelithiasis have jaundice (transitory, recurrent, or continual), while of those harbouring calculi without showing symptoms only 5 per cent. have jaundice; but a certain number of these have latent jaundice. The maximum degrees of hyperbilirubinæmia are naturally found in cases of severe jaundice, when there is common bile-duct obstruction from impacted calculus, cancer of the head of the pancreas, or angiocholitis, and in these cases we only use the bilirubin test to estimate the course of the jaundice.

The study of hepatic insufficiency has also been advanced by this test. In experimental degeneration of the hepatic cell produced by phosphorus injection into dogs the elimination of phenoltetrachlorphthalein through the bile was delayed as the amount of bilirubin in the serum increased. This relation between bilirubin and the retention of dye has also been proved by Snell, Greene, and Rowntree. In man we have seen after chloroform anæsthesia increase the amount of bilirubin by liver damage. Given equal quantities of anæsthetic the increase of the biliary pigment will depend on the liver state; the already diseased cell will tolerate the chloroform worse and the hyperbilirubinæmia will be greater; when it is not severe enough to produce jaundice only serum examination reveals the hepatic lesion. At the same time bilirubin can be injected into the blood stream and the time elapsing before its disappearance can be noted.

Diagnosis of hepatic cirrhosis that offers few symptoms at the beginning—so that diagnosis is usually only made at a late stage—will be greatly helped by the determination of bile-pigment. We have found in hypertrophic cirrhosis, many years before an icteric tint appeared, a small hyperbilirubinæmia which, together with some digestive troubles and the result of the bile examination, put us on the track of an early diagnosis. In most cases of portal cirrhosis with ascites Greene, McVicar, Snell, and Rowntree have noted that the amount of blood bilirubin was not increased. There is an early increase of pigment in most cases in which there is a gland lesion, and during the digestive periods, especially if hepatic insufficiency exists, there is a slight hyperbilirubinæmia which is often found, also, during menstruation. We have found it, though not above 4 mg., in subjects with cardiac weakness, specially of the right ventricle; the degree of weakness bears a close relation to the amount of bilirubin, but we do not agree with Gottlieb that this is an infallible guide to prognosis. In all cases of active or passive congestion of the liver there is an increase of bilirubin; Schiff found the highest amounts in patients with mitral lesions. Pigment increase has been recorded in pneumonia, but we have been unable to confirm this in five cases; it may only be present in pneumonia of the right base, thus giving rise to the belief that there is an anatomical relationship by which secondary hepatitis is produced. The great increase of urobilin in the blood of pneumonic patients cannot support the idea of a consecutive hepatic lesion, since this urobilin might be formed in the diseased lung.

The presence of jaundice in a syphilitic patient under arsenical treatment has given rise to much literature, some authors regarding it as specific but most as due to the toxic action of the drug on the liver. We have seen many cases in which treatment with neosalvarsan was followed by jaundice and phenoltetrachlorphthalein retention; rest, a non-toxic diet for the liver, and the discontinuance of the drug sufficed to dispel the jaundice, but the bilirubin increase went on for some time and increased markedly when we again injected a small dose of neosalvarsan. Two patients treated with bismuth preparations did not show an increase of pigment. The small percentage of cases in which jaundice occurs shows that it is due to a functional insufficiency in some cases produced by specific hepatitis; the determination of the bile-pigment in the blood will disclose that insufficiency. Chargin and Orgel and Covisa advise making this estimation in every syphilitic patient who has arsenical treatment to foretell those who are liable to jaundice and thus to avoid it. Schamberg and Brown suggest using it from time to time to see how the liver is reacting to the drug. Some headaches have biliary causes, and these cases can be distinguished by this test.

Takats found hyperbilirubinæmia in pernicious anæmia, while in secondary anæmia, especially if due to cancer, the amount is normal or reduced. This test is therefore useful for differential diagnosis. Gottlieb noted hyperbilirubinæmia in malaria and still more in typhoid fever. Bang says that hyperbilirubinæmia is always a symptom of severe appendicitis produced by concomitant toxic hepatitis.

THE ICTERUS INDEX OF THE BLOOD SERUM.

By G. W. MILROY, M.D. Edin.,
LATE HOUSE SURGEON TO THE ROYAL INFIRMARY, EDINBURGH, AND THE ROYAL ALBERT EDWARD INFIRMARY, WIGAN.

At the present time clinicians are showing a markedly increased interest in the study of diagnostic methods designed to increase our knowledge of the functional activity of the liver.

Probably the latest development in liver function tests is that described by Bernheim,[1] called the icterus index. This index is an estimation of the bilirubin content of the blood serum; it is not a true quantitative estimation, but an estimation by means of a colorimeter of the intensity of the staining of the serum by bilirubin as compared with an arbitrary standard of colour. Variations in the normal amount of bilirubin in the serum are caused by: (1) disturbances of the biliary system, (2) hæmolytic conditions, (3) toxic conditions, and it is claimed by Bernheim that by means of the icterus index a hyperbilirubinæmia caused by any of the above can be detected and that, once detected, the variations in the icterus index in different diseases are of value in diagnosis, treatment, and prognosis.

I have carried out observations on a series of cases of various diseases with a view to confirming Bernheim's findings. The results obtained were not perhaps quite so consistent as those of Bernheim and other American writers, but the general impression obtained from the results to be given below was that in the icterus index we have a simple and accurate test for hyperbilirubinæmia which, if used in correlation with the clinical findings of the case, is of value in diagnosis, treatment, and prognosis.

Technique.

Venous blood is allowed to clot and the serum pipetted off and centrifuged until clear. The serum is then compared in a Dubosc colorimeter with an arbitrary standard of 1 in 10,000 potassium dichromate (0·05 g. in 500 c.cm. of distilled water). The indicator on the scale of the standard solution is set at a suitable figure (e.g., 15 or 20), and a reading of the "unknown" serum is taken at the point on its scale at which the two solutions match. The index is then calculated by dividing the reading of the standard by that of the unknown. With deeply pigmented sera dilution may be necessary before an accurate reading can be obtained. This dilution must be made with normal saline, and when the calculation is made the figure obtained must be multiplied by the number of dilutions. Thus we find that the deeper the colour of the serum the higher the icterus index.

Errors and Fallacies in Technique.

1. The standard solution becomes paler on exposure to light. The addition of two drops of sulphuric acid per 500 c.cm. will preserve the colour.

2. The serum must be clear when the reading is taken, cloudy or lipæmic sera giving high faulty readings. Serum usually becomes opaque if allowed to stand for more than 24 hours, and is also cloudy during the ingestion periods.

3. Hæmolysis must be avoided, either by using dry sterilised needles to withdraw the blood or by washing syringes and needles in normal saline.

Several modifications of Bernheim's technique have been described. Both Brown[2] and Murphy[3] have devised methods which consist primarily in the comparison of the "unknown" serum with a series of dilutions of potassium dichromate in standard tubes. A similar method described by Davis[4] makes use of capillary blood, thus avoiding venepuncture.

The serum from 55 normal persons was examined and in every case the index lay between three and six. Also, in every case in the series with an index over six there was some pathological condition present. Normal indices, as was expected, were also found in some diseases such as renal, venereal, and gynæcological conditions, gastric ulcer and carcinoma of the stomach, rheumatic fever, and tuberculosis.

Gall-bladder Dysfunction, Duodenal Ulcer, and Appendicitis.

Sixteen cases of proved gall-bladder disease were investigated. Twelve showed active cholecystitis or cholelithiasis with obstructive symptoms; only five showed clinical jaundice. All gave indices between 10 and 50, and in every case the index returned to normal after operation. The remaining four cases showed indolent cholelithiasis and normal indices. It follows then that, while the icterus index will not indicate the mere presence of gall-stones, a raised index will appear as soon as there are any signs of active disease, even in the early stages before clinical jaundice appears. De Wett Stetten,[5] who showed that cases of suspected stomach disorder showing indices of nine or ten were found at operation to be biliary disease, suggested that the icterus index is a means of differentiating renal and biliary colic, acute appendicitis, and perforated duodenal ulcer. This is true up to a point, but my results do not enable me to make a definite distinction between all four.

Pathological renal conditions do not raise the icterus index, which fact may make a differential diagnosis between renal and biliary colic. It is with acute appendicitis and duodenal ulcer, however, that difficulty arises. Nineteen cases of appendicitis were examined; five showed indices between 6·1 and 7·8, and seven showed normal figures. The remaining seven were cases of chronic appendicitis and showed normal indices. Of 19 cases of duodenal ulcer, ten gave indices between 6·4 and 8·6; six gave normal figures, and three, which had recently had hæmatemesis, showed subnormal indices. In both these conditions then, as in biliary dysfunction, the icterus index may be raised. This at first sight may seem to confuse the issue, but it was found that the lowest index obtained in active biliary dysfunction was ten, whilst the highest due to duodenal ulcer was 8·6. One may therefore conclude that an index of nine or over points to gall-bladder trouble rather than duodenal ulcer or appendicitis.

The figures obtained with duodenal ulcer and acute appendicitis are more confusing. The former gave figures between 3·4 and 8·6, and the latter figures between 3·8 and 7·8. This does not enable one to differentiate the two conditions by the icterus index alone, although the average index (6·2) of duodenal ulcer as against the average of 5·5 for acute appendicitis shows a tendency to a higher figure in the former disease. The icterus index, therefore, is of little value in differentiating acute appendicitis and perforated duodenal ulcer. American writers regard a raised index as a constant accompaniment of duodenal ulcer and as a means of differential diagnosis from gastric ulcer, which shows normal figures. My figures did not show a constantly raised index in duodenal ulcer, though—as gastric ulcer invariably shows a normal index—in cases where the diagnosis lies between the two a raised index would indicate the former.

From the fact that the icterus index returns to normal after operation for gall-bladder disease it is reasonable to deduce that a raised post-operative index is indicative either of an overlooked gall-stone in the duct or, in old-standing cases, of an associated hepatitis, both of which involve a less favourable prognosis.

The icterus index is of great value in cases of frank or suspected jaundice where the need of a simple and practical method of accurately estimating the degree of jaundice present at a given time has long been felt. I investigated 13 cases of jaundice and found in all that the index rose or fell as the jaundice increased or diminished. The indices obtained varied from 14·2 to 243·2. It is generally agreed that 15 is the index at which clinical jaundice appears, though I have found it possible to have indices above 15 for a few hours with no clinical jaundice and vice versa, owing to the hyperbilirubinæmia being demonstrable before the tissues took on the icteric hue.

The advantages of a method of estimating the degree of jaundice and also its daily fluctuations are obvious when one considers, for example, the differential diagnosis between carcinoma of the head of the pancreas and an impacted stone in the common duct. The index is valuable, moreover, in assessing operative indications. In a case of biliary obstruction by stone, for example, it will permit us to determine increase or decrease of the jaundice, thus enabling us to decide whether to operate before the jaundice is too far advanced or to wait until it has subsided. The icterus index will probably prove of great value in the detection of jaundice in coloured races.

Hyperemesis Gravidarum, Pernicious Anæmia, and Secondary Anæmia.

Only two cases of hyperemesis came under observation, but in both the icterus index was raised, the figures being 8·1 and 10·7; the latter patient died. It seems probable that, if the icterus index behaves in these cases as in other diseases, it might be of value in prognosis if successive readings were made, and also in determining whether termination of pregnancy was advisable.

In eight cases of pernicious anæmia the index was raised to between 7·8 and 20, the last case being jaundiced. All were treated by liver; in every case there was a marked improvement in the blood picture in five weeks and the index fell to normal in the same period. It seems, therefore, that we have in the icterus index an additional indication of the prognosis of the disease. The fact that there is a raised index in pernicious anæmia and a subnormal one in carcinoma of the stomach provides an additional means of diagnosis.

Nine cases of secondary anæmia showed a low index, between 2·1 and 3·6. These low figures open up the possibility of a fallacy in icterus index readings, as it has been found that a patient suffering from a disease which usually raises the index, but who also has a secondary anæmia, sometimes shows a normal index, but always a much lower one than is to be expected from the principal condition.

Cardiac Disease.

Of seventeen cases of cardiac disease, twelve showed decompensation and the index varied from 6·9 to 25, and in every case rose or fell as the clinical condition became worse or improved. The remaining five cases with no decompensation showed normal figures. Bernheim states that every case in her series with an index over 12·5 died within a few weeks. My observations bear this out, and it seems that we have in the icterus index a method of following the progress of cases of heart failure, which is so difficult to estimate by clinical observation alone.

Cases under Arsenical Treatment.

Owing to the well-known vulnerability of the liver to arsenic, any test which could be employed as a routine and which would indicate the toleration of the liver for the drug would be of great value, for example in the treatment of syphilis by prolonged courses of arsenic. Twenty-two cases of syphilis under intravenous arsenical medication were examined, and the icterus index was taken every three weeks for varying periods. It was found that in the majority of cases the index remained normal, even after prolonged treatment. In a large percentage, however, there was a rise in the index at the commencement of treatment, followed by a gradual fall. In some cases the index rose above normal at this stage. This rise is apparently due to the toxic effect of the arsenic in persons unaccustomed to it, the return to normal denoting acquired tolerance. Two cases of arsenical dermatitis both gave a raised index which fell to normal with the cessation of treatment. In one of the cases when treatment was recommenced the index again rose above normal, to subside once more when a second "rest" was given. Two cases of arsenical hepatitis, both with clinical jaundice, showed markedly raised indices, one being 243·2, the highest in my series. In both cases the index fell to normal as they recovered under treatment.

The icterus index, therefore, anticipates toxic effects from arsenic. The blood can easily be withdrawn when giving an injection and should be examined at regular intervals. Patients with indices within "the period of latent jaundice" (i.e., 6 to 15), should be watched carefully, and a steady rise of the index through that period must be regarded as a danger signal. Similarly, in cases recovering from toxic hepatitis, a raised icterus index is a contraindication to the recommencement of arsenical treatment, despite the disappearance of clinical jaundice.

Pneumonia.

Eight cases of pneumonia showed indices between four and ten. Bernheim gives an index of 7·5 as the limit for a definitely favourable prognosis in pneumonia. My results bear this out, in that every case under 7·5 recovered and the higher the index the worse the clinical condition, but it is not possible to be dogmatic in prognosis since, though a high index is definitely less favourable, it has been shown by Bernheim that patients with an index as high as 15 may recover.

The chart shows at a glance the figures obtained in various diseases. It has been suggested that by comparing the index of any given case with the chart it would be possible to make a diagnosis. This, of course, is impossible, owing to the "overlapping" of the indices in various diseases, and one must deprecate any tendency to use the icterus index as a specific test while emphasising the necessity of bearing in mind the clinical findings in every case, the index to be used as an additional factor in diagnosis.

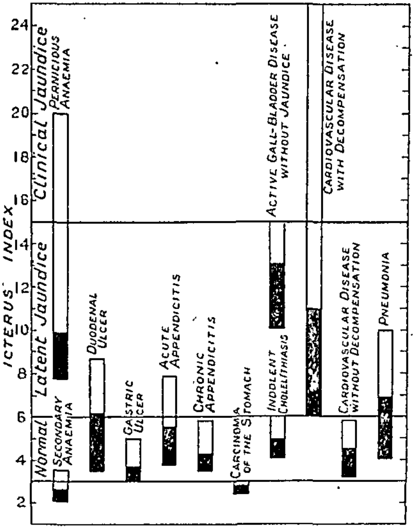

Diagram showing the icterus index in various diseases. The solid black areas represent the minimum to the average index. The white areas represent the average to the maximum index.

In conclusion, I would emphasise particularly the value of the index in: (1) distinguishing biliary conditions from renal, gastric, duodenal, and appendicular conditions; (2) differentiating carcinoma of the stomach and pernicious anæmia; (3) controlling toxic effects due to arsenical medication; (4) detecting variations in clinical jaundice.

DONATIONS AND BEQUESTS.—Sir John Robinson, of Worksop Manor, Notts, brewer, besides other bequests, left all his stock, shares, debentures, and other interests in the New Leicester Club and County Racecourse, Ltd., for division into ten parts, of which he left four parts each to the Nottingham General Hospital and the Victoria Hospital, Worksop, and one part each to St. Dunstan's Hostel for the Blind and the Nottingham and Nottinghamshire Adult Deaf and Dumb Society; £5000 for the endowment of almshouses, and £5000 to St. Dunstan's Hostel for Blinded Sailors and Soldiers.—Mr. Frederick Victor Johnson, of The Limes, Barlaston, Stoke-on-Trent, left £1000 to the North Staffordshire Royal Infirmary.

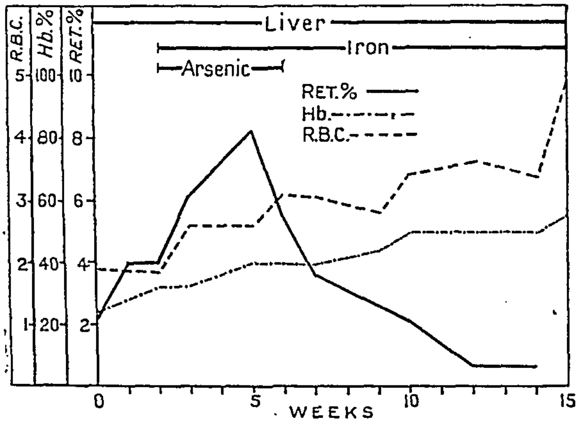
LIVER THERAPY IN SECONDARY ANÆMIA.

BY S. C. DYKE, D.M. OXF., M.R.C.P. LOND.,
CONSULTING PATHOLOGIST, THE ROYAL HOSPITAL, WOLVERHAMPTON.

THE efficacy of liver, either as whole gland or in some suitable preparation, in restoring to normal the blood picture in primary or pernicious anæmia is now one of the firmly established facts of medicine. Its effects in secondary anæmia are by no means so clear. So startling were the early results obtained by liver treatment in pernicious anæmia and so relatively meagre the results in the secondary anæmias that there was an initial tendency to deny any usefulness to this form of therapy in the treatment of any form of anæmia other than Addisonian. The experimental work of Whipple, Robscheit, and Minot and Murphy, which led to the application of liver therapy to the treatment of pernicious anæmia, was carried out on dogs rendered anæmic by repeated bleedings and therefore suffering from secondary anæmia, and it is difficult to believe that what was experimentally found to be effective in dogs should not be clinically effective in human beings. How carefully this experimental work was controlled and how accurately the response to treatment was estimated can only be appreciated by a study of the original papers. It is, however, open to doubt whether under the less carefully controlled conditions of clinical work the responses obtained would have been regarded as definitely significant; certainly they were not of the same order as those obtained by the use of liver in human pernicious anæmia.

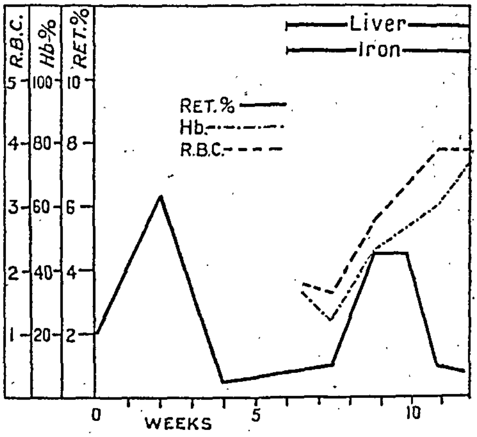
The present investigation was undertaken to ascertain whether any definite response to liver therapy could be obtained in human secondary anæmia. One reason for our lack of knowledge on this subject is undoubtedly the fact that secondary anæmias do not constitute a well-defined entity like Addisonian anæmia. They form a large and amorphous group falling roughly into two classes, depending upon whether the anæmia is due to hæmorrhage, acute or chronic, or to the action of some "toxin." In anæmia following acute hæmorrhage it is almost impossible to disentangle the effects of therapy from the natural recovery process; in cases associated with chronic hæmorrhage the response to therapy is obscured by the possible continuance of the bleeding, and in cases due to the action of "toxins" treatment must be directed to the eradication of the toxin; when this has been accomplished it is impossible to differentiate the results of the treatment from that directed immediately towards remedying the anæmia.

FIG. 1 (Case 1).



The mere study of the red cell count and hæmoglobin content of the blood will in many cases give little valuable information about the response to treatment. Some help, however, may be given by the "reticulocyte response." It has been shown by Greener and the present author[1] and by many others that the immediate effect of the application of liver therapy to a case of pernicious anæmia is the appearance in the blood stream of many reticulated red cells or reticulocytes; this "reticulocyte response" is invariable in cases responding well to treatment and serves as a most valuable index to the degree of the response. In secondary anæmia Vaughan[2] has been able to find evidence of this response, though not of the same order as that in primary anæmia. Minot, Murphy, and Stetson[3] also found definite evidence of a reticulocytosis in certain though not all of their cases of secondary anæmia. These authors, working mainly on pernicious anæmia, appear to have established a very high standard of response; they do not publish full tables of their results in secondary anæmia, but it appears from their discussion of these cases that had they accepted a lower standard many more of their cases would have been accepted as showing a response. Various other authors have brought forward evidence of the beneficial effects of liver therapy in cases of secondary anæmia without, however, having paid any attention to the reticulocyte response; among these Molfino [4] has reported striking results.

FIG. 2 (Case 2).

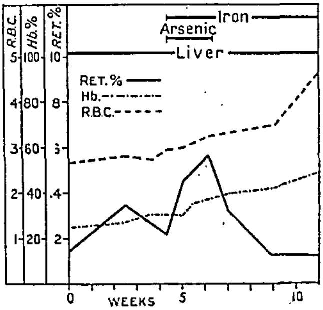


I have tested the response of a dozen cases of secondary anæmia to liver treatment. In many of these cases the anæmia was of long duration and in some it proved impossible to trace its source. In five, however, the anæmia definitely dated from a hæmorrhage or a series of hæmorrhages, in two due to gastric ulceration, and in the remaining three associated with parturition or abortion. Of all the cases investigated only these five showed definite improvement under the liver treatment. In four there was a definite increase in the reticulocyte percentage early in the course of the liver treatment; one case failed to show a response. In the cases showing a reticulocyte response the exhibition of the liver was followed by an increase in the red cells and in the hæmoglobin percentage; in the one case showing no response there was no increase in the red cells, and such improvement as occurred in the hæmoglobin percentage may, with some probability, be attributed to the action of the iron given with the liver.

Cases showing Reticulocyte Response.

CASE 1.—Female, aged 41, had a history of indigestion for two years; ten days before admission she had vomited about two cupfuls of blood and thereafter brought up small quantities at irregular intervals. There was also melæna. She was admitted on March 24th, 1928, and was treated by alkalis and diet until April 18th, when, although the melæna had ceased, it became apparent that the anæmia was not improving. A blood count showed 1,990,000 red cells per c.mm., hæmoglobin 25 per cent., and reticulocytes 2·4 per cent. of red cells. At this time it was discovered that the patient was three months pregnant. She was placed on a dose of two ounces of liver extract (Oxo) daily. On May 15th a mixture of iron and arsenic was added. On May 29th this was replaced by pil. ferri, grs. 5, t.d.s. The progress is shown on Chart 1.

FIG. 3 (Case 3).



CASE 2.—Male, aged 57, had a severe hæmatemesis on July 1st, 1928, and was admitted on the following day. He was very pale, had much melæna, and his pulse was feeble. He was treated by alkalis and diet with much improvement; melæna persisted until July 14th. He was discharged on August 20th considerably improved but still anæmic. At this date the blood showed hæmoglobin 30 per cent. and red cells 1,890,000 per c.mm. On August 27th the patient was seen again and it was obvious that he was making no further improvement. His red cells numbered 1,810,000 per c.mm., and his hæmoglobin 25 per cent. He was treated as an out-patient on liver extract (Oxo), half an ounce thrice daily, and pil. ferri, grs. 5, t.d.s. Subsequent progress is shown on Chart 2.

CASE 3.—Female, aged 37, had had ill-health since the birth of her last child two years previously, at which time she had lost a great deal of blood. She was seen as an out-patient on April 21st, 1928, when she was pale, had œdema of the ankles, a large ulcer on the right shin, and a loud, rough mitral systolic bruit. The Wassermann reaction was negative, the hæmoglobin 26 per cent., and the red cells 2,620,000 per c.mm. She was admitted on May 7th, and treated by liver extract ("Hepatopson"), half an ounce thrice daily. As shown in Chart 3, the blood picture improved until May 22nd, when the condition became stationary. The patient was then put on a mixture of iron and arsenic; from June 4th this was replaced by pil. ferri, grs. 5, t.d.s., with liver extract as before. Her subsequent course is shown on Chart 3.

CASE 4.—Female, aged 42, had an abortion on Dec. 16th, and was curetted on Dec. 19th, 1928. Since then she had been very pale and weak with swelling of the ankles. The hæmoglobin was 27 per cent., the red cells 1,310,000 per c.mm., the colour-index 1·04, and the reticulocytes 1·6 per cent. of red cells. She was admitted on Jan. 10th, 1929, and treatment commenced with liver extract (Oxo), two ounces daily, and pil. ferri, grs. 5, four times daily. Four days later the hæmoglobin had risen to 29 per cent. and the red cells to 2,300,000 per c.mm., while reticulocytes were present to the extent of 8·4 per cent. of red cells. This striking response, together with the rather high colour-index at the first count, led to the suspicion that this might be a case of pernicious anæmia. That this was not so was shown by the presence of free hydrochloric acid in normal amounts in all specimens from a fractional test-meal. The subsequent progress of the case is shown in Chart 4.

Case showing no Reticulocyte Response.

CASE 5.—Female, aged 25, had a post-partum hæmorrhage on July 4th, 1928, since when she had been pale and easily tired. She was seen as an out-patient on Oct. 8th, when she was still nursing the child, and her hæmoglobin was 39 per cent., her red cells 4,100,000 per c.mm., and her reticulocytes 1·3 per cent. of red cells. She was treated as an out-patient with liver extract (Oxo) two ounces daily, and pil. ferri, grs. 5, t.d.s. The red cell count showed little alteration and four months from the commencement of treatment still stood at 4,300,000 per c.mm. The reticulocytes also showed no increase at any time during the exhibition of the liver extract. The hæmoglobin, however, rose steadily until by February, 1929, it stood at 70 per cent. The general condition of the patient steadily improved. It is probable that in this case the improvement was entirely due to the iron.

In using the reticulocyte percentage to gauge the response to therapy which aims at the stimulation of blood formation after hæmorrhage, it is very necessary to bear in mind that hæmorrhage alone is followed by a marked increase in these young red cells. Chart 5 shows the response in a patient who had a severe gastric hæmorrhage and who received no treatment but rest, alkalis, and diet. The graph is plotted from the fourth day after the hæmorrhage and shows the reticulocytes standing at 8 per cent. of the red cells; four days later they have dropped to the neighbourhood of 2 per cent., a level which they thereafter maintain in spite of a progressive improvement in the blood picture. The normal response of the reticulocytes to hæmorrhage is also shown in Case 2, in which, before the commencement of any treatment aimed at the improvement of the blood picture, they attained a level of 6·1 per cent. Six weeks later they had fallen to about 1 per cent. and the patient was becoming more and more anæmic. This is an illustration of the fact, further exemplified by Cases 1 and 4, that in certain instances of anæmia due to hæmorrhage the production of reticulocytes may fall in spite of the demand for new red cells.

The Value of Iron.

Minot, Murphy, and Stetson, in the paper referred to above, have produced evidence that in the secondary anæmia which they produced by controlled bleedings in their dog experiments, improvement of the blood picture could be brought about either by liver or by iron. They further state that "the influence of feeding large amounts of liver or liver extract with large doses of iron can sometimes produce an effect which is not observable from the administration of either alone."

FIG. 4 (Case 4).

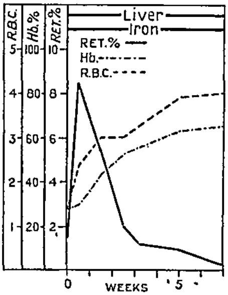


FIG. 5 (Case 5).

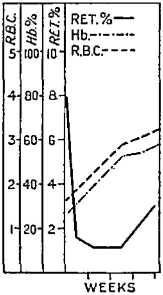

Some light is thrown upon the effect of the administration of iron along with liver by Cases 1 to 4. In Case 1 it will be seen that after two weeks' treatment by liver alone the blood count had, in spite of an initial rise of the reticulocytes to 4 per cent. of the red cells, become stationary. When iron and arsenic were given the reticulocytes rose rapidly to 6·1 and later to 8·2 per cent. and the blood count again improved, an improvement which was maintained in spite of a later fall of the reticulocyte percentage. This rise was maintained after the arsenic had been discontinued and the patient was on iron and liver alone. In Case 3 the same phenomenon appears. In spite of a slight rise in the reticulocytes, the blood count as a whole showed little improvement on liver treatment alone for four weeks; on the exhibition of iron and arsenic the reticulocytes rose to nearly 5 per cent., and the improvement in the blood count was maintained when the arsenic was stopped.

The continued improvement of the blood count in these two cases, after the withdrawal of the arsenic and while the patients were on liver and iron alone, raised doubts as to the efficacy of arsenic in cases of this sort. The effect of iron and liver only is shown in Cases 2 and 4. In Case 2 a good reticulocyte response followed liver therapy, but unfortunately in this case the behaviour of the red cells was not observed during this period. Six weeks from the commencement of the liver therapy the patient was put on iron as well; this was followed by a rise of the reticulocytes to over 4 per cent. and by the rapid improvement of the blood picture, shown in the graph. Case 4 received iron and liver from the initiation of treatment, a fact which may account for the very marked reticulocyte response shown by this case, and for the rapid improvement of the blood picture. In Cases 1 and 3 the improvement in the blood picture persisted after the arsenic had been dropped.

The series is too small to justify any extensive deductions, but it shows quite clearly that in certain cases of secondary anæmia following hæmorrhage liver or a suitable liver extract has a markedly beneficial effect in improving the blood picture and, further, that this effect is enhanced by the use of iron along with the liver. The fact that those cases in which there was a reticulocyte response early in the course of liver treatment showed an increase in the number of red cells, while the one case in which this response was lacking showed no such increase, appears to indicate that any extensive rise in the blood count must be preceded by the appearance in increased numbers of these young red cells, and that unless a reticulocyte response occurs an increase in the total number of red cells is not to be expected. Case 5 illustrates the necessity of making a distinction between improvement in anæmia due to increase in the hæmoglobin percentage, to increase of the total number of red cells, and to both.

It is probably significant that the four cases which showed both a reticulocyte response and an improvement in the blood picture were all suffering from shortage of red cells resulting from old or recent hæmorrhage. A large hæmorrhage is usually followed by speedy blood regeneration, but in certain cases there appears to be a failure of blood restitution which, as in Case 3, may persist over a long period. In these cases of failure of blood regeneration after hæmorrhage, liver, particularly in combination with iron, appears to have great value.

Conclusions.

1. In certain cases of secondary anæmia liver therapy is effective in causing a reticulocyte response and in raising the blood count.

2. The best results are to be looked for in those cases of secondary anæmia due to failure of blood regeneration after hæmorrhage.

3. The effect of the liver therapy is greatly enhanced by the simultaneous exhibition of iron.

Clinical and Laboratory Notes.

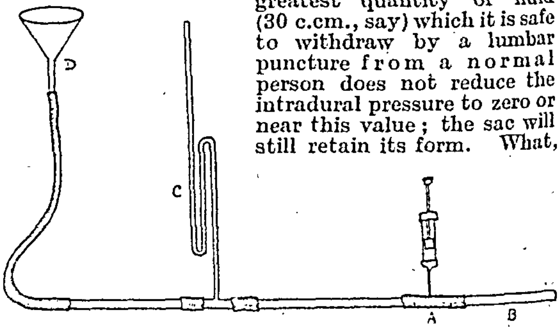
A NOTE ON SPINAL ANÆSTHESIA.

By CHARLES A. PANNETT, B.Sc., M.D. Lond., F.R.C.S. Eng.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF LONDON; SURGEON TO ST. MARY'S HOSPITAL.

A FEW months ago some observations on the use of a heavy solution of novocaine for the production of spinal anæsthesia were published in THE LANCET.[1] The paper provoked some discussion on the manner of spread of an anæsthetic agent in the spinal canal. That precise knowledge of this subject does not exist was the one certain fact which emerged. It supplied the stimulus for a further study of the phenomenon. The result has been the development of a very simple technique for spinal anæsthesia, which as far as can be judged from a small experience, is an unusually reliable method of ensuring the spread of the anæsthesia to a segment high enough to permit of operations in the upper abdomen.

Physics of the Dural Sac.

The dural sac is composed of inextensible white fibrous tissue. A sac removed post mortem was found to accommodate 30 c.cm. of liquid from the level of the fourth cervical segment to the lower end. The appearance of the flaccid dural sac when exposed by dissection of the dead body is, however, not a true picture of what exists in life. For the subarachnoid pressure varies between 12 and 20 mm. Hg, whereas the pressure between the dura and bony wall of the spinal canal is of the order of –1 to –18 mm. Hg.[2] The inevitable result is that the dural sac always assumes its maximal capacity. In other words, its transverse section is always a circle and it is incapable by any deformation of increasing its internal volume. It might from this point of view have rigid walls; it would act no more impassively in the withdrawal or injection of fluid. For the greatest quantity of fluid (30 c.cm., say) which it is safe to withdraw by a lumbar puncture from a normal person does not reduce the intradural pressure to zero or near this value; the sac will still retain its form. What, then, takes the place of the evacuated fluid? It is taken by an increase in the size of the numerous thin-walled vessels which lie within the spinal and cranial cavities. But here it is to be noted that the large vessels in the spinal canal are confined to the region of the cord. They are not present below in the region of the cauda equina. Suppose, then, a definite volume of liquid be injected into the spinal dural sac at the level of the second lumbar interspace. As it is slowly injected it is likely to find its path blocked in the caudal direction because the sac is distended to its fullest capacity, and there are not here present thin-walled vessels which can diminish in size to make room for the introduced fluid. It will have to travel cranialwards.



---

[2] Heldt, T. J., and Moloney, J. C.: Amer. Jour. Med. Sci., 1928, clxxv., 371.

How far up it will reach will depend upon its volume. That such is the distribution of an injected fluid under the conditions assumed is proved by a simple experiment with the apparatus shown in the Figure.

The blind end B represents the closed lower end of the dural sac; the open funnel D acts as the compressible vessels in the brain and cord; the manometer C registers the pressure. A coloured dye injected at A through the rubber tube is seen to flow only towards D and to spread scarcely for any distance at all towards B. If it is of greater specific gravity than the contained fluid it will soon settle down to the lower half of the tube, and then its movement will be dependent upon the slope of the whole apparatus.

Conditions in Life.

Are the conditions in life comparable with those of such an experiment? Obviously, if there is an active circulation of cerebro-spinal fluid a disturbing factor will be at once introduced. The statement[3] that cerebro-spinal fluid secreted within the skull passes down the posterior part of the spinal canal behind the cord and returns upwards along its anterior surface is not warranted by experimental facts. It seems certain that absorption does occur through the endoneural lymph spaces of Retzius, but the whole circulation is a very sluggish one when the dura is intact. In the rabbit, under urethane anæsthesia a dye injected under the dura has scarcely spread at all after the lapse of one hour. It is true that Weed[4] states that potassium ferrocyanide and iron ammonium citrate injected into the lumbar sac travelled up the whole spinal sac and filled it and the basilar spaces very speedily, but a perusal of his records reveals the fact that in all his experiments the injected fluid was at a considerably higher pressure than the cerebro-spinal pressure of the animals used. Naturally, under these circumstances the large vessels in the spinal canal and cranial cavity contracted to allow the new fluid room. All he really did was to push the cerebro-spinal fluid out of the canal into the cranial cavity, the very phenomenon which our above-mentioned experiment with the apparatus demonstrated to be possible.

A further argument has been adduced to prove that fluid passes upwards from the spinal canal to the brain. When a spinal cord tumour blocks completely the dural sac it is found that the composition of the fluid below is different (appearance of protein for one thing) from that of the fluid above, and it is said that this is due to the accumulation of the products of metabolism which now have their upward path of escape shut to them. But there is a much better explanation. Below the block the mechanism of absorption from around the nerve roots remains intact; it still goes on, whereas renewal from the choroid plexuses above is prevented. The space formerly occupied by the absorbed fluid would now seem to be taken by an exudation from the blood-vessels. Hence the change of composition. Based upon such reasoning the following technique of high spinal anæsthesia was devised.

The Technique of High Spinal Anæsthesia.

A preliminary injection of morphine (to allay anxiety) and atropine (to inhibit the vagus since it works unopposed as the cardio-accelerator nerves are blocked) is given. The patient is made to curl up lying on his left side. The space between the second and third lumbar spines is then anæsthetised with 1 per cent. novocaine and the spinal anæsthetic needle, which is 7·5 cm. long and only 0·8 mm. in diameter, is introduced into the dural sac. Eight cubic centimetres of cerebro-spinal fluid are slowly withdrawn into a 10 c.cm. syringe which is detached and the needle in situ occluded with its own obturator. Through the nozzle of the syringe 1 c.cm. of 15 per cent. novocaine in distilled water is introduced into the 8 c.cm. cerebro-spinal fluid, space having been made by further withdrawal of the piston. The novocaine is drawn into a 1 c.cm. syringe provided with a hypodermic needle to enable this to be done. The hypodermic needle is then fixed to the large syringe to allow it to be turned up and down to ensure proper mixing. All air is expelled, the hypodermic needle detached, and the syringe fitted to the lumbar needle whose stylet is removed. The 9 c.cm. of liquid containing the dose of novocaine is slowly injected, the patient turned on to his back, and the head end of the table sloped downwards 5° or 10° since the specific gravity of the injected fluid is necessarily raised somewhat. This volume of fluid will reach up to and bathe the third or fourth dorsal nerves. The concentration of novocaine in it is about 1·66 per cent.—i.e., sufficiently strong to soak into nerve trunks. It should never be forgotten that the power of penetration into nerve tissue is a function of the concentration of novocaine. If it is too low no anæsthesia will be obtained. When the patient is turned over 50 mg. ephedrine are injected hypodermically. In ten minutes' time the surgeon may begin his work, but he must get done what he wants to do in one hour. This is the only drawback to spinal anæsthesia. It is usual in any operation done under local anæsthesia with novocaine to find sensation returning in an hour. It is not peculiar to the spinal method. A drug which will produce prolonged anæsthesia is much wanted.

This preliminary note is published because the method so simple has proved so extremely satisfactory and does appear to be based upon sound physiological and mechanical principles. The method described should, however, be meticulously followed.

A "PERMANENT WAVER'S" CRAMP.

By G. Arbour Stephens, M.D., B.Sc. Lond.,
CONSULTING CARDIOLOGIST, KING EDWARD VII. MEMORIAL HOSPITAL.

A YOUNG woman, aged 21, after four years' strenuous employment as a "permanent waver," was compelled to give up work on account of severe pain in the right wrist.

On examination it was found that she was suffering from teno-synovitis over the lower part of the right forearm.

She complained of nothing else; her appearance was quite healthy and she said her appetite was very good. On further examination it was found that there was a marked hypersensitiveness over the areas shaded in the figures corresponding to the parts supplied by the fifth, sixth, and seventh cervical nerves and by the second to the eighth dorsal nerves on the right side of the body.

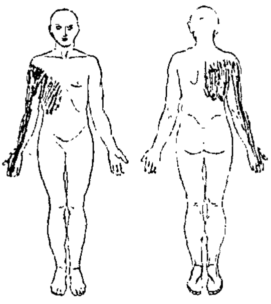

Diagram showing the hypersensitive areas.

The work of a "permanent waver" is very strenuous as it means standing for several hours every week, oftentimes in awkward positions in a badly ventilated room. In order to produce a satisfactory æsthetic effect, a considerable amount of tension needs to be applied, and it is in the application of this tension that the strain is placed upon the muscles of the right forearm. The patient is a well-built young woman who gets her exercise by rowing, but owing to a very serious accident to a member of the family there is no doubt that the tone of her general nervous system has been disturbed.

A CASE OF NEPHRITIS.

BY E. WORDLEY, M.D. CAMB., M.R.C.P. LOND.,
PATHOLOGIST TO THE SOUTH DEVON AND EAST CORNWALL HOSPITAL, PLYMOUTH.

THE following case of nephritis is described in some detail because I believe that it presents some unusual features. It is a case of chronic azotæmic nephritis of quite sudden onset in a young adult.

Family history.—Father died of uræmia, aged 58, in December, 1927. Mother alive and healthy; one brother, aged 36, in good health.

Past history.—Had scarlet fever when 5 years old, no other illnesses. Patient had worked as a painter since he was 14. For the past year he had worked in Devonport Dockyard at heavy manual work and could do anything a normal man could do without any headache, fatigue, or shortness of breath.

History of present illness.—Was in perfect health until about the time of his father's death in December, 1927. This appeared to upset him. About January, 1928, he first noted some impairment of health. He used to get dizzy while at work and was easily tired and rather short of breath. He continued at full work until the beginning of June, 1928, though with increasing difficulty. He consulted his doctor at this time on account of the dizziness and palpitation. Albumin was noted in the urine, but no other physical signs. Some blood was taken for urea estimation, when the surprising figure of 443 mg. per cent. was obtained. He was forthwith admitted to hospital, and by the kindness of Dr. A. B. Soltau he was admitted under me for further investigation.

Condition on admission.—On admission, July 8th, 1928, he complained of very little; the palpitation for which he had previously consulted his doctor had passed off, and except for a feeling of lassitude and an unpleasant metallic taste in the mouth, said he felt fairly well. He was a bright-complexioned man and did not look anæmic. The cardiac impulse was in the nipple line. The heart sounds were normal in character. The blood pressure was 128/90 mm. Hg. No œdema was present. No abnormal physical signs in respiratory system or abdomen or central nervous system. Teeth good, no blue line. Urine: specific gravity, 1010; reaction acid; albumin, 0·1 per cent.; no casts or cells present.

U.-c.t. = Urea-concentration test.
P.p. = Plasma protein. P.c. = Plasma chlorides.

Mr. J. R. Rolston reported that the fundus generally was myopic in character; otherwise no pathological features were present.

Course of illness.—The patient remained in hospital from July, 8th, 1928, to Sept. 15th, 1928. After the first fortnight he appeared to be in very fair health; he was up most of the day helping in the work of the ward and was quite active and energetic. He was at once put on a diet containing as little protein as possible, and it will be seen in the Table. detailing the various clinical and biochemical findings that the blood-urea fell somewhat. The metallic taste in the mouth vanished. He passed three pints of urine daily containing 0·1 per cent. of albumin. The specific gravity was constant at 1010. The systolic blood pressure on discharge was 128 mm. Hg and the Wassermann reaction was negative.

Repeated blood counts gave about 3,200,000 red cells and 45 per cent. of hæmoglobin. Stained films showed no evidence of stippling of red cells. In view of the fact that he had worked for many years in a paint shop the urine was examined carefully for lead by Aub's micro-chemical method [1] in which lead is crystallised out as a hexanitrite of potassium lead and copper. This test was negative. Since Hunter and Aub [2] have shown that lead is rapidly eliminated after giving parathyroid, the above test was repeated after giving this gland, but the results were again negative. Andrews's diazo test [3] was strongly positive. The urea-concentration test on admission gave figures 1·2, 1·2, 1·3.

He remained at home until Jan. 15th, 1929, when he was readmitted to hospital. During this time, until just after Christmas, he was in very fair health, his appetite was good, and he used to take long walks every day, and talk about going back to work. He had been promised a light job and felt quite equal to doing this. He used to attend every fortnight for examination and blood was usually taken at these visits. His mother said that at Christmas time he had been up and about most of the day while shopping and apparently was not at all fatigued. Having attended on Jan. 15th, 1929, he complained of feeling rather tired and of having an unpleasant taste in the mouth. His blood-urea was found to be 352 mg. and he was forthwith readmitted. His condition on examination was similar to that already described on his first admission. His colour was good, he was well nourished, and he himself did not think that he was particularly ill. Blood pressure was 143/93, no œdema was present anywhere. He was able to get about, and helped in the ward work in the afternoons. On Jan. 31st he began to complain of severe headache and nausea, and also of the still present unpleasant taste in the mouth. Blood pressure 135/82. Blood-urea 430 mg. per cent. He felt depressed and was rather drowsy. No œdema was present.

On Feb. 5th he felt very ill and started vomiting everything he took. He had severe headache; the blood pressure was 133/75, and there was no œdema. On Feb. 6th he was drowsy and constantly vomiting. Blood pressure 130/75. On Feb. 8th he was very drowsy and had severe headache. The blood-urea was 670 mg. per cent. and the blood pressure 100/55. There was still no œdema. He died suddenly on Feb. 9th.

Autopsy.—With difficulty permission was obtained for a post-mortem examination limited to the removal of the kidneys.

The body was well nourished; no œdema was present anywhere. On incision of the abdominal wall, the subcutaneous fat was not diminished. No free fluid was present in the peritoneal cavity. The kidneys were small and several small cysts were scattered over the external surface. They were pale in colour. The capsule was adherent and on stripping it a raised rough papilliform surface was left. The right kidney weighed 60 g., the left 55 g. The cortex was 4·5 mm. in depth and well demarcated. The cut surface was a pinkish yellow colour and finely mottled. The medulla was paler and almost of a yellowish colour. The peripelvic fat was increased.

Microscopical examination of the kidneys showed them to be completely disorganised. Extremely few approximately normal glomeruli or tubules were present. Nearly all the glomeruli were completely fibrosed and embedded in fibrous tissue, and the substance of the kidney mainly consisted of fibrous tissue infiltrated uniformly with small round cells. Most of the few tubules present were filled with colloid material, the epithelium flattened or defective. All the smaller vessels showed marked thickening of the intima.

Discussion.

Clinically the outstanding feature of this case is the very short and indefinite story of ill-health, at the most a vague feeling of malaise for three or four months, before on examination it was noted that his blood-urea was over 400 mg. per cent. And on examination, beyond a cloud of albumin in the urine, nothing abnormal whatever was found; the man was of a good colour in spite of the low red cells and hæmoglobin, and was well nourished and generally felt in very fair health. The blood pressure was very little raised. MacLean[4] has recently described cases of this nature.

Another curious feature of the case was the complete absence of œdema throughout the whole time he was under observation. As a result of a low protein intake the blood-urea fell considerably from 400 to 200 or just below and the patient was in very fair health and able to take long walks. It will be seen from the Table that the serum calcium did not fall very low, nor the plasma phosphates rise very high in relation to the very high urea figures; indeed, the calcium throughout was practically normal, in marked contrast to cases reported by de Wesselow[5] and Izod Bennett.[6] The peculiar metallic salty taste in the mouth described by Bennett was at times very troublesome to this patient but was only noted when the blood-urea was over about 300 mg. per cent. As happens so often in this type of case the symptoms of uræmia came on with great suddenness.

The case is interesting because it shows the great value of a thorough chemical examination in some cases of nephritis. It is, I think, certain that on a clinical examination alone in the early stages of the disease no one would have realised how hopeless the condition was. Further, I think no class of disease would repay better than nephritis a long-continued clinical study over many years, undertaken by practitioners who could observe and describe the whole course of the disease with the care that was so successfully employed by the late Sir James Mackenzie in diseases of the heart.

Reviews and Notices of Books.

RECENT ADVANCES IN PSYCHIATRY.

By H. DEVINE, M.D., B.S., F.R.C.P. Lond., Medical Superintendent, Holloway Sanatorium, Virginia Water. London: J. and A. Churchill. 1929. Pp. 340. 12*s.* 6*d.*

THE central theme of this well-written book consists of an exposition of a particular philosophical conception of the nature of mental disorder. A number of the principal modern tendencies in psychiatric research are summarised, and their supposed implications ingeniously dovetailed into the philosophical scheme. The latter consists fundamentally in a conception of the organism as a whole, with an indissoluble relation to its environment. To contemplate the organism and its functions, apart from environment, is, according to Dr. Devine, a philosophical and methodological absurdity; functions have to be defined in terms of environmental stimuli and organic responses. This bipartite conception has no need for a dualism of body and mind. Mental disorders are really "organic" disorders, the result of more or less durable disharmonies between the organic cravings and the environmental conditions.

This particular application of the main conception colours completely the scientific outlook of the book. Following an introductory chapter on the fundamentals of psychiatry, in which the conception of mnemic causation is adopted, there is a discussion on toxic-infectious and similar factors in the causation of the psychoses. Much of the emphasis of this section is laid upon showing that a confusional syndrome can arise on a basis of physical or emotional perturbation alike. This is, of course, generally known; here it is made to contribute ingeniously to the main thesis—that there is an organic basis of all or most mental illness. But in his eagerness to make this point, the author is in danger of obscuring one of the cardinal rules of clinical psychiatry—namely, wherever confusion exists, to suspect the presence of a recognisably physical component in the ætiology. Confusion explicable in purely psychological terms seems hardly to be considered. The importance of the isolation of the confusional syndrome by Meynert is stressed; but the opportunity is lost of pointing a moral—much needed at the present day in psychiatric circles in this country—namely, the possibility of clear determination, by means of clinical mental characteristics alone, of a mental reaction found principally in association with discoverable organic disease. Wider recognition of the significance of this clinical type would prevent certain errors in therapeutic claims. This touches upon an important point in the author's conceptions. For him a psychosis is an "organic" disease; but the meaning of this statement to him is that a psychosis is "the interpretation in the psychic life of endogenous excitants or disturbances originating in the depths of the organic life." The fact that this is not the usual meaning of "organic" disease is nowhere made explicit. Yet surely organic disturbance of the kind may be "functional" nevertheless. It would seem helpful if instead of the distinction between "functional" and organic, the essential delimitation were between reversible and irreversible. Organic and structural are not synonymous; organic, in Dr. Devine's sense, may be "functional"; and functional may or may not be psychological.

The contributions to the psychopathology of the psychoses made by C. G. Jung, J. T. MacCurdy, and A. Storch are dismissed in less than a paragraph each. The stratification of the psyche itself is not mentioned, which may be partly the result of the omission of any detailed consideration of these writers; and it helps to explain the impression one obtains from the book of a psychiatrist standing helpless in face of the—to him—incomprehensible psychological farrago presented by his patients and their utterances. Sullivan's recent work on the mental experiences of schizophrenics is not mentioned at all. There is another curious omission—curious because it would perhaps have supported the author's thesis of an organic basis for the psychoses; the recent work on mescal in normals and in psychotics is not alluded to. A useful emphasis is laid on hereditary studies, while at the same time the author deprecates putting too much weight on the heredity of any particular case. Rudin, the principal present-day explorer in this field, does not receive the honourable mention which is his due; nor in a discussion on the inheritance of acquired characters do W. McDougall's experiments on white rats find a place, although if valid they are more precisely relevant than those discussed in the text. H. A. Cotton's work on focal infection in the psychoses is quoted largely, and cautiously approved in principle. The facts that no one else has ever approached the results claimed by Cotton, and that the latter has for some years substituted colonic wash-outs for catastrophic colectomies are not explicitly mentioned.

There is an attractive chapter on the effect of somatic disease in psychotic subjects; but we cannot help thinking that from the physiological point of view the French theory of colloidoclasia as applied to the psychoses, by which an emotional shock is supposed to sensitise the organism in a way strictly homologous with anaphylactic sensitisation, is as airy a speculation as any of which the lesser Freudians have ever been accused.

Part III., "the behaviour of the organism in mental disorders," is an interesting attempt to fit a number of discrete physiological observations into the author's general thesis; and the attempt furnishes a useful object-lesson. It shows well how experimental results and data of laboratory observation—in this case those of F. Golla and his co-workers at the Maudsley Hospital—may be endowed with a significance of which the original observers did not dream, and which will probably surprise them. Moreover, A. A. Osman has recently described similar acid-base changes in the blood in a random group of debilitated children. The chapter on the basal metabolism in the psychoses is difficult to follow on account of the varying notation employed.

The ingenious elaboration of the conception of hysteria as a mythomania is attractive; but like so much of the French inspiration of this work, its attractiveness is seductive. It would be a pity if hysterics in general were regarded as "mythomanic"; there are a great many different types of personality in whom hysterical symptoms can appear; and simple generalising alignment (after Jung) of hysteria with "extroversion" will not do. The Freudians are repeatedly asked to supply statistical evidence of their views; but Kreschmer's type-characterology is less critically accepted. It would have been interesting to have had the personal observations of an experienced psychiatrist like Dr. Devine on the relationship of manic episodes, for example, to the "asthenic habitus." In the chapter on treatment no reference is made to Pearce Clark's claim to treat psychotic depressives successfully with a modified psychoanalytic technique; while Meyer's classical article on the treatment of paranoia and paranoid states is not mentioned. No reference is given to the recent increasing interest in children and in their "nervousness"; and the statement that the general intelligence is unaffected "after epidemic encephalitis" takes no notice of the best work so far done on this topic—namely, that of S. Dawson and Conn, who claimed that a fairly persistent retardation commonly occurs. Perhaps the least forgivable, because most fantastic, flight of Dr. Devine's physiological fancy occurs when he speaks of overstrain of the neurones leading to their degeneration and so to dementia, e.g., to dementia præcox; but so preoccupied is the author with the "organic" substance of everything mental that when towards the end he admits "pure psychogenesis"—sometimes—it is with an air of surprise. The book is preponderantly French in inspiration; references to German literature are disproportionately few.

We have considered it worth while criticising this book at length, partly because the series to which it belongs has had such deserved success, and partly because the present work is so well constructed, and welds into such a compact whole so many diverse facts. It is bound to have an effect in forming the opinion of the young psychiatrists in this country; but the emphasis on the organic basis (in Dr. Devine's special sense) of mental disorders leads to a comparative neglect of what most people regard as important recent contributions and therefore to a somewhat one-sided presentation of recent psychiatric work.

THE PSYCHOLOGY OF PHILOSOPHERS.

By ALEXANDER HERZBERG. London: Kegan Paul, Trench, Trübner and Co., Ltd.; New York: Harcourt, Brace and Co. 1929. Pp. 228. 10*s.* 6*d.*

IN this, the latest addition to the International Library of Psychology, Philosophy, and Scientific Method, Dr. Alexander Herzberg does justice to his inclusive theme. Musing in his preface on how a particular neurosis comes to be developed with its associated symptoms, he inquires what kind of person it is that develops a neurosis, and what kind it is that does not; and then, by analogy, he asks how any individual arrives at a particular theory of life, and what the make-up must be in order to work out any theory at all, seeing that the majority of the world undergo no such process. The purpose of the book is to answer the last of these questions—namely, what sort of man formulates a constructive outlook upon life for himself; and he enumerates the factors which he holds must be present to the subject's mind in order that he may become a constructive thinker.

Discussing what constitutes philosophy, he compares the modern and the ancient position, when philosophy was an undifferentiated whole, comprising religion, poetry, and science. To-day, under the pressure of practical requirements, we perceive independent divisions of thought — mathematics, astronomy, physics, chemistry, and biology, for example, all yielding to this process of differentiation, leaving psychology, logic, and ethics to comprise philosophy. Dr. Herzberg makes it clear that he does not consider this whittling process to be justified, and he doubts if it has occurred, putting forward here a definition that philosophy is the science of the widest problems in all fields, and of those problems which affect mankind most closely. Following a justification of the argument that philosophy should be regarded as a homogeneous science, he inquires into the nature and objects of philosophic interest and the characteristics of philosophic thought, and then in a series of essays discusses the professional lives of some of the best known philosophers—Socrates, Plato, Aristotle, Epicurus, St. Augustine, Bacon, Hobbes, Descartes, Locke, Leibniz, Berkeley, and a score of more modern exponents. He finds that 27 out of 30 of the great philosophers display in the matter of choosing a profession conspicuous divergencies from the normal, and, curiously enough, many of them have shown either hesitation in embarking upon any career at all, or inefficiency when they have embarked upon it—or both. Many seem to have had no business-like sense of the value of money, many showed conspicuous peculiarities in relation to love, marriage, social intercourse, active politics, or the whole practical side of life, but all of them have been men of great intensity of impulse, and more than normally intense inhibitions.

The biological value of philosophy the author finds is threefold, serving as a substitute for practical action in the discharge of excess impulse energies, creating in the place of harsh and intractable and therefore unsatisfying reality, a painless and tractable world, and leading by means of a detour, to the real satisfaction of powerful interests.

PROCTOLOGY.

By FRANK C. YEOMANS, A.B., M.D., F.A.C.S., Professor of Proctology, New York Polyclinic Medical School. London and New York: D. Appleton and Co. 1929. Pp. 661. 45*s.*

THIS text-book is a magnificent production which will take its place as one of the leading books in the English language on diseases of the rectum and pelvic colon. The author clearly writes with a vast personal knowledge of the subject and of its literature. Old and well-proved methods are given their due position, and at the same time the newer methods are described in detail, with the author's opinion of their value. Of some of recent and much-vaunted remedies he speaks with caution and scepticism. E. P. Clemons's method of treating rectal strictures with CO_2 snow is described, and J. A. Bargen's researches on the diplococcus which he has found in ulcerative colitis; Dr. Yeomans modestly notes his own recent work on the treatment of pruritis ani by the subcutaneous injection of benacol—a new anæsthetic solution in oil. The chapter on diverticulitis is an excellent summary of what is at present known of this interesting condition; attention is drawn to the dangers of infection following resection and end-to-end anastomosis; Dr. Yeomans considers that if resection is possible it should be done in stages by the Mikulicz method. In discussing the question of excision of the rectum for cancer, the author points out that the surgeon must be familiar with the different methods available and must fit the operation to the individual case; an interesting table is given of results of excision of the rectum according to different authorities. A general discussion of the indications and results of radium therapy for carcinoma of the rectum is given, and some description of treatment by radon seeds and radium packs. The modern technique of the "surgery of access" and radium-needle barrage as described by Neumann and Coryn is not mentioned.

In this excellent treatise the subject matter is clear, accurate, and sensible; the references at the end of each chapter are complete and up to date; the print is clear and the illustrations are numerous and excellent. In fact, the book is one which every surgeon and practitioner interested in proctology will read for pleasure and study with profit.

THE FACTS OF MODERN MEDICINE.

By FRANCIS W. PALFREY, M.D., Instructor in Medicine and in Hygiene, Harvard University. London and New York: D. Appleton and Co. 1929. Pp. 190. 21*s.*

Dr. Palfrey has written a useful book. He defines his own work as a simplified statement of established knowledge on medical subjects, which implies the clearing up of certain current misconceptions; the purpose is to place the basic facts of medical knowledge before the educated public that their comprehension may lead to a better mutual understanding between such a public and the medical profession. So we have here an intention to supply a scientific, though popular, book to take the place of those terrible "family medical advisers" published in response to the desire of patients to treat themselves without consulting the doctor. Aware of the criticism to which the book will be subjected—criticism which invariably takes the form of quoting Pope—on the ground that the attempt to be scientific must fail where an unequipped audience is addressed, Dr. Palfrey replies that the growing recognition of the fact that the public should have more opportunity of learning the truths of medicine justifies his work, and we think that he is right. For, as the author says, "the dangers of popular attention to medical subjects do not lie in an understanding of facts by those capable of assimilating them: they lie rather in erroneous impressions derived from partial or imperfect understanding of facts." With a view to an explanation of these facts we have some 200 pages forming a summary of the fundamental sciences, and 250 pages containing a categoric though necessarily brief description of various diseases. The first part of the work is decidedly well done. The notes on elementary biology are clear; the essentials of anatomy and physiology are given carefully; and in a sense the instruction is simple, but whether it will be simple for those who have not already mastered the sciences in a more detailed manner we considerably doubt. Concerning the second part of the book, which is the reason for its writing, it depends entirely upon the way that the information is used whether it proves of value or no to the lay reader. He who thinks that perusal of these able summaries will free him of worry, rooted in imperfect knowledge, will be disappointed, unless he obtains a perilous amount of self-confidence; but he who reads with the desire to ascertain medical views along a particular line, as they are expressed, will be a far more alert disciple of the truth.

THE SCHICK TEST.

A Practical Guide to the Schick Test and Diphtheria and Scarlet Fever Immunisation. By GUY BOUSFIELD, M.B., B.S. Lond., Medical Officer, Diphtheria Immunisation Clinics of Camberwell and Lambeth; Bacteriologist, Camberwell and Hackney. London: J. and A. Churchill. 1929. Pp. 72. 5*s.*

THIS small book, written for those beginning or already engaged in active immunisation against diphtheria and scarlet fever, covers the ground fairly well, though references to the copious literature are rather scanty. Most of the text relates to diphtheria and to English practice. After a short discussion of the fallacies of swab diagnosis, the technique of the Schick test, and the way to read results, active immunisation and the various problems arising at the initiation of a clinic are described. In the control of epidemics Dr. Bousfield suggests that the main reliance should be placed upon Schick testing, with swabbing as a necessary adjunct. In his hands double immunisation against diphtheria and scarlet fever has not been satisfactory. He does not discuss fully the difficulty of a decision when an indefinite small reaction appears in retesting after immunisation. The five-minute interval recommended between desensitising doses of serum is too short, for a reaction after a small test dose in a sensitive patient may not appear for an hour. The illustration of a "positive and pseudo" reaction is not very clear.

The book contains some useful hints on minor points; the discarding of a white overall and a timely gift of sweets may often avert unwelcome tears at an inoculation clinic. Most of the information required by the novice as well as the more experienced worker is supplied in handy form, and public health administrators and many practitioners will be well advised to place this book on their shelves.

LIGHT AND HEAT IN THERAPY.

With a Chapter on Foam Treatment. London: The Actinic Press. 1929. Pp. 174. 6*s.* 6*d.*

THE Proceedings of the Second International Conference on Heat and Light in Medicine and Surgery, held in London in October–November, 1928, have been published in book form. It contains contributions on heat and light treatment in nervous affections, gynæcology, surgical and pulmonary tuberculosis, and in diseases of the ear, nose, and throat, as well as on technique and apparatus, and a brief report of the discussion which took place on each subject.

THE KAHN TEST.

A Practical Guide. By R. L. KAHN, M.S., Sc.D. London: Baillière, Tindall and Cox. 1928. Pp. 201. 18*s.*

THE considered opinion of the League of Nations Serological Congress at Copenhagen (1928) served to confirm the generally accepted view that the Kahn test for the sero-diagnosis of syphilis is the most reliable of the numerous precipitation reactions. Prof. Kahn's latest book is an elaboration of the section on Procedure of his "Serum Diagnosis of Syphilis by Precipitation," published in 1925, and is designed to be a companion to two other volumes as yet unpublished. One half of the book is devoted to the standardisation of every aspect of the three variables used in the test, with the object of producing optimum sensitivity and eliminating false positives, whilst the technical description of methods is elaborated with a valuable discussion on the rationale and theory of precipitation reactions. The procedure of the test proper, both quantitative and qualitative, with blood-serum and cerebro-spinal fluid includes also recommendations for glassware and apparatus and a description of a micro-technique. Medical men as a whole will welcome any sero-diagnostic test for syphilis which can be rendered sensitive enough to detect latent disease during the course of treatment; in this respect, the especially sensitive antigen of Kahn for use in the "presumptive procedure" for treated cases of syphilis indicates an advance not yet achieved in the technique of the Wassermann reaction.

The book, which has a good bibliography, is essential to any worker performing the test, and is of value to those interested in the practice and theory of precipitation reactions.

A History of Pathology.

By E. R. Long, Professor of Pathology, University of Chicago. London: Baillière, Tindall and Cox. 1928. Pp. 291. With 45 plates. 22*s.* 6*d.*

Prof. Long has attempted what no one has done before, and he has succeeded quite well. Pathology is slowly settling down to be itself, and, if it has not yet quite made up its mind what it is after, it has achieved a special place in the academic world, a literature and a priesthood. The present is the fulfilment of the past and the promise of the future, and pathologists might well spend a little time reflecting where they are and how they got there, in the light of what Prof. Long has to tell them. Rather too large a proportion of the book is given to the ancients; the tale hardly becomes of much moment before the nineteenth century.

Jahresbericht Radiologie.

Compiled by K. Frik. Vol. I. Berlin: Julius Springer. 1929. Pp. 388. R.M.38·80.

This is a most complete bibliography of recent radiological literature, exceedingly well classified as regards subject matter, and with adequate cross references. That the volume contains approximately 7000 references is some index to the extent of the work that is being done in radiology as applied to medicine. This painstaking compilation appears to be exhaustive and accurate; we note, however, that a defect is the omission in most instances of the year of publication, although the volume and page are given. We trust that in future editions the author will include this information, which shows at a glance which communications are likely to be useful for any special purpose and which are likely to be out of date.

Sexual Life of Savages in North-Western Melanesia.

By Bronislaw Malinowski, Ph.D., D.Sc., Professor of Anthropology in the University of London. With a Preface by Havelock Ellis. London: George Routledge and Sons. 1929. Pp. 506. 42*s.*

Dr. Malinowski's ethnological work is already well known, and in this book, which deals in detail with the natives of one small island group, he describes his methods and makes clear the mental attitude necessary to success in understanding savage customs. It is assumed that his readers accept the standpoint that an account of sexual life must be as free from limitations as the account of any other human activity. Setting aside any preference he may have for our own customs and taboos, he is able to enter into personal friendships with his subjects; thus he has obtained spontaneous confidences and intimate gossip, in contrast to what he describes as "the mechanical pumping of informants by the question and answer method at so many sticks of tobacco an hour." Without drawing any moral, he shows a close parallel between the mental processes of the Trobriand Islanders and our own. Their social rules are different from ours, but not their reactions to them. They show the same reticences that we do, the same lifting or intensification of conversational taboos to correspond with the social occasion, and they present to the outsider a rigid code the frequent violations of which are revealed only through intimate personal acquaintance. Spencer and Gillen have described Central Australian tribes whose members believed that sexual intercourse had no relation to conception, and the writer, finding the same belief among the Trobrianders, was unable to convince them of the physiological facts of paternity even in regard to the breeding of goats and pigs. Descent is of course matrilineal, but government is in the hands of chiefs whose influence is economic and dependent upon polygamy. Dr. Malinowski thinks that efforts to abolish that custom will lead to social disorganisation and the gradual extinction of the race. Another practice placed under a ban by reformers from without is that of sexual freedom among the young, which by a process of trial and error leads to marriages not lacking in loyalty or affection and generally permanent. Love-magic and sorcery play their part in courtship, but seem to serve the purpose of allowing personal inclinations to disguise themselves as the product of irresistible external forces.

The subject of the book involves the whole social organisation of the community, of which the author gives a vivid picture, that is made more lifelike by the many excellent full-page plates. His theoretical discussions are marked by a dislike for speculating as to past evolution or cultural history; he regards customs as fitting into the actual social scheme and finds in their fitness sufficient reason for their existence. He has so come to appreciate the native's cultural qualities that he sees in them no more food for speculation about origins than we may observe in our own. This may disappoint theorists, but in no way lessens the value of a most interesting book.

Percussion of the Chest.

By J. B. McDougall, M.D. Glasg., F.R.C.P. Edin., Medical Director British Legion Village, Preston Hall, Aylesford, Kent. London: H. K. Lewis and Co., Ltd. 1929. Pp. 143. 6*s.*

This little book will be read with pleasure by those interested in percussion and the production and variation of sound. After a brief historical sketch and a short chapter on the technique of thoracic percussion, a long chapter is devoted to the acoustic aspect. The author divides the sounds elicited by percussion into two groups, the musical and non-musical, and a full description is given of the various notes which may be obtained. The final chapter describes the variations in the percussion note in certain diseases of the chest and contains an interesting description of the reflex bands of dullness which have been described in cases of pulmonary tuberculosis. A useful bibliography is appended.

JOURNALS.

Revue Belge des Sciences Médicales.[1]—The first number of this new journal, which promises to be a valuable addition to medical literature, came out in January under the guidance of a distinguished editorial board, including clinicians, pharmacologists, and pathologists. Appearing in ten numbers per annum it is intended for the publication both of original papers and of reviews on special subjects, together with abstracts of papers of the Belgian medical literature and a critical bibliography. The contents of the February number may be briefly summarised as an indication of the scope of the journal. It contains a paper by Dr. von Goidsenhoven on the treatment of essential thrombopenia by ligature of the splenic artery to which more detailed reference was made on p. 1159 of our last issue. This is followed by an "annual review" by Dr. A. Dupont, entitled Dermatologie et Syphiligraphie, which is confined to a summary of papers published during 1928, so that the reader is kept abreast of the most recent international literature. The review of the Belgian medical literature is in this number represented by abstracts of papers dealing with pharmacological subjects. The number closes with signed reviews of recent books.

DON: SATURDAY, JUNE 8, 1929.

Y MORTALITY FROM TUBERCLE.

the least profitable duties of a tuberculosis that which concerns the examination of ." The most readily accessible contact is l child, whose mother is seldom averse from iose "proper examinations" which have urped the place of a bottle of medicine in esteem. The candidate himself is seldom to forgo the tedium of an afternoon's for the sake of a medical adventure which to be painless, and may be rewarded with nalted oil. The average mother may, there- lied upon to bring to the dispensary all the f school age she possesses. Infants inevitably y their only nurse, and what has been ho "procession of contacts," duly takes e result is highly gratifying to all concerned, the tuberculosis officer's imagination has ivated by the possibilities of paravertebral n, he is able to report that the "contacts" uffering from tuberculosis. Children suffer- lupus, *Pott's disease, or even cervical* lo not appear in the queue, for the least mother will already have sought treatment bvious manifestations of non-pulmonary is. As a social investigation, as an oppor- giving a little elementary instruction in the ygiene the expedition may have been rom any other point of view the examina- tacts as usually conducted is futile, for, enerally, *children of school age do not* pulmonary tuberculosis. At the more entres the examination may include the ys and graduated skin tests. The appli- hese methods may, indeed, enable the officer to determine whether a child has cted to a "primary infection" with it as evidence of this will only be obtained ee of immunity has been established it is the finding has much practical value. l "tuberculous seedling" is not the pre- he consumptive adolescent who from pressure of business is usually reluctant e dispensary as a contact.

rent in value is an investigation of the undertaken by the Lancashire group of officers, the result of which is given in a ort edited by Dr. LISSANT COX.[1] The investigation was to determine the fate ldren living in tuberculous households. ose the histories of nearly fifteen hundred r five years of age, living in homes in more adults suffering from tuberculosis resided, were compared with those of children of the same age and living under comparable conditions, but not subjected to the risk of tuberculous infection. The most significant finding was that the death-rate from non-pulmonary tuberculosis among the children exposed to the risk of infection by a sufferer from "open" tuberculosis was greatly in excess of the rate occurring among the controls. The death-rate among the contacts in the first twelve months of life was nine times greater than that of the controls, fourteen times greater in the second year, and nineteen times greater in the next three years. Two-thirds of this mortality was due to tuberculous meningitis. The importance of intimacy of contact as a factor in the transmission of the disease is shown *by a mortality-rate significantly greater among the* children whose mothers were tuberculous than among those exposed to infection from tuberculous fathers. It is interesting to note that the death-rate from *all causes* in the first year of life was less among the contacts than among the controls. Dr. COX suggests that this may be due to the supervision of tuberculous households by the medical and nursing staffs of local authorities. It is relevant to note that the *reduction of mortality attributed to the use of BCG* vaccine in France extends to causes of death other than tuberculosis.

Prof. A. CALMETTE has calculated that in France 24 per cent. of the children of tuberculous mothers died from tuberculosis in the first year of life. The corresponding figure for Lancashire children was estimated as 3·2 per cent. The Lancashire death-rate for "contact" infants is, in fact, less than that *claimed for French infants protected by BCG* vaccine. But though the death-rate from tuberculosis in infants in Lancashire compares very favourably with that recorded elsewhere, the fact remains that a needless sacrifice of child life continues. The experience of Papworth has shown that it is possible for the child population of a fair-sized village to live in more or less constant contact with parents suffering from open tuberculosis and yet to *remain free from any manifestations of disease.* Where social conditions are satisfactory and where there is a scrupulous observance of the laws of hygiene the child of tuberculous parents is in no danger. But conditions at Papworth are admittedly exceptional. Might not more be done to lessen the risk of infection in areas where home conditions are far from ideal? The simplest solution of the difficulty would be either to remove the source of infection *from the home by arranging for the permanent* segregation of the tuberculous, or to provide an alternative home for the contacts. *The latter system* appears to have worked well in France, but it has the grave disadvantage that the children of a tuberculous father are deprived of both their parents. Even where legislation permits of compulsory segregation of an infectious patient experience proves that it is seldom enforced. The number of hospital beds *available for the treatment of advanced pulmonary* tuberculosis is notoriously inadequate. Reluctance to enter a poor-law institution prevents many patients from accepting relief of this kind from the guardians, even in those areas where harmonious relations exist between the poor-law and the public health authority. The provisions of the Local Government Act, if applied with humanity and intelligence, should remove many of the present difficulties and should enable the medical officer of health to use his powers of compulsion for the protection of threatened child life without violence to his charitable instincts.

Young Children in Tuberculous Households. ancashire Group of Tuberculosis Officers to the ittee of the Joint Tuberculosis Council, 1929. ing and Co., Ltd.

OCULAR IMBALANCE.

The equilibrium of the extra-ocular muscles of the two eyes is a subject which it is necessary for all those engaged in the prescription of spectacles thoroughly to understand, and the recent discussion on the subject at the congress of the Ophthalmological Society, reported in our issue of April 20th, will, it is hoped, do something to further this understanding. The first essential is familiarity with the anatomy of the extra-ocular muscles and their actions on the axis of each eye separately, especially of the four muscles whose combined actions move the eye in the vertical meridian. The second essential is to understand the difference between concomitant defects in the movements of the two eyes dependent on peculiarities of innervation of the centres for convergence, divergence, &c., and paretic defects dependent on weakness of particular muscles. When a defect due to either of these causes is so great as to cause an obvious squint the patient does not attempt to overcome it, but either sees double or suppresses the image in the squinting eye. When, however, the defect is so slight that the patient is able to overcome it by an effort of attention, either it may cause no symptoms at all or the effort may be attended by such a nervous strain that it may be accompanied by various uncomfortable nervous symptoms, often including headache which, according to Dr. E. E. Maddox, is generally of the occipital variety. These cases in which there is want of balance between the corresponding muscles of the two eyes, not great enough to cause a squint, are termed heterophoria, and according to the direction in which the movement of one or the other eye is defective there are a number of varieties of this condition which have received special designations, such as eso-, exo-, hyper-, and cyclophoria. There is a further distinction between the paretic cases, in which the defect varies in degree according to the direction in which the eyes are placed when the test is made, and concomitant cases in which the defect is equal in degree in whatever position the eyes are tested. Dr. Maddox, whose rod-test is familiar to all ophthalmic surgeons, distinguishes as many as 24 varieties, 12 paretic and 12 concomitant. It is consoling, however, to know that comparatively few cases of heterophoria require any treatment, when they are found in people leading an ordinary life. In airmen, however, the case is different. As a rule, the call on the reserve power of the eye-muscles to correct any slight defect of horizontal movements or of convergence involves no undue strain on the nervous system of those engaged in the ordinary pursuits of life. But when the nervous tension is at a very high pitch, as in a forced landing from an aeroplane, any extra call on the nervous system necessary to correct a faulty balance of the eye-muscles may prove to be the needle which breaks the camel's back. Group-Captain E. C. Clements, who took part in the discussion, has done yeoman service in bringing this aspect of the matter to the notice of the authorities of the Royal Air Force, and instituting not only tests for the condition but ocular exercises designed to cure it. For the ordinary civil population, however, there is a general agreement that the only variety of heterophoria that commonly needs treatment is hyperphoria. The reserve power of the vertically acting muscles when they are called upon to adjust a difference in height between the two eyes is comparatively slight. In these cases symptoms, and even occasional diplopia, are not infrequently found, and can be counteracted by the prescription of appropriate vertically-acting prisms. In extreme cases operation by advancement may be called for. The prescriber of prisms is faced at the outset by the complication that there are at least four different systems of nomenclature of prisms commonly used. Fortunately in the case of three of them the differences in deviating power for corresponding numbers is negligible for prisms of low power such as are generally used. In the case of the fourth system (angle of deviation) the number of the prism represents just about double the deviating power of that of the corresponding number of the other systems. The wholesale prescribing of prisms is indefensible; the one condition other than hyperphoria in which the prism may serve a useful purpose is that of weakness of convergence. In young people the range of convergence often varies with the state of health, and the proper treatment for weak convergence is often tonic, assisted by exercises rather than the prescription of prisms. In old and debilitated people, however, the condition may be more or less permanent, and much benefit may accrue from the wearing of low prisms, base in, for reading. If it be asked how can a low prism of one or two degrees have an appreciable effect in dealing with deviations many times that amount, the answer was supplied by Dr. Maddox when he pointed out that it was the last degree of stretch of the fusion reflex which was most fatiguing. In esophoria prisms are seldom called for; in the case of hypermetropes it is better to order a fully correcting spherical glass, so as to cancel the reinforcement of the tendency to converge which accommodation for a near point naturally brings with it. Similarly with presbyopes who show exophoria it is better to order them weaker spherical lenses than would be given if they were orthophoric.

MASTURBATION AND THE CHILD.

Any youth walking in a London street some thirty years ago ran the risk of having thrust into his hand a pamphlet describing the terrible results of "solitary vice" and urging him to seek treatment from some pernicious quack. Police action has checked this indecency, but it occasionally reappears as an advertisement in some shady periodical where allusion to "lost manhood" is calculated to stir up those dreads that plague many physically healthy people who have at some time or other passed through a phase of masturbatory practice. Such an appeal to fear succeeds because there exists a widespread belief in disastrous results from masturbation, for which, however, modern medical literature offers no evidence. This frame of mind appears to be a survival from the eighteenth century, when Tissot, a physician of Basle and Fellow of the Royal Society of London, wrote a treatise upon Onanism which enjoyed a European reputation and appeared in several languages, an English translation having been published in 1766. Masturbation he describes as a corruption more baneful perhaps than small-pox, and he tells the reader in a preface that "where the writer must have less grounds to expect he shall convince by reasoning, than he has to hope he shall terrify by examples, too many cannot be recited." This lurid promise is well kept, and after some of his gruesome descriptions the impression upon his victim would certainly be, as the author hoped, "a dreadful portrait sufficient to make him retreat with horror."

Voltaire further popularised this method of approach; in 1836 Lallemand wrote a book in which masturbation was made the source of all evils, and the bogy flourished through the nineteenth century. Havelock Ellis, in the first volume of his "Studies in the Psychology of Sex," cites 29 authorities, including Gowers, who between them furnish a wonderful list of the signs and consequences of masturbation, ranging from insanity to warts on the hands, a list which should emphasise the advantage medicine now derives from the use of statistical methods and control groups. Even without these checks upon fantasy the influence of Tissot has greatly weakened, inasmuch as the subject is now rarely mentioned in text-books except to note the necessity of removing the torturing fears and remorse so frequently associated with masturbation, whether past or present, for the effect of the superstition upon the nervous and sensitive of either sex, both in childhood and adult life, is still familiar to those practitioners who deal with nervous people and have the courage to face the matter frankly. It is therefore with regret that we notice the circulation of a set of booklets, issued by an imposing authority and lately recommended in a letter to the *Times* as guides for giving sex instruction to boys, in which the terrifying method is perpetuated. The boy of 14 is to be told that because of the connexion of the private parts of the body with the spine and brain "it follows that, if you meddle improperly with these parts, your brain will suffer"; he is also to be warned that "many lives have been cut short by disease brought on by giving way to this bad habit in boyhood."

To place this literature, under the guise of sex instruction, in the hands of boys or parents can do only harm, especially when we recognise that a masturbatory phase occurs commonly in the development of boys and girls—though the terrorists fortunately exclude girls from their scheme of activity. The late Dr. Clement Dukes estimated that masturbation occurred in about 90 to 95 per cent. of all boys at boarding school, and although he traced it entirely to the example of the already initiated yet we know now that it quite commonly arises spontaneously and remains a solitary practice. It has not yet been shown to be a primary cause of trouble, though even without specific external influence it often attracts to itself the sense of dread and shame with which the subject of sex is often invested in the mind of the badly instructed child; but the withdrawal of a child from wholesome interests into a world of solitary indulgence must be regarded as a signal of nervous or temperamental difficulties. It is these difficulties that call for treatment, and any emotion about masturbation should be checked by the investigator asking himself what is the object of treatment in any particular case. When that question is fairly answered we may hope to help the child without adding to his difficulties or sowing the seed of later troubles.

THE MEDICAL GROUP IN PARLIAMENT.

Medicine has increased its representation and the new House of Commons, when it assembles on June 25th, will include 18 members of our profession. Their number is some 50 per cent. greater than ever before, and although we have never said a good word for vocational representation in Parliament, we heartily rejoice that there will be so many able to place medical knowledge and experience at the service of the two Houses. The Commons are increasingly occupied with large measures of social reform which have a medical side, and whatever Government may be directing the destinies of the nation, the closer application of hygiene to industrial life can hardly be long delayed. For the first time in our Parliamentary history a medical woman will sit in the House, and in Dr. Ethel Bentham we have one who associated herself with the care of infant life and child-bearing long before they became the concern of all thoughtful people. Dr. Stella Churchill, another protagonist of child welfare, who was unsuccessful at the poll, nevertheless made a good show with nearly 11,000 votes to her credit.

A complete list of medical candidates, successful and unsuccessful, with the voting figures, is given on p. 1210, from which it may be seen that the proportion attached respectively to the Conservative, Liberal, and Labour organisations matches closely the political complexion of the new House as a whole. As an illustration of how little anyone can be regarded as a candidate for medicine, we need only recall that in two constituencies medical men opposed each other, to their own discomfiture. In one case this has resulted in the exclusion of Sir Thomas Watts, whose unconventional views on many matters, especially health insurance, enlivened the House. Two other medical members who were sitting at the dissolution have failed to re-establish their seats, and will be keenly missed. Sir Richard Luce's occasional contributions to debate were always marked by reasonableness and by intimate knowledge of his subject, and medical men in the Services found a good friend in him. The loss of Sir Henry Jackson is palpable, and we hope that he will be given the opportunity of entering the House in some other way. Of the new medical Members several, including Dr. Forgan, Dr. Morgan, and Dr. Spero, have already fought at previous elections. Mr. Somerville Hastings resumes the seat which he occupied in the 1923-24 Parliament, and Mr. Christopher Addison returns to the arena where he formerly occupied a prominent position. Among the 20 unsuccessful candidates, we may specially regret the failure of Dr. Lyster at Winchester in his attempt to gain a seat as an active member of the public health service.

While the party element must, as we have seen, have played a large part in the election of these 18 Members, they will now take their places as units of a Parliamentary Medical Committee which is quite outside party and considers with a single eye the broad interests of medicine. On this Committee they will no doubt be joined, as heretofore, by certain coöpted University representatives as well as by the two medical peers, Lord Dawson and Lord Moynihan. The Chairman of this Committee, Dr. Fremantle, has on public health questions an authority which has been enhanced by his recently published books, and Dr. Drummond Shiels, whose Parliamentary and professional life cover almost the same period of time, will, it may be presumed, continue to be the active and efficient honorary secretary of this group. In practice a common finding has been secured on most important medical questions of the day, and if there should be some divergence of view on the function of the State in regard to hospitals and the provision of health services, it is well that there should be within the precincts of the House of Commons a medical forum for their quiet discussion and for the discovery of a common policy.

Portsmouth Eye and Ear Hospital.—It was stated at the annual meeting of the Portsmouth and Southern Counties Eye and Ear Hospital that the work was hampered for lack of space; last year there were 24,500 out-patient attendances. It is the only specialised hospital in Hampshire.

Annotations.

"Ne quid nimis."

THE KING'S HEALTH.

ON the eve of public thanksgiving for his complete recovery to health the King's convalescence has had a setback. Early last week he was confined to his room with a feverish attack, the announcement of which, with characteristic considerateness, was kept back until the general election had taken place. On Saturday it was added that an abscess had formed under the site of the old scar on the right side of the chest, and was then draining. After the week-end a bulletin signed by Sir Stanley Hewett and Lord Dawson, as well as by Mr. Henry Martyn, Surgeon-Apothecary to the King's Household at Windsor, contained the news that healing of the abscess was following a normal course, which in the nature of things must be tedious. This announcement and the fact that no necessity has been seen for the issue of daily bulletins have had the effect of restoring confidence, which was inevitably shaken by the association of a feverish attack with a fresh effusion. The trouble is clearly a local one and although confined to bed, His Majesty is able to transact public business and we may look forward with confidence to complete closure of the wound. There is happily nothing in the occurrence to dim the achievement of those who have borne the responsibility of the King's treatment during his illness, and whose names are fittingly mentioned in the list of Birthday Honours which follows.

BIRTHDAY HONOURS.

IN the official list of honours conferred by the King on the occasion of his sixty-fourth birthday the medical recipients include those who were His Majesty's advisers during his recent serious illness. In this important connexion Lord Dawson of Penn is created a Privy Councillor, baronetcies are conferred upon Sir E. Farquhar Buzzard and Sir Hugh Rigby, while Dr. Stanton Woods is knighted. Further, Sir Humphry Rolleston has been created G.C.V.O., Sir Frederick Stanley Hewett K.C.B., Dr. F. E. Shipway K.C.V.O., Dr. F. D. Howitt and Dr. L. E. H. Whitby C.V.O., and Dr. E. C. Dodds M.V.O.

The general list of members of the medical profession, including the one or two who are closely associated with it, who have received honourable recognition of their work, includes Dr. Grafton Page, Treasurer of the Commonwealth of Australia, who has been created a Privy Councillor. In the Orders of Chivalry the O.M. has been conferred upon Dr. Robert Bridges, Poet Laureate; in the Order of the Bath, Dr. M. A. Cassidy, chief medical officer of the Metropolitan Police, receives the civil C.B. (the occasion being the centenary of the Force) and Rear-Admiral H. C. Whiteside and Maj.-Gen. H. P. W. Barrow, Director of Hygiene at the War Office, receive the Military C.B.; the C.M.G. has been awarded to Dr. W. J. D. Innes, Director of the Medical and Sanitary Services of the Gold Coast, and to Mr. O. F. H. Atkey, F.R.C.S, Director of the Sudan Medical Service; in the Order of the Indian Empire Maj.-Gen. R. W. Anthony, Surgeon-General with the Government of Bombay, and Mr. Charles Albert Bentley, Director of Public Health in Bengal, have received the C.I.E., and in the Royal Victorian Order, in addition to those already mentioned, Lt.-Col. Gordon Carter has been created a K.C.V.O. In the Order of the British Empire, Maj.-Gen. T. H. Symons, the Director-General of the Indian Medical Service, and Dr R. H. Stawell, President of the Melbourne Hospital, have been created K.B.E. The following have received the C.B.E.: D.M. Macrae, P.M.O., Bechuanaland Protectorate, Col. A. H Safford, late R.A.M.C., Assistant Director of Medical Services, Baluchistan District, Dr. A. Sandison, P.M.O., Ministry of Pensions, and Lt.-Col. J. W. Watson, I.M.S., Civil Surgeon, Ajmer and Chief M.O. Rajputana and Ajmer-Merwara; the following have received the O.B.E.—namely, Maj. D. G. Cheyne, R.A.M.C., Deputy Assistant of Hygiene in the China Command, Maj. Jamshedji Nusserwanji Duggan, I.M.S., Professor of Ophthalmic Medicine and Surgery, Grant Medical College, Bombay, Capt. P. F. A. Grant, I.M.S., Squadron Leader (Hon. Wing Commander). E. Huntley, R.A.F., Mr. P. F. Mathias, Superintendent of the Government Royapuram Medical School, Maj. J. C. Pyper, I.M.S., late M.O. Equitation School, Saugor, India, Dr. I. D. Ramsay, Civil Surgeon, Ministry of Interior, Iraq, Surg.-Commander F. L. Smith, R.N., Mr. George Stuart, Assistant Director of Laboratories, Department of Health, Palestine, and Capt. S. H. Woods of the Army Dental Corps; while the following have received the M.B.E.: Dr. T. Fawsitt (for Public and charitable services in Oldham), Mr. W. P. S. Mitchell, M.O. of the Bastár State, Central Provinces, Dr. Socrates Noronha, M.O. in charge of the Anti-venereal Department in the Bombay Municipality, Dr. C. B. Philip, M.O., Kenya, and Mr. J. H. Theodore of the Indian Medical Department, King Institute, Guindy, Madras. Dr. P. Chalmers Mitchell, the secretary of the Zoological Society, and long associated with medical education as a biologist, and Professor Colin MacKenzie, Director of the National Museum of Australian Zoology, have been knighted.

To all these we offer our sincere congratulations, while we note the progressive wiping-out of the old reproach that in these awards workers in distant parts of the Empire fail to be forgotten.

A NEW ZEALAND RADIUM CENTRE.

THE annual report of the Radium and Deep Therapy Department of the Christchurch Hospital, New Zealand, which has just reached us, is the fourth from the pen of Dr. P. Clennell Fenwick, and is commended by Dr. Walter Fox, the medical superintendent, as evidence of progress abreast of that to be observed in other radium departments. Only in our issue of May 25th we published some interesting observations from this department on malignancy following trauma. With the exception of the treatment of menorrhagia, where there is a concise description of the method employed and a detailed account of the results, not only with regard to the main symptom of hæmorrhage, but also as to the occurrence of menopausal symptoms, it is not altogether easy to obtain information from the report itself as to the exact technique in use at Christchurch. A total of 508 milligrammes of radium element seems to be distributed amongst seven small plaques and 81 tubes or needles, none of which exceeds 25 mm. in gross length, with an active length of, say, 15–20 mm. As, however, in treating epitheliomata of the skin, needles each containing 5–10 mg. of element are implanted in and around the lesion, it may be surmised that the technique employed is largely one of high intensity with short duration. If the application is repeated two or three times within a period of three or four weeks, as practised at Stockholm for carcinoma of the cervix uteri, this line of treatment will be seen to conform to some modern practices, although in Great Britain, in America, and on the Continent of Europe the present tendency is to employ relatively small linear intensities for periods of a week at least in the treatment of carcinoma of the mouth and tongue, carcinoma of the skin, and carcinoma of the breast—to mention three main sites of application. The explanation of this practice may lie in the fact that only radium element is used at Christchurch, a procedure which does readily allow of changes in technique. The extraction of radium from fixed containers, its remeasurement, and, finally, its redistribution, is a lengthy business, even where highly skilled technical help is available. It is for this reason that radium centres which at their conception adopted principally an emanation technique have reaped the benefit of being able to adopt any technique which the experience of other schools has shown to give better results than their own. At Christchurch the best results were apparently obtained in menorrhagia where, of 76 cases treated since 1924, 73 are free from symptoms. The routine treatment for this condition was 50 mg. RaE screened by 1 mm. of platinum and 1 mm. of rubber for 24 hours. In carcinoma of the cervix uteri 26 out of 48 cases treated between 1925 and 1929 are alive, and of 13 cases treated in 1925 4 are still living. The report emphasises the fact that no cases are refused treatment, and that this tends to make the results suffer by comparison with centres where cases are selected. Two cases of primary carcinoma of the breast were treated by implantation for 24 hours with satisfactory immediate results, but the treatment of carcinoma of the breast, recurrent after surgical operation, is described by Dr. Fenwick as a sorry business—an opinion which will be shared by most experienced workers. Some 88 cases of "ulceration and growth on lip" have been treated since 1924. Rightly, in the opinion of an increasing number of workers, tissue was not removed for diagnostic purposes; as no case was treated that had "any sign of glands under the chin," Dr. Fenwick must have had a remarkably early series of cases to deal with. Unfortunately, 34 of the series failed to report again. Of 117 cases of previously untreated rodent ulcer, 112 responded fully to treatment, the technique of which is not given. Cases recurrent after treatment by X rays, caustics, or surgery did not respond so well. For nævi and angiomata radium is said to have proved a specific remedy; of 115 cases treated, 12 are still under treatment and 103 are symptomless. These are striking figures if it is implied that no stigmata such as telangiectasis remained. Deep X ray treatment is also given at Christchurch, either alone or to the lymphatic drainage area after the primary growth has been treated by radium. The activities of the department also include treatment by ultra-violet light and endothermy.

THE SERUM TREATMENT OF ACUTE ANTERIOR POLIOMYELITIS.

A FEW months ago, at a symposium on poliomyelitis held in Melbourne, Dr. Jean Macnamara commented on the encouraging results recorded[1] in Australia and New Zealand with the serum treatment of this disease. In 1924–25 the serum of convalescents was used extensively in Wellington, Dunedin, and other centres, and from the observations made during this trial period the New Zealand Department of Health drew such favourable conclusions that in its report to Congress it stated: "Human convalescent serum was found to be a specific in producing prompt recovery and preventing paralysis if given in the preparalytic stage" It is agreed that once paralysis is established no benefit is to be got from the administration of serum except in the uncommon cases of the "spreading" (so-called Landry) type. The difficulty of recognising poliomyelitis in the preparalytic stage has often been emphasised, but in Wellington after the first few weeks of the epidemic, as a result of the awakened interest of the public and the alertness of the medical profession, 60 per cent. of the patients were admitted to hospital at a stage suitable for serum treatment. In Victoria, Australia, the experience of serum treatment in the outbreak of 1925 was such as to lead to the establishment of a serum service for the State, and, although no figures are yet available, Dr. Macnamara's remarks on the results obtained with its help in the 1928 epidemic were very encouraging. In two papers published within the last few weeks records have been given of the results of similar treatment in Canada and in the United States. In the *Canadian Medical Association Journal* a résumé[2] is given of the results in the Manitoba outbreak last year, and in a paper read before the American College of Physicians in February, 1927, but only now appearing in print, Dr. Wardner Ayer[3] gives the results of 126 cases in which serum was administered, representing his personal experience of the treatment up to the end of 1926. In Manitoba last year it appears that 161 cases were recognised; 74 were treated with serum in the preparalytic stage, 54 received no serum, and 33 had serum after the onset of paralysis. We may consider first the group in which no serum was given, as it shows the results of the disease uninfluenced by immune therapy; in this group 26 per cent. of the patients recovered without paralysis, 63 per cent. were paralysed, and 11 per cent. died. In the group in which serum was given late there were many severe cases, and allowing for this the outcome was similar to that of the untreated group; 22 per cent. recovered without paralysis and 45 per cent. with residual paralysis, while 33 per cent. died. Of the cases treated with serum in the early stages 93 per cent. made a complete recovery, 7 per cent. had residual paralysis, and there were no deaths. The group is divided into two subgroups, the first consisting of 57 cases which received a single dose of serum intramuscularly and the second of 17 other cases in which serum was given by other routes or in more than one dose, but the results in the two subgroups were almost identical. The figures of the epidemic are subjected to considerable analysis, and the results of treatment are given for separate months and for town and country cases. From the second paper we learn that of the 126 patients to whom Dr. Ayer gave serum at Syracuse, New York, in the six years 1921–1926, 93 (74 per cent.) recovered without paralysis. Forty-six cases were seen in the first 24 hours of the illness; in these there was one death, one extensive and three mild paralyses, while 41 patients (85 per cent.) recovered without demonstrable involvement of the spinal cord. Sixty-nine were seen and given serum during the second 24 hours, and the percentage of complete recoveries was 71 (49 patients). But of 11 patients to whom serum was given more than 48 hours after the onset, three died, three were severely paralysed, two mildly paralysed, and only three recovered without paralysis. (In this group the proportion of recovery is approximately that of the untreated disease.) The best average results seem to have been obtained in 1924, when Syracuse had 133 cases with 12 deaths; 61 cases were diagnosed in the preparalytic stage and treated with serum, and 50 of them (82 per cent.) ended in complete recovery without paralysis.

In Victoria, from the experiences of 1925 and 1928, it was judged that the best results were secured by combining intravenous and intrathecal administration of serum. The doses were varied according to the size of the patient but were not less than 50 c.cm. In Manitoba the serum was given intramuscularly, the standard dose was 25 c.cm., and the recorded results are as good as any. In Syracuse Ayer used the spinal route exclusively, considering the intravenous route wasteful of serum; the amount given was from 10 to 25 c.cm. according to the size and age of the patient, but it should be noted that with these doses it is his practice to give in some cases a second dose of serum. Further, Ayer, who got his serum by advertising for donors, apparently had not always a sufficient supply available. In 31 cases he gave patients antipneumococcal serum, and in eight of these he followed it up with a dose of human convalescent serum; but as far as he could determine there was no great difference between the results of giving antipneumococcal serum and those of specific therapy by human serum, and he suggests that the beneficial effect of non-specific sera may be partially due to phagocytic action consequent upon additional aseptic meningitis excited by the introduction of serum into the theca. At the same time he strongly urges the use of human convalescent serum when available.

[3] Ayer, W.: Amer. Jour. Med. Sci., April, 1929, p. 540.

The greatest difficulty in the application of serum therapy to poliomyelitis in this country lies in recognising the disease in the preparalytic stage, and it has been seen that in other countries that difficulty has not been insuperable. Diagnosis depends on examination of the cerebro-spinal fluid—which must be done at once—but the clinical signs and symptoms by which the preparalytic stage is provisionally recognised are as follows (Ayer):—

1. *Fever:* never high, the average being 102° F.
2. *Headache:* severe, frequently general but may be only nuchal: it may be absent but is then replaced by severe pain in the back.
3. *Rigidity of the neck:* distinct resistance to anterior flexion; there is never lateral limitation of movement. (The "spine sign" consists in an unwillingness to bend the body forward.)
4. *Tremor:* fine trembling of the lips and hands especially during movement, as when taking a glass of water: there may also be coarse twitching in sleep.

Accompanying symptoms are: vomiting (once or twice on the first day), constipation, retention of urine for 12–24 hours, sweating about the lips and neck, and a certain degree of mental apathy, though the patients when once roused are bright and alert and may be irritable.

Early diagnosis is naturally easier when an epidemic is in progress, but even in the absence of any definite epidemic much could probably be done during the season when poliomyelitis is prevalent to facilitate its early recognition not only by putting practitioners on the look-out for its early signs but also by guarded instruction of parents and teachers through the newspapers and wireless, with insistence on the importance of calling the doctor immediately to a suspected child, time being an essential factor.

LIVER IN SECONDARY ANÆMIA.

THE value of liver in pernicious anæmia requires no further confirmation, but its effect on secondary anæmia has so far remained somewhat uncertain. Since the experiments which originally led to the adoption of treatment were done on dogs suffering from anæmia induced by hæmorrhage it is hard to believe that liver has no influence on secondary anæmia of this kind at least. The matter has recently been investigated by Dr. W. P. Murphy and Dr. J. H. Powers[1] at the Peter Bent Brigham Hospital at Boston. Working on 17 cases of anæmia due to acute or chronic hæmorrhage they have found ample evidence of the beneficial effect of whole liver, their patients receiving at the same time a carefully prepared diet comprising large quantities of fresh fruits and green vegetables and iron in full therapeutic doses. In our present issue Dr. S. C. Dyke reports on a smaller series of cases observed at the Royal Hospital, Wolverhampton. Instead of whole liver Dyke used a commercial liver extract and he also early came to the conclusion that the effect of the liver was greatly enhanced by the simultaneous administration of iron. Arsenic was found to have little effect in improving the blood picture, but Dyke's series of observations is admittedly small. Comparing these two papers it is interesting to observe that while the Boston patients were on a specially designed dietary and the Wolverhampton ones on the ordinary hospital diet, the results were very much the same. Whipple and Robscheit-Robbins[2] having stated that the action of whole liver and of liver extract are not identical, it may be noted that Dyke's patients on a commercial liver extract and those of Murphy and Powers on whole liver showed a very similar response. Even better results might perhaps have been got by combining whole liver with an extract, and this is a possibility which needs further exploration. It must be noted that in both the American and the English series all those patients recorded as showing a response to liver therapy were suffering from secondary anæmia resulting from hæmorrhage. It remains to be seen what the effect of the treatment may be in other types of anæmia.

THE ASSESSMENT OF PHYSICAL FITNESS.

IT is hard to estimate physical fitness accurately, and if serious mistakes are not very common we must attribute this to experience and common sense rather than to the scientific exactness of the methods at our disposal. A person's general fitness depends essentially, though not entirely, on his cardiac efficiency, and this is the factor investigated by most of the usual tests. Modern radiological and electrocardiographic examination not being possible in the vast majority of cases in which the heart's action is to be studied, the practitioner must often turn to readily available and simple methods. These are based upon the heart's response to a varying degree of exertion, and are almost numberless in their modifications. Two such tests,[1] used in the examination of the University crew at Cambridge are the "dumb-bell test" and the "40 mm. Hg U-tube test"; in the former the effect upon the pulse-rate of hard dumb-bell exercise for one minute is noted, and in the latter, which is also employed in examining candidates for the Royal Air Force, the pulse-rate is counted in 5-second periods whilst the subject is maintaining the level of a column of mercury which he has blown up to a height of 40 mm. In both cases rapid and undue increase of pulse-rate and a delayed return to normal are considered unsatisfactory. Such moderate physical exercise should not increase the pulse-rate in a fit man by more than 20 or 30 beats per minute; at the same time the amount of the rise is possibly less significant than the length of time taken before its return to normal, which should be not more than 1½ minutes at most. All such tests, as well as those relying upon changes in systolic and diastolic blood pressure with movement or exertion, are open to many fallacies. They depend largely on the reserve strength of the heart muscle and do in fact offer a fair indication of this power; but they do not give a reliable answer to the question how much exertion may be harmful to a heart and how much may be beneficial. And this, of course, is often just what the medical man and his patient want to know. Dr. F. W. Law's investigation, to which a reference has already been given, leads him to conclude that no exercise, however strenuous, can permanently harm the healthy trained man, and quotes F. Bainbridge as saying that "there is no direct evidence that, provided a man is physically sound and in good health, exercise, however severe, is ever harmful or followed by serious after-effects." It is, however, exactly in the elimination of those not "physically sound" that the difficulty arises. Daily heavy work, and still less our cardiac efficiency tests, may not always bring to light latent cardiac weakness; as Hoffmann has written "the heart gives no warning of the moment at which exertion becomes harmful." Clive Rivière, for example, noted cardiac dilatation persisting two and a half months after a week's holiday of walking and climbing in 10 out of 40 school-boys he examined (as noted by Law), and there is no doubt that definite dilatation of the heart may follow over-exertion in the unfit, with but little subjective evidence of disorder. On the other hand, the healthy heart becomes slightly smaller immediately after violent exercise, as has been shown radiographically by Moritz, Mobitz and others, and many deny that physiological hypertrophy ever follows excessive athletics. Deutsch[2] found that 90 per cent. of swimming and ski racers had hearts of normal size, and holds the view that "sport-training means heart-training," true fitness implying an absence of enlargement of the heart with exertion. According to this view, hypertrophy of the heart in an athlete suggests over-strenuous exercise of an "unfit" subject, but Law, after his own rowing career, finds definite enlargement of his heart which by all clinical and subjective signs is perfectly healthy, and concludes that physiological enlargement of a healthy heart may result from hard and prolonged exercise. Deutsch says that approximately one-quarter of rowers he examined had enlarged hearts, the proportion being much greater than among men going in for any other sport. Whether the "sports heart" is always a heart which was already unhealthy before athletics were begun is still a matter for discussion, but it will be generally agreed that lasting damage to the heart from over-exertion is exceedingly rare in a previously healthy person; the figures of Morgan, quoted by Law, concerning the after-histories of the 255 survivors of the Oxford and Cambridge boat-race crews from 1829 to 1869 bear out this opinion. The practitioner's task of detecting people in whom harm may result is thus all the more important, and the decision may be one of the most difficult of those he is called on to make. A careful clinical history, a detailed physical examination, a judicious consideration of the results of functional efficiency tests, combined with a study of the urine and if possible of radiological and electrocardiographic records are his guides. First and foremost, however, he must be given the chance of examining his patients properly. The necessity for medical examination—if possible at suitable intervals—of all those who undertake strenuous exercise can hardly be too strongly emphasised.

THE COCKTAIL HABIT.

ALCOHOLISM has for several generations been regarded as a disease of the poorer classes. It is, however, becoming increasingly obvious that the balance is shifting, and some authorities consider that before long the incidence will preponderate among persons of wealth and leisure. The reason for this change lies in the increase of the "cocktail habit." Before the war cocktails were regarded as an American innovation; they have now become a part of the social life of every European country. They are taken primarily as appetisers, but tend to degenerate easily into a pastime. Their attraction is partly due to their endless variety, and their chief danger lies in the powerful effect which they exert by reason of their aromatic constituents. The alcohol in a cocktail, which composes 15 to 30 per cent. of its volume, may be contained in gin, whisky, or brandy, the vermouth, angostura, and liqueurs, which are added as flavourings to the different varieties, contain essential oils with a strongly exciting action on the central nervous system. The reason why the alcohol in a cocktail produces an effect in the central nervous system more than four times as great as that of the same amount of alcohol taken in beer is explained by Prof. W. E. Dixon in the *British Journal of Inebriety* for January. The spirit is absorbed very rapidly from the empty stomach, its absorption being facilitated by the irritant oils. During its passage from the blood into the nerve-cells it produces a great and sudden increase of tension on the outside of the membranes, thus causing a powerful stimulant action which continues until the tension becomes equal in the nerve-cells and the blood. This action, which lasts for about a quarter of an hour, is different from, and much more potent than, the subsequent ordinary effect of the dose of alcohol. According to Prof. Dixon, the persons who take a cocktail to diminish nervous strain and stimulate the appetite are not the true cocktail addicts. The most deleterious effects are produced in young men and women who drink to remove their shyness and to produce excitement. The continuous use of cocktails injures the stomach and lays the foundation for the drinking habit, which is easily acquired by the young. They supply for a moment the new sensations, strong emotions, and varied interests which youth desires, and tend more surely and rapidly, in Prof. Dixon's opinion, to become a habit than do any other kinds of beverage. Prof. Georges Guillain, in a recent lecture before the Academy of Medicine,[1] which we noticed in our issue of May 25th,[2] takes a serious view of the increase of cocktail drinking in France. Cocktail parties, he says, have replaced tea parties in many modern drawing-rooms. The miniature bar has become an article of household furniture, and is part of the equipment of the furnished flat and the motor-car. The cult is not confined to Paris, but pervades country houses, watering-places and even spas. He gives recipes for ten of the commonest cocktails, to show the large quantity of alcohol they contain, and remarks that young persons never used to take whisky or gin before their meals, but that nowadays they drink several of these mixtures every day. He maintains that he is constantly observing most serious symptoms among the young people who indulge in this habit. Their ailments include all kinds of digestive trouble, permanent tachycardia and attacks of syncope, insomnia, neurasthenia, anxiety, and failure to concentrate. Many divorces, motor accidents, and ruined careers are, he holds, due directly to habitual indulgence in cocktails, but it is possible that cause and effect are here rather difficult to disentangle. Prof. Guillain claims to have witnessed a dramatic transfer of the incidence of alcoholic polyneuritis which formerly predominated among the working classes, especially, it seems, those suffering from tuberculosis, to young men and women of the wealthy classes. He draws a picture which has fortunately not yet been equalled in this country, but the evil, even here, is none the less well established and demands the determined opposition of every medical practitioner. The rigid rules laid down by all physicians for cases of suspected or established juxta-pyloric ulcer concern the avoidance of alcohol on an empty stomach, and the universal application of the precept would prevent much chronic dyspepsia and be found in the long run not to detract from the gaiety of social life.

REALITY.

IT is not so long ago that what were called "functional diseases" were treated with a mixture of contempt and brutality by all except a few medical men in advance of their times. It was a period when to be "real" was to be concrete; diseases had to have a tangible morbid anatomy and the deepest probings of the chemists and physicists into the structure of experience found their most complete satisfaction in the production of models made of billiard balls or machinery. Biologists in general, and those involved in medicine in particular, often felt dissatisfied, especially when they were assured (as they frequently were) that the only road of progress was the "real" path carved by the "exact sciences." It is therefore particularly impressive that it should be a physicist in Prof. A. S. Eddington's unrivalled position who comes to tell us that the physical explanation of the world is no more concrete than anything else, and that it is quite incomplete in that it fails to include large parts of our experience. He restated his position recently in the Swarthmore Lecture before the Society of Friends.[3] The modern physicist has given up his old objective of models; he aims instead at a set of symbols and mathematical equations which they will satisfy. And, strangest change of all, he no longer cares what the symbols stand for: he seeks to know how reality behaves, not what it is. In consequence he no longer wants to condemn the spiritual side of our experience as illusory because it is not concrete. "Mind," he says, "is the first and most direct thing in our experience; all else is remote inference."

[2] THE LANCET, May 25th, p. 1113.

[3] Science and the Unseen World. George Allen and Unwin. 1s. 6*d*.

The physicist moreover not only does not dogmatise about the nature of the reality with which his symbols deal, he insists that his professional methods of inquiry cannot penetrate behind the symbols and are quite unsuited to throw light on what they represent. Prof. Eddington—we do not know how far his colleagues are with him here—is not content to leave it at that: he frankly claims that it is by our spiritual nature that we may attain the interpretation of the symbols which science cannot give. No one will suspect the Plumian Professor of advocating loose thinking when he urges upon us the necessity of a mystical outlook. If we limit ourselves and take no cognisance of anything but "scientific facts" as ascertained through our sense organs, we are denying one of the most real items of experience, that consciousness is not wholly or even primarily a device for receiving sense impressions. Science is good enough as far as it goes: the scientist is guided by no false or mean light. But it has nothing to tell us of its own passion for truth, of men's response to beauty, of our inner light of guidance and conviction: they are none the less "real."

THE REOPENING OF THE WELSH NATIONAL MEDICAL SCHOOL.

THE terms on which the wards of the Cardiff Royal Infirmary will be reopened to students in September next, of which the main provisions were announced in THE LANCET last week, have been formally and unanimously ratified at a meeting of the Board of Management of the hospital. The unanimity was the result of a special appeal made by Sir William James Thomas, the benefactor to whose unquenchable optimism the School owes not only its inception but also continuous encouragement in the struggle against direct and indirect opposition. The new agreement provides that the unit system shall continue, but that the non-professorial clinics are to be organised in future under the supervision of a Board of Clinical Studies on which members of the honorary staff are to be fully represented. This Board is, moreover, to have direct access to the Board of Medicine of the College, though before any action is taken the Faculty of Medicine of the University, on which the full-time professors have a predominant vote, will be consulted. In this way the honorary staff of the Royal Infirmary are aasured that attention will be given to their views on matters connected with clinical teaching. A clause providing that assistants in the professorial units shall "normally" be full-time officers will be put into force as soon as funds permit. The only clause which still evoked a protest even at this final meeting, though it had already been modified to the limit of safety, was the provision that the infirmary shall hold all its beds at the disposal of the School for the purpose of clinical teaching. The very fact that objections were offered to this clause suggests that the College authorities were wise in their resolution to refuse to enter into any agreement without such a safeguard. In its absence, the resignation of certain members of the honorary staff of the hospital from their posts as university teachers reduced the number of teaching beds below that required for recognition of the clinical school by the University of London and the Conjoint Board and led to its closure. These licensing bodies will have to be convinced of the impossibility of a recurrence of such a withdrawal before they reconsider their decision, and, moreover, if the students scattered through the country are invited to return to their National School their careers must not again be imperilled. The new agreement has been drawn up expressly with a view to ensuring that the clinical curriculum and the organisation of the teaching are acceptable to the honorary staff of the hospital, and is to continue in force for a period of seven years. Machinery is, however, provided for the revision of the terms in three years, should this be considered desirable by either party. Ample opportunity will thus be found for adjustment of difficulties through legitimate channels, and in view of the disaster of last year, no clause designed to render ineffective a threat of direct action can be fairly stigmatised as either unnecessary or harsh. The early history of some of the most successful medical schools has been a stormy one, and the staff of a hospital which has become part of a teaching school cannot be expected immediately to welcome the changes involved. But now that agreement has been reached we trust that the Welsh National Medical School will be re-established on a firm foundation and will fulfil its early promise.

THE FATE OF PATIENTS WITH PLEURISY.

APPRECIATION of the tuberculous nature of most cases of "idiopathic" pleurisy has focused attention on the treatment to be given after the acute symptoms have ceased. Is it enough to send the patient away for a month's holiday, with vague injunctions about rest and exercise, or should he be kept under close medical supervision and given several months of educational treatment in a sanatorium? There are some interesting statistics wherewith to answer these questions. Among the most important are those of the Swedes, Allard and Köster, whose investigations in the period 1910-11 showed that in approximately half their cases of pleurisy pulmonary tuberculosis became active at a later date. The more recent investigations of the Norwegians, Scheel and Föien, showed that of 812 patients suffering from pleurisy in the period 1916-25, and examined early in 1927, as many as 182, or 22·4 per cent., had subsequently developed pulmonary tuberculosis which in 80 cases proved fatal. In the *Norsk Magazin for Laegevidenskapen* for April, 1929, Dr. L. B. Smith shows how the expectation of tuberculosis in this class of case can be bettered by a strict régime. At the Landeskogen Sanatorium, to which he is attached, his chief, Dr. E. T. Holter, if he cannot find room in his sanatorium for a patient with "idiopathic" pleurisy, gives him definite instructions on what he shall do. He is told to rest on his bed or a sofa for five to six hours every day, and is forbidden to do any work at all for at least three or four months, this prohibition holding so long as the rate of sedimentation of the erythrocytes is abnormal. In the period from May, 1916, to June, 1924, there were treated at the Landeskogen Sanatorium 90 patients whose pleurisy was the only clinical sign of pulmonary tuberculosis. Their subsequent fate was investigated in 1928. Of the 90 cases 66 were associated with a pleural effusion, whereas in the remaining 24 the pleurisy was "dry." The patients' ages ranged from 13 to 41 years, and the average duration of the interval between the onset of the pleurisy and admission to the sanatorium was six months. As many as 62 were under normal weight, and in 74 cases the patient's general health was poor. The average duration of residence in the sanatorium was 121 days. On discharge, 82 were fully fit for work, and 8 were partially so. Only one of these patients could not be traced in 1928. Of the remaining 89, as many as 79 were perfectly well. Three suffered from tuberculosis, and were only partly fit for work, while seven were found to have died of tuberculosis. Looked at only from the statistical angle, these figures are, of course, far too small to carry much weight. But in conjunction with our present-day knowledge of the evolution of pulmonary tuberculosis they do emphatically indicate the profit accruing to a patient from the interpretation by his medical adviser of "idiopathic" pleurisy as a condition requiring rigorous treatment and supervision for a long time.

SMALL-POX RESTRICTIONS IN FRANCE.—The regulations imposed last April on travellers from England obliging them to produce evidence of vaccination or submit to supervision of their movements has now been abandoned by the French Government.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXXIII.—PLEURAL FLUIDS.*

ALTHOUGH it is unwise to place too much reliance on laboratory reports of a pleural effusion, these may be very valuable, not only as additional evidence for diagnosis, but also as an aid to treatment.

Pleural fluids may be considered under the following headings: (1) clear; (2) thick, of which the second class may be further subdivided into (*a*) non-purulent, (*b*) purulent.

CLEAR PLEURAL FLUID.

On inspection the liquid is usually pale yellow in colour and clots on standing. The clot is firmer in cases where the effusion is the result of inflammatory changes—i.e., an exudate—than when it is a transudate, for example, in a case of heart failure. A small quantity of blood may be present, but a large amount makes the liquid thick. The fluid is usually odourless unless contaminated, in which case it will rapidly become purulent.

Cytology.

Blood.—A few red corpuscles may be seen and are not important. To be of any clinical significance the blood must be present in sufficient quantity to be visible on naked-eye inspection.

Polymorphonuclear neutrophil leucocytes are seen in acute inflammatory conditions. Where polymorphonuclear cells are in excess the infection is probably due to a pyogenic organism, and if they are found in a clear effusion it is probable that the fluid will become purulent. These leucocytes are present in normal blood, so that in any effusion containing blood they will be found in the normal proportion to the red corpuscles; this, of course, does not indicate a pyogenic infection.

Small lymphocytes are present in excess in chronic inflammatory diseases, of which tuberculosis is by far the most common. In rare cases of long-standing effusion from other causes, an excess of small lymphocytes may be seen. Syphilis of the pleura is extremely rare, but if present would cause a preponderance of small lymphocytes in the effusion.

Widal and Ravaut in 1900 expressed the opinion that in cases of pleural effusion an excess of small lymphocytes indicates tuberculosis, and an excess of polymorphonuclear neutrophils indicates infection by a pyogenic micro-organism, and this view is generally upheld to-day.

Endothelial cells derived from the lining of the pleura may be present in excess and indicate a transudate. They are seen, therefore, in effusions occurring in cases of renal disease, heart failure, or obstruction of the circulation from neoplasm or other causes. It is often stated that an excess of endothelial cells is diagnostic of neoplasm. This is not so, but it is rarely present in cases of tuberculosis or pyogenic infections; thus, if there is no evidence of renal or cardiac disease in a case with a preponderance of endothelial cells in the pleural fluid, new growth must be suspected by a process of exclusion.

Eosinophil cells are rarely found in excess and are of no great clinical significance. They may be regarded as intermediary between the acute infection characterised by an excess of polymorphonuclear leucocytes, and the chronic stage where small lymphocytes are in excess. It is said that the presence of a large number of eosinophils in a pleural effusion is evidence against tuberculosis, and very few of the recorded cases have turned out to be tuberculous. In the uncommon cases when a clear effusion develops after pneumonia an excess of eosinophils makes it probable that the fluid will not become purulent, and is, therefore, evidence of a good prognosis. If the fluid is not from the pleural cavity but from a hydatid cyst, eosinophils will be present in great excess.

Tumour cells.—Cases have been described where a diagnosis has been made by finding free carcinoma or sarcoma cells in the pleural fluid. I have never come across such a case myself, and although they do occur they are extremely rare. It must be remembered that it is often impossible to tell the exact nature of certain cells in various stages of degeneration. Lymphocytes or endothelial cells might well be confused with sarcoma or carcinoma cells.

Bacteriology.

In a clear effusion the usual organism is the tubercle bacillus; in a purulent effusion the pneumococcus; in a cloudy effusion the streptococcus. Other organisms, such as staphylococci, the influenza bacillus, Friedländer's bacillus, the typhoid bacillus, &c., have been found but very rarely.

In the early stages of a tuberculous pleural effusion tubercle bacilli are not found as a rule, and even injection into a guinea-pig generally gives a negative result. In long-standing tuberculous effusions, and in nearly all cases of tuberculous empyema, however, the bacilli are almost always to be found. Various methods of looking for tubercle bacilli in pleural effusions have been described, but in doubtful cases the most reliable method is injection into a guinea-pig.

Chemical Examination.

This is not of great importance. The fluid is alkaline. Albumin is present in greater quantity in exudates than in transudates, and an exudate may become practically solid on boiling. The specific gravity of a transudate is usually below 1018, and that of an exudate above this.

The following table shows the chief characteristics of the common types of clear pleural fluids.

—	Appearance.	Coagulable proteid.	S.G.	Cytology.
Transudates—		Per cent.		
Renal	V.p.y.	2	1008	Endothelial cells.
Cardiac ..	P.y.	3	1016	
Neoplasm ..	P.y. or hæmorr.	3	1016	
Exudates—				
Tuberculous ..	Straw coloured.	Over 4	1020	Sm. lymph.
Pyogenic infections ..	Yellow and sl. turbid.	Over 4	1024	Polymorph.

V.p.y. = very pale yellow; hæmorr. = hæmorrhagic; sl. = slightly.

THICK EFFUSIONS.

Non-purulent.

Non-purulent effusions vary from the cloudiness seen when there is a slight excess of cells to the dense opacity of true chylous effusions. Blood may be present in any effusion and render it opaque. Hæmorrhagic effusions are said to indicate the presence of new growth, but they are not infrequently seen in cases of tuberculous effusions, and in the majority of cases due to malignant disease the fluid is clear.

In an analysis of 26 cases of carcinoma of lung, Dr. T. C. Hunt[1] found that an effusion formed in 13, and of these it was hæmorrhagic in 5, clear in 6, purulent in 1, and pseudochylous in 1. Bleeding, however, is more common in such cases, so that a large quantity of blood in an effusion may be taken as some evidence of new growth. In most cases the bleeding has taken place into an effusion; a true hæmothorax is usually the result of trauma. Sometimes the fluid appears milky owing to the presence of albuminous bodies or leucocytes. In the early stages of an inflammatory effusion, before it has become purulent, the fluid is often cloudy owing to the polymorphonuclear neutrophils, this is commonly seen in cases of streptococcal effusions.

---

* An article on the Treatment of Empyema, by Dr. Burrell, will appear next week.

[1] THE LANCET, April 13th, 1929, p. 759.

Cholesterol may be present in an effusion of long standing, and gives the fluid a shimmering appearance like gold paint dissolved in spirit.

Chyliform fluids are sometimes seen when the cells are undergoing fatty degeneration. They are not common, but have been found in cases of endothelioma of the pleura or of chronic tuberculosis. The fat globules can be seen microscopically and stained with osmic acid. They can also be dissolved out with ether. True chylous effusions are very rare, but may result from rupture or injury to the thoracic duct, filariasis, pressure on the thoracic duct from tumours, &c., or occlusion of the left subclavian vein.

Purulent Effusions.

As a rule the pus is not offensive, but in some cases it may be extremely so. The offensive odour is due to contamination by a saprophytic organism, and is evidence of a communication either with the lung or the alimentary tract.

Empyema following spontaneous pneumothorax in cases of bronchiectasis or abscess of lung has very offensive pus, and, in any case, when there is a bronchial fistula the pus is apt to become offensive. The three usual types of empyema are those due to the pneumococcus, streptococcus, and tubercle bacillus.

Pneumococcal empyema.—This usually follows pneumonia. The pus is yellow, very thick, contains many flakes of lymph, and is so characteristic that it is possible to tell a pneumococcal empyema by the mere inspection of the pus in the great majority of cases. Pneumococci are present in large numbers, and usually in pure culture.

Streptococcal empyema.—In this case the effusion is usually clear or only slightly turbid in the early stages, but gradually becomes thicker and more purulent as the disease progresses. Streptococci are present in long chains. The condition is usually secondary to a streptococcal pneumonia such as that following influenza.

Tuberculous empyema.—The pus in these cases varies from a rather dirty yellow to a greenish-yellow colour. It may resemble pneumococcal pus, but has not the same thick cream-like appearance. Tubercle bacilli are usually present in large numbers, and the fact that no other organisms are found in the majority of tuberculous empyemata suggests that the pus is the result of the tubercle bacilli alone and not of a super-imposed infection by other organisms. The peculiar greenish tint of tuberculous pus is not seen in cases due to pyogenic organisms, and this also is opposed to the view that purulent effusions are due to mixed infections and not to the unaided action of the tubercle bacilli.

L. S. T. BURRELL, M.D., F.R.C.P.,
Physician, Royal Free Hospital and Hospital for Diseases of the Chest, Brompton.

MANCHESTER'S TUBERCULOSIS DISPENSARY.—A writ has been served on the Town Clerk of Manchester, by which a resident seeks to restrain the Corporation from building a new tuberculosis dispensary and offices on a vacant site in Oxford-road opposite the Royal Infirmary.

HOSPITAL PLANNING.—Mr. H. Percy Adams, F.R.I.B.A., last week read a paper before the Royal Institute of British Architects on "English Hospital Planning." He pointed out that the ideal site for a hospital is on high ground and of large area. Fifty beds to the acre, as had been suggested, would be all very well in the country, but impossible in towns. There should be a gentle slope from north to south or south-east, with good approach roads on the northern side. The buildings should be well sheltered by trees or rising ground, a sub-soil of chalk, rock, or gravel was best, and water, gas, and good drainage should be available. The advantage to patients of hospitals outside urban areas would be enormous; the disadvantage would be the slight inconvenience to the medical staff and friends visiting patients.

MEDICAL CANDIDATES FOR PARLIAMENT.

SUCCESSFUL AND UNSUCCESSFUL.

THE following is a complete list of medical men and women entitled to sit in the new House of Commons. The result of the Scottish Universities poll had not reached us as we went to press:—

Members.	*Constituency.*	*Party*
Rt. Hon. C. Addison ..	Wiltshire (Swindon) ..	Lab.
Dr. Ethel Bentham ..	Islington (East) ..	Lab.
Dr. A. Vernon Davies ..	Lancashire (Royton) ..	C.
Dr. Walter E. Elliot ..	Glasgow (Kelvingrove)	C.
Dr. R. Forgan	Renfrew (West) ..	Lab.
Dr. F. E. Fremantle ..	Hertford (St. Albans) ..	C.
Mr. H. C. Haslam ..	Lincolnshire (Horncastle)	C.
Mr. Somerville Hastings	Reading	Lab.
Dr. J. Hunter	Dumfriesshire	L.
Dr. E. Graham Little ..	London University ..	Ind. C.
Dr. H. B. Morgan ..	Camberwell (North-West)	Lab.
Dr. J. H. Morris-Jones	Denbigh (Denbigh) ..	L.
Dr. Drummond Shiels ..	Edinburgh (East) ..	Lab.
Dr. Alfred Salter	Bermondsey (West) ..	Lab.
Prof. T. Sinclair	Queen's University, Belfast	C.
Dr. G. E. Spero	Fulham (West) ..	Lab.
Dr. J. H. Williams ..	Carmarthen (Llanelly) ..	Lab.

List of Medical Candidates for Parliament.

A list of medical candidates is here given, showing the individual position at the poll, and the number of votes registered. A dagger sign indicates membership of the last House of Commons, while an asterisk indicates that the candidate contested this or some other seat at the last General Election.

MEDICINE AND THE LAW.

Charge of Unauthorised Reception of Lunatics.

PROCEEDINGS taken at the South-Western police-court against two defendants charged with receiving five lunatics into their nursing-home at Clapham Common, not being licensed so to do, ended on May 30th in the dismissal of the summonses. The case had apparently arisen as the result of the operation of the Nursing Homes Registration Act. If an offence was to be established under the Lunacy Act, it was necessary to prove that the patients at the nursing-home were lunatics. Dr. Worth, medical superintendent of the Springfield Mental Hospital, Tooting, expressed the opinion that the five patients were certifiable, though the magistrate took the view that the opinion had not been given without hesitation. A second witness for the prosecution was Dr. Guy Foster Barham, medical superintendent at the London County Mental Hospital, Claybury, Essex; he confirmed Dr. Worth's opinion, but, under cross-examination, stated that with the exception of one patient, in whose case there was a possibility of suicide, he saw no evidence that the patients were dangerous to themselves or others. For the defence the medical attendants of the five patients were called; they denied that the cases were certifiable or that there was any occasion for placing the patients under restraint. One patient, it was stated, was an old lady of 89, suffering from senile decay, who had been sent to the nursing-home to be looked after. Mrs. Gowan, one of the defendants, said the patients were principally elderly people; all were attended by their private doctors. Sir Robert Armstrong-Jones, she said, had visited her establishment for the Master in Lunacy, and had certified none of the patients. A representative of the Director of Public Prosecutions sought to support the charge by contending that two mental experts had declared the patients certifiable, while the three witnesses who took the opposite view were general practitioners not necessarily experts in mental disease. The magistrate, however, preferred the opinion of the witnesses for the defence. Though not mental experts, they were, he said, qualified to express an opinion; they saw the patients frequently, whereas Dr. Worth had seen them only once. And so, with a comment from the magistrate that the legal definition of a lunatic was somewhat nebulous and with an expression of his surprise that the proceedings should have been deemed necessary, the case came to an end. It would appear unlikely that a magistrate would convict the proprietors of a nursing-home upon a charge of this kind under the Lunacy Act if there were any reasonable doubt of the patients being certifiable. It is common knowledge that there are few matters of medical opinion on which witnesses are found to be so far from unanimity.

Plea of Dual Personality.

In two recent cases lately it has been suggested for the defence that the accused was suffering from a dissociated mind, a form of neurosis which in its higher degree is sometimes described as dual personality. As usual, this has caused a reference in court to Stevenson's story of Dr. Jekyll and Mr. Hyde, as though Stevenson was a mental expert and his tale a case of actual observation. In one of the recent cases the magistrate asked the natural question whether the plea was put forward as a defence to the charge or as an appeal for mitigation of sentence. This is a question to which the legal advisers of the accused must always address themselves; the answer depends upon the expert witnesses' evidence. In that particular case the accused was committed for trial to the sessions, the magistrate being disinclined to decide the issue of insanity. In the other case, the plea of dissociated mind was not supported by the opinion of the senior medical officer of Brixton Prison, where there had been opportunity of observing the accused. The accused had pleaded "guilty" to charges of forgery and false pretences; the suggestion of dual personality was therefore not an attempted defence but an appeal for lessened punishment. Sentence was passed by the Recorder at the Central Criminal Court of three years' penal servitude.

Pharmaceutical Society's Prosecution.

The statutory penalty of £5 (with costs) was imposed last week in the Bow County Court upon a Walthamstow chemist for not having on a specified date conspicuously exhibited on his premises his certificate of registration. An inspector of the Pharmaceutical Society gave evidence of having purchased a disinfectant containing poison at the defendant's shop. The defendant was not on the premises and (as was admitted at a subsequent visit) his certificate was not exhibited. Judge Owen Thompson, K.C., in imposing the penalty, remarked that he had often wondered what was the motive—whether pride or otherwise—which impelled the display of the Pharmaceutical Society's Certificate. The observation seems to convict the learned judge of judicial ignorance of the Pharmacy Act, 1868, and the Poisons and Pharmacy Act, 1908. Where Parliament prescribes or recognises the grant of professional qualifications by some supervisory body, it is clearly to the public interest that there should be means of knowing whether a practitioner possesses the qualification or not.

INTER-STATE POST-GRADUATE ASSEMBLY OF NORTH AMERICA.

VISIT TO LONDON, MAY 27TH–29TH, 1929.

(Concluded from p. 1165.)

THE session of this assembly ended in London on May 29th. In the morning Sir W. **Arbuthnot Lane**, who took the chair, spoke on

Intestinal Stasis.

He said that any laborious occupation pursued for a long time resulted in such definite and characteristic changes in the bones and joints of the body that the labour-history of the subject could easily be identified. Six fundamental laws could be enunciated: (1) The skeleton represented the crystallisation of lines of force. (2) Pressure produced changes in the skeleton, altering the form of bones and joints, destroying normal ones and developing new ones, and changing hyaline cartilage into bone. (3) Strain had the same effect as pressure. (4) When it was of advantage to the individual, an old mechanism might be altered and a new one developed. (5) We bore a simple mechanical relationship to our surroundings, and any change in that relationship had associated with it a corresponding change in anatomy. (6) To this there was the solemn corollary that any change which ensued to meet altered relationships to surroundings tended to shorten life. As a result of formulating these laws, the speaker had started operating on simple fractures and on cleft palate in infants, and the application of the laws to the gastro-intestinal tract had revealed certain remarkable changes. Robust primitive races, living almost entirely on the fruits of the soil and dairy produce, had an action of the bowel after each meal, and this normal functioning excluded the incidence of all the familiar diseases of civilisation. The milk of the civilised mother was usually wanting in necessary components, so that material was delayed in the intestine, and evacuations were infrequent and irregular. In any case the child was soon taught only to have one action a day. In consequence a portion of the large bowel, which for thousands of years had been evolved to contain a quantity of the products of digestion proportionate to the intake, now had to deal with 24 hours' accumulation. To prevent enormous elongation and distension the bowel had become fixed by a series of ligamentous bands in the lines of strain. These were developed early in life, and had been described as congenital. Fixation led to obstruction, and obstruction to inflammation and spasmodic muscular action which further increased the obstruction, which was gradually transmitted back to the cæcum, small intestine, and duodenum, so that the duodenal mucosa was overstretched, bled readily, and ulcerated. To obviate this the pylorus contracted spasmodically, and the stomach became dilated and lost its pumping efficiency. The overloading of the stomach caused ulceration. When ulceration and irritation became chronic, carcinoma frequently supervened. Organisms thrived in the material accumulated in the bowel, and toxic products entered the circulation, causing malnutrition and degeneration of all the tissues of the body, disease, and lower resistance to other organisms. Cancer never affected a healthy organ. Sir Arbuthnot Lane then showed a number of slides illustrating the skeletal changes produced by various occupations, and the "first and last kink" as the cause of all the diseases peculiar to civilisation, more properly called "filth diseases," for they never affected people with a normal drainage system. He thought that the present relationship between doctor and patient was all wrong; the physician should watch his patient regularly, and follow him "from the cradle to the grave."

Dr. **Donald Hunter** spoke on the

Clinical Significance of the Suprarenal Cortex.

He quoted Addison's original paper, describing two important discoveries, "Addison's disease" and "Addisonian anæmia," reviewed the history of research on the suprarenals, and described a number of cases showing the functions of the suprarenal cortex. Tuberculous disease had only been found in 20 out of 28 cases of Addison's disease in the London Hospital during the last 20 years. In eight of them the only lesion had been atrophy of the cortex. The organs included under the "chromaffin system" all belonged to the same system, embryologically, chemically, and physiologically. The medulla of the suprarenal was not essential to life, but only to the emergency mechanism of reaction to danger. Cannon had gradually removed the entire sympathetic system from a cat, and when this animal was confronted with a dog no reaction occurred. The cortex, on the other hand, was essential to life. Accessory suprarenals usually consisted of cortex only. Investigators seemed to be on the verge of discovering the hormone of the cortex; this would probably keep patients of Addison's disease alive. Simple adenomata of the cortex were harmless and symptomless; carcinoma was usually a true hypernephroma giving the signs of renal tumour. Dr. Hunter then recounted cases of sexual precocity associated with tumour of the suprarenal cortex; he said that the condition was commoner in girls, the precocity being of a male type. In one case the growth of secondary deposits had been associated with very marked advance of the sexual precocity.

Mr. **Donald Armour** spoke on

Head Injuries.

He reviewed the anatomical relationships governing the spread of infection and hæmorrhage in the scalp. Were there no emissary veins, infections of the scalp would be much less serious. No wound of the scalp was unimportant; hæmostasis, cleansing, and closure with drainage, under anæsthesia, should be promptly undertaken. No cosmetic consideration should prevent the shaving of a wide area. The site of injury should then be thoroughly scrubbed with a nailbrush, soap and water, and every particle of foreign matter removed, the wound being enlarged if necessary. Careful search for bone injury should be made in a good light. The wound should be dressed daily for the first few days and watch kept for signs of deep infection. If large vessels had been cut, a curved needle should be passed under them, and they could then be secured easily. Any fracture discovered at operation should be followed along its entire length, and the wound should be regarded with suspicion for a few days. If a fissured fracture were found, wider implication of the inner table was probable, especially if blood continued to ooze, and if foreign matter were caught in it. Fractures should not be examined by probe, but opened up with chisel and mallet, the chisel being held almost parallel with the skull, and the inner table investigated. If it were comminuted all fragments must be carefully removed, the dura being cautiously separated. If the dura were torn, a mess of bone fragments, blood-clot, and brain tissue would be found at the bottom of the fracture; it was best cleared up by irrigation or with tiny swabs, used with great caution and delicacy. A bleeding cortical vessel was best tied by passing under it a suture carrying a ligature. Sudden hæmorrhage might follow removal of bone fragments. Oozing from diploic veins was easily stopped with bone wax, or by crushing the two layers of bone together at the edge. A ruptured meningeal vessel should be underpinned, like a cortical vessel: bleeding at the cut edge of the dura could be stopped by crushing or by ligature. Most difficult of all to stop was bleeding from a torn sinus; sometimes the tear could be closed by suture, or a piece of muscle might be put over it. When the exact site was not ascertainable a gauze plug might have to be used. When the depressed bone could not be removed without injury to the brain because of high cerebral tension, a subtemporal decompression should be performed first. Sometimes a trephine opening would provide access to a depressed piece of bone.

The danger of fracture in a head injury was often exaggerated at the expense of the functional damage done to deeper structures. Thus the importance of "minor" head injuries was under-estimated. Increase in intracranial pressure was the first result, due to œdema or hæmorrhage or both, and might be increased later by blockage, which set up a vicious circle by displacing the midbrain. The pressure was exerted on the blood-vessels and caused focal or general neurological symptoms. "Concussion" was a term with varied interpretations. It was more than a temporary functional disturbance. Post-concussion neurosis was a result of the change, usually a rise in tension. Under violence there was a change of shape, a flattening, which drove out cerebro-spinal fluid. Any fluid that could not get out must pass into the perivascular spaces and this, acting on the ganglionic cells, had been held to account for the phenomena of concussion. French workers had evolved a "formula of concussion" (of cerebro-spinal tension) which they applied even in the absence of any history of injury. The determination of pressure of the fluid was, therefore, of great importance in acute or chronic head injury, and must be made with a manometer. The absence of blood in the fluid did not exclude intracranial hæmorrhage, and had no significance in treatment. Papillœdema or papillary stasis might be produced by increased tension, and ophthalmoscopic observation of dilatation of the retinal arteries and venous stasis was of great value. After six hours of increased tension blurring of the disc appeared, and was more marked in tentorial injuries. The therapeutic value of lumbar puncture was insufficiently appreciated; it often allowed decompression to be postponed until conditions were suitable or obviated it altogether. The pressure and not the quantity withdrawn was the determining factor. Repeated puncture mitigated the distressing symptoms of restlessness, headache, vertigo, and irritability in less serious cases. Intravenous hypertonic solutions were useful for lowering intracranial tension—e.g., 50 c.cm. of 30 per cent. sodium chloride or 100 per cent. dextrose. Half an ounce of saturated magnesium sulphate by the mouth, hourly, or 30 per cent. sodium chloride per rectum might be used. In the intermediate group, between mild and severe injuries, only careful observation could decide whether decompression was advisable or not. No operation whatever should be performed while the patient was in a state of shock, nor should the surgeon intervene in the very severe cases of medullary collapse which could not recover anyhow. The ideal period was the stage of capillary anæmia, shown by slow pulse and slight rise in arterial blood pressure, before increasing headache and delirium indicated venous stasis. The operation was a right subtemporal decompression.

Corrigendum.—Dr. H. C. Semon writes that he did not intend to suggest (THE LANCET, June 1st, p. 1161) that in treatment with ultra-violet light "the patient was the best judge of overdosage." His actual words were: "The effects of overdosage are so immediate that the patient himself is the best security against them, and there are no real dangers, *qua* skin such as apply in X ray therapy."

DONCASTER ROYAL INFIRMARY.—The Doncaster Collieries Association has given a second instalment of £10,000 promised towards the cost of the new Doncaster Royal Infirmary.

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, 1929.

PENAL CASES.

TUESDAY, MAY 28TH.

ACCORDING to custom the Council heard the cases in public but deliberated upon them in camera, and the President announced the decisions.

Reported by the Dental Board.

The Case of Harry Patrick Jones, registered as of 4, Aberford-road, Woodlesford, Yorks, "Dentist, 1921," who had been summoned to appear before the Council as the result of the finding of the Dental Board that his name ought to be erased from the Dentists Register in consequence of his having canvassed for the purpose of procuring patients and of his having employed a canvasser for a similar purpose. The complainants were the Public Dental Service Association. This case had been adjourned from May 28th, 1928, when the respondent had appeared before the Council and judgment had been postponed for twelve months.

The Dental Board reported that Mr. Jones had not attended the inquiry on May 8th of this year, but had sent a letter from Wakefield Prison asking for an adjournment. He had been convicted at the Leeds Assizes commencing on March 4th, 1929, of the following misdemeanour and felony, viz: (1) Of fraudulently converting on Dec. 8th, 1928, at Leeds, a banker's cheque for the sum of £100 entrusted to him for the purchase of shares by Sarah Helen Williamson, and (2) of bigamously marrying Dulcie Mona Morgan on Dec. 22nd, 1928, at Manchester, and had been sentenced to six months' imprisonment in the second division upon each indictment, the sentences to run concurrently.

The Board, therefore, recommended that the respondent's name be erased from the Dental Register. The Council decided that it should be so erased on each of the two counts, for canvassing and for conviction of a felony.

Adjourned from May, 1928.

The Case of Reginald Francis Edmund Austin, registered as of 41, Wimpole-street, W.1, M.R.C.S.Eng. 1891, L.R.C.P.Lond. 1891, who had appeared before the Council on the following charge:—

> "That, being a registered medical practitioner, you have sought to attract to yourself patients and to promote your own professional advantage by means of an article upon appendicitis written by you and published in the number for December, 1927, of the magazine *Health and Efficiency*, in which you extolled your own methods and depreciated those of other practitioners; and that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

The complainants were the Medical Defence Union.

After considering a number of testimonials furnished by Dr. Austin, and hearing his own assurances for the future, the Council decided not to erase his name from the Register.

Charges Concerning Advertisement.

The Case of Elizabeth Caroline Mudie, registered as of 3, Windsor-quadrant, Kelvinside, Glasgow, W., L.R.C.P. Edin. 1925, L.R.C.S. Edin. 1925, L.R.F.P.S. Glasg. 1925, who had been summoned to appear before the Council on the following charge:—

> "That, being a registered medical practitioner; (1) you have associated yourself with and/or been employed by a Company, namely, Ultra-Violet Rays (Glasgow), Limited (of which you are also part proprietor), which advertises for the purpose of obtaining patients: (*a*) By means of an advertisement in the *Glasgow Herald* of Jan. 21st, 1929; and (*b*) by means of a printed pamphlet entitled Ancient Sun Worship, indicating and recommending the methods of treatment employed by the said Company; (2) you have acquiesced in the publication of such advertisements for the purpose of obtaining patients to your own professional advantage. And that in relation to the facts so alleged you have been guilty of infamous or disgraceful conduct in a professional respect."

The complainants were the Medical Defence Union.

Dr. Mudie appeared, and was represented by Mr. T. Carthew, counsel.

Mr. Oswald Hempson, in opening the case for the complainants, said that Dr. Mudie had associated herself for her own ends with a company in which she was a large shareholder. The attention of the Medical Defence Union had been called to an advertisement in the *Glasgow Herald*, announcing that the Directors of "Ultra-Violet Rays (Glasgow), Limited," had acquired certain premises which had been fitted up for intensive treatment of disease by ultra-violet ray therapy, and that the whole-time services of an experienced physician had been secured. The Union had ascertained that Dr. Mudie was the physician referred to; that the company had been registered in January of this year and that Dr. Mudie held 350 out of a total of 701 shares. One of the objects of the company, as stated in its memorandum, was "to adopt such means of making known the business of the company as may seem expedient, and in particular by advertising in the press or by circulars." Miss Jessie Watson Gordon, who had consulted the respondent under instructions from the Union's Glasgow agents, had deposed that respondent had said "When I started this company I had to get a name for it, and as it was really ultra-violet rays I could not get a better name." This intimated that Dr. Mudie had been the originator of the company. She could not have been ignorant of the objects for which it was formed, as set out in the memorandum and articles of association, nor of the advertisement in the *Glasgow Herald*. The address of the institute given in the pamphlet on Ancient Sun Worship was that of Dr. Mudie's consulting room, outside which her name appeared. The pamphlet itself was of the type which was got up solely for the attraction of the layman; it suggested an ancient origin for the treatment and covered it with an air of mystery, and gave a list of diseases which the treatment was alleged to cure.

Miss Jessie Gordon testified to her statutory declaration. She was a typist in the employ of the Glasgow agents of the Medical Defence Union, and had written and sent by their instructions a letter saying that she was suffering from debility, that she would like to receive particulars, and that she was prepared to call at the home. An appointment was fixed by a letter written by Dr. Mudie in the third person, and subsequently by telephone with her. When witness went to the address given, she found a brass plate with Dr. Mudie's name and nothing else. A nurse had received her, and had said that Dr. Mudie had telephoned instructions to give witness a sun-bath. Dr. Mudie had then arrived and interviewed the witness, saying she was very much in need of the treatment and that it would make a new girl of her and would do instead of a holiday. She had asked how witness had heard of the company; witness had said she had heard of it from a friend who had had ultra-violet treatment, and gave her the name of a "Miss Gavin." Dr. Mudie had replied that she had had a patient of that name some time ago. Dr. Mudie had then explained the name of the company. She had offered to give witness a letter to her insurance society, saying that if they would not pay she could change her society.

Cross-examined, witness said she had made notes of the conversation on her way home and had drafted the statutory declaration that night. The symptoms she had related to Dr. Mudie were in fact correct, as she had recently had an operation for the removal of tonsils. She maintained that her declaration was a perfectly accurate report.

Dr. Mudie, called on her own behalf, stated that she had been interested in ultra-violet ray therapy since 1912, but had had to work for several years in order to pay for her medical studies. She had qualified in 1925, and had studied the effects of light treatment on the patients she had sent to the hospitals which gave it, but had not been able to afford the apparatus. She had acquired a good nucleus in her first year of practice, but had been badly handicapped by the strike. She had been very desirous of undertaking research in actinotherapy, and had begun to specialise in it. She had met a Mr. Woodside, who had also been interested and had possessed capital, and her solicitor had advised them to form a company. She herself had no business experience, but had consulted the secretary of the Local Panel Committee; he had told her that there could be no objection provided that she was not a director. The company had been incorporated in January of this year. Mr. Woodside was managing director and secretary, and a Mrs. Walker was the other director pro forma, holding only a single share. The company was to acquire apparatus to the value of £350, provided by Mr. Woodside and credited to witness in one-pound shares. She was to receive £500 per annum, and board and lodging, and Mr. Woodside £350 per annum, but they had not drawn any of this. She had never seen the memorandum and articles of association, but had left the arrangements entirely in the hands of her solicitor. She had always had the plate on the door, and had not thought to alter it. A clinic had been started at another address. Mr. Woodside had drawn up and inserted the advertisement in the *Herald* without consulting her. The data for the pamphlet on "Ancient Sun Worship" had been some notes of a lecture she had delivered to a local society. She had not thought there was anything wrong in having it printed and in her consulting-room. Miss Gordon's letter had come to her private address by mistake. She denied having telephoned instructions to give Miss Gordon a sun-bath. The remark about the name of the company attributed to her was an absolute fiction. She had never had a patient named Miss Gavin. No patient, apart from Miss Gordon, had come as a result of the advertisement in the *Glasgow Herald*.

Cross-examined, witness said that she had asked how Miss Gordon had come for treatment, not how she had heard of the company. She did not open letters addressed to the company at the registered office, but Miss Gordon's letter had come to her by accident. She had not noticed that it was addressed to the company. She maintained that she had an accurate recollection of the conversation with Miss Gordon. She denied having discussed the name of the company with Miss Gordon. She had seen the circular in draft and approved of it; it was to be used for the people who had been to the clinic. She did not think there was anything unprofessional about it. She now admitted that her conduct in giving the directors a free hand had been unwise. She had never seen the advertisement until the morning when the warning notice arrived. The matter of profits had never entered her head. Although the articles of association provided for treatment by Mr. Woodside of male patients, and did not stipulate for her personal supervision, she actually supervised all treatments.

In answer to the Legal Assessor, witness said that the object of the company was to relieve her of the business side of the work and enable her to do research in the intervals of practice, but admitted that the expenses had to be derived from the work. She maintained that patients were to have been obtained through the ordinary ethical channels. She had never inquired whether any of the circulars had been posted or left, or whether advertisements had been inserted in the Press. She had never looked at the register of patients, but knew it was used for making accounts with patients and giving receipts. On examining the register she declared that she could account for all the patients shown in it. Mr. Woodside's capital was to have gone to found the new clinic. She had been prepared to wait for her salary until matters improved, and Mr. Woodside had so far not received any of his salary. She had expected to obtain sufficient patients to cover all the outgoings.

In answer to the President, witness admitted that a passage in the circular relating to unqualified practitioners did not come from the notes of her lecture. She again pleaded ignorance of the article in the memorandum relating to treatment by Mr. Woodside. It was true that the circular might attract patients to go to the witness's house where they would meet witness and nobody else, and that she would then take charge of them. She had taken the Council's letter to Mr. Woodside and he had shown her the proof of the advertisement. She had then expressed her regret that it had been inserted. She had not originated the company, but had acted on the advice of the secretary to the local panel committee, a solicitor. She had not, however, shown him the articles of association. He had said that she could act as medical advisor if she kept off the directorate. She had had nothing to do with the allotment of shares, but had followed the dispositions of her legal adviser. She had thought of nothing but of going on with her work.

Mr. John D. Woodside testified that he had acted as doctor's assistant in two hospitals. He had been anxious to go into practice. He had been introduced to Dr. Mudie, who had told him of her desire to carry out research in ultra-violet therapy and that she needed extra plant. The company was formed with this object. He had carried on the business side of the company, and Dr. Mudie had had nothing to do with this department. He sent out accounts to patients. Some patients, who required only one or two treatments, paid cash, and their names did not appear in the receipt-book. The money he had brought into the company had been devoted to buying apparatus and developing the clinic. The articles of association, when drawn up, had been sent to him and Dr. Mudie had not seen them. The order for the insertion of the advertisement had been given by witness, and Dr. Mudie, as far as he knew, had not been aware of it. He had not told her, as she had nothing to do with the administration side of the business. In answer to the President, witness said that he had known that doctors were liable to limitations, but had not been acquainted with the full regulations. Dr. Mudie had been only the medical advisor, although he admitted that all the profits were derived from her. He had himself prepared the circular, from some notes and a list of treatments supplied by Dr. Mudie.

Cross-examined, Mr. Woodside said that the advertisement had not necessarily been inserted for the purpose of attracting patients, but to announce the formation of the company; he admitted, nevertheless, that he expected some return from it. He had circularised, on his own account, persons who had been patients and who might become patients. Asked whether he had not realised that, from the professional standpoint, he had been doing a very heinous thing *in sending out these advertisements*, he replied "Yes, and no." He did not suggest that he had any doubts about which he could take advice; he knew that the course was professionally heinous, but had not realised that there was any danger. In answer to the President, he admitted having decided to take the risk without consulting Dr. Mudie. She had given him the list of indications for treatment—mentioned in the circular—at his request; he could not remember whether he had told her that he had required it for this purpose. He admitted to the President that he had prepared the circular with the object of increasing the business of the company.

Examined by the Legal Assessor, he declared that no patients had come in response to the advertisements or circular. He admitted, in answer to a question put from the chair, that the company consisted in practice entirely of himself and Dr. Mudie.

Addressing the Council on behalf of the respondent, Mr. Carthew pointed out that, while technically Dr. Mudie's ignorance of Mr. Woodside's proceedings might not exonerate her, it must necessarily carry much weight. She had taken the precaution of consulting the secretary of the local panel committee and her own solicitor; possibly inadequate precautions, but they had seemed adequate to her. Few women took any interest in articles of association, and when she said she had accepted her solicitor's word that they were suitable she was telling the truth. The advertisements had been issued without her knowledge, and her fault if any had lain in lack of precaution. Her attitude throughout had been "Let me get on with my work, and you look after the business side." This attitude was reflected in the articles of agreement, and in the circular itself. That Dr. Mudie's name still appeared outside the premises where patients of the company were directed to come was a mere oversight. Any fault was a fault of carelessness, and not of deliberate wrongdoing.

Mr. Hempson remarked that there was a degree of blindness and acquiescence which was culpable. Dr. Mudie had known of the warning notices and of the feeling of the profession about advertising. She knew that commercial methods generally included advertising, but had instituted no safeguards of any kind. The fact that no patients had resulted from the advertising was not material to the charge.

The Council found that the facts alleged against the respondent had been proved to their satisfaction, but suspended judgment until their next summer session subject to the usual provisos.

WEDNESDAY, MAY 29TH.

The Case of Haydn Brown, registered as of 53, Bedford-square, London, W.C.1, L.R.C.P. Edin. 1892, L.R.C.S.Edin. 1892, who had been summoned to appear before the Council on the following charge:—

> "That, being a registered medical practitioner, you have associated with and/or acquiesced in the publication of announcements in the *Daily Record and Mail* of Glasgow of Jan. 11th, 16th, and 21st, 1929, for the purpose of obtaining patients with a view to promoting your own professional advantage. And that in relation to the facts so alleged you have been guilty of infamous or disgraceful conduct in a professional respect."

The complainants were the Medical Defence Union.

The respondent was represented by Mr. W. Frampton, counsel. Mr. Hempson said that Dr. Brown was not a young man and had had several years' experience of medicine, for he had qualified in 1892. He could not therefore plead ignorance. The case was a peculiarly flagrant one. The attention of the Union had been called to three articles in the *Daily Record* of Glasgow. This journal had been conducting a campaign to interest its readers in the cure of asthma. It had given an account of a dinner held at the Mansion House to inaugurate the Asthma Research Committee, and had published a letter from the four eminent physicians who were sponsoring the committee to the public. Meanwhile, the article ran, a certain cure for asthma had been discovered by a London doctor, who had offered to treat Scottish sufferers free.

The article gave an account of his method, which was known as Autonomous Relaxation. The editor of the *Daily Record* had forwarded to Dr. Brown large numbers of letters from persons in Scotland suffering from asthma. He had treated some of these, and the newspaper had then published enthusiastic accounts from them of the success of the treatment. Dr. Brown had subscribed to a press-cutting agency, and therefore must have known the type of articles which were appearing. A further article contrasted the opinion of the four specialists with the cures that were claimed for the respondent's method. In a subsequent issue, a long article appeared written or authorised by Dr. Brown giving an account of his method and his treatment of the patients with whom the *Daily Record* had put him in touch. The fact that his actual name never appeared did not make his conduct less reprehensible.

Mr. Hempson had instructed his clerk to communicate with Dr. Brown as a patient. A reply was received from the newspaper syndicate in acknowledgement, and subsequently two letters were received from Dr. Brown, making an appointment and informing the applicant that the fee was three guineas. The clerk had attended Dr. Brown's consulting-room, and had received a short treatment, which had not benefited him. The clerk had then written another

Dr. Mudie appeared, and was represented by Mr. T. Carthew, counsel.

Mr. Oswald Hempson, in opening the case for the complainants, said that Dr. Mudie had associated herself for her own ends with a company in which she was a large shareholder. The attention of the Medical Defence Union had been called to an advertisement in the *Glasgow Herald*, announcing that the Directors of "Ultra-Violet Rays (Glasgow), Limited," had acquired certain premises which had been fitted up for intensive treatment of disease by ultra-violet ray therapy, and that the whole-time services of an experienced physician had been secured. The Union had ascertained that Dr. Mudie was the physician referred to; that the company had been registered in January of this year and that Dr. Mudie held 350 out of a total of 701 shares. One of the objects of the company, as stated in its memorandum, was "to adopt such means of making known the business of the company as may seem expedient, and in particular by advertising in the press or by circulars." Miss Jessie Watson Gordon, who had consulted the respondent under instructions from the Union's Glasgow agents, had deposed that respondent had said "When I started this company I had to get a name for it, and as it was really ultra-violet rays I could not get a better name." This intimated that Dr. Mudie had been the originator of the company. She could not have been ignorant of the objects for which it was formed, as set out in the memorandum and articles of association, nor of the advertisement in the *Glasgow Herald*. The address of the institute given in the pamphlet on Ancient Sun Worship was that of Dr. Mudie's consulting room, outside which her name appeared. The pamphlet itself was of the type which was got up solely for the attraction of the layman; it suggested an ancient origin for the treatment and covered it with an air of mystery, and gave a list of diseases which the treatment was alleged to cure.

Miss Jessie Gordon testified to her statutory declaration. She was a typist in the employ of the Glasgow agents of the Medical Defence Union, and had written and sent by their instructions a letter saying that she was suffering from debility, that she would like to receive particulars, and that she was prepared to call at the home. An appointment was fixed by a letter written by Dr. Mudie in the third person, and subsequently by telephone with her. When witness went to the address given, she found a brass plate with Dr. Mudie's name and nothing else. A nurse had received her, and had said that Dr. Mudie had telephoned instructions to give witness a sun-bath. Dr. Mudie had then arrived and interviewed the witness, saying she was very much in need of the treatment and that it would make a new girl of her and would do instead of a holiday. She had asked how witness had heard of the company; witness had said she had heard of it from a friend who had had ultra-violet treatment, and gave her the name of a "Miss Gavin." Dr. Mudie had replied that she had had a patient of that name some time ago. Dr. Mudie had then explained the name of the company. She had offered to give witness a letter to her insurance society, saying that if they would not pay she could change her society.

Cross-examined, witness said she had made notes of the conversation on her way home and had drafted the statutory declaration that night. The symptoms she had related to Dr. Mudie were in fact correct, as she had recently had an operation for the removal of tonsils. She maintained that her declaration was a perfectly accurate report.

Dr. Mudie, called on her own behalf, stated that she had been interested in ultra-violet ray therapy since 1912, but had had to work for several years in order to pay for her medical studies. She had qualified in 1925, and had studied the effects of light treatment on the patients she had sent to the hospitals which gave it, but had not been able to afford the apparatus. She had acquired a good nucleus in her first year of practice, but had been badly handicapped by the strike. She had been very desirous of undertaking research in actinotherapy, and had begun to specialise in it. She had met a Mr. Woodside, who had also been interested and had possessed capital, and her solicitor had advised them to form a company. She herself had no business experience, but had consulted the secretary of the Local Panel Committee; he had told her that there could be no objection provided that she was not a director. The company had been incorporated in January of this year. Mr. Woodside was managing director and secretary, and a Mrs. Walker was the other director pro forma, holding only a single share. The company was to acquire apparatus to the value of £350, provided by Mr. Woodside and credited to witness in one-pound shares. She was to receive £500 per annum, and board and lodging, and Mr. Woodside £350 per annum, but they had not drawn any of this. She had never seen the memorandum and articles of association, but had left the arrangements entirely in the hands of her solicitor. She had always had the plate on the door, and had not thought to alter it. A clinic had been started at another address. Mr. Woodside had drawn up and inserted the advertisement in the *Herald* without consulting her. The data for the pamphlet on "Ancient Sun Worship" had been some notes of a lecture she had delivered to a local society. She had not thought there was anything wrong in having it printed and in her consulting-room. Miss Gordon's letter had come to her private address by mistake. She denied having telephoned instructions to give Miss Gordon a sun-bath. The remark about the name of the company attributed to her was an absolute fiction. She had never had a patient named Miss Gavin. No patient, apart from Miss Gordon, had come as a result of the advertisement in the *Glasgow Herald*.

Cross-examined, witness said that she had asked how Miss Gordon had come for treatment, not how she had heard of the company. She did not open letters addressed to the company at the registered office, but Miss Gordon's letter had come to her by accident. She had not noticed that it was addressed to the company. She maintained that she had an accurate recollection of the conversation with Miss Gordon. She denied having discussed the name of the company with Miss Gordon. She had seen the circular in draft and approved of it; it was to be used for the people who had been to the clinic. She did not think there was anything unprofessional about it. She now admitted that her conduct in giving the directors a free hand had been unwise. She had never seen the advertisement until the morning when the warning notice arrived. The matter of profits had never entered her head. Although the articles of association provided for treatment by Mr. Woodside of male patients, and did not stipulate for her personal supervision, she actually supervised all treatments.

In answer to the Legal Assessor, witness said that the object of the company was to relieve her of the business side of the work and enable her to do research in the intervals of practice, but admitted that the expenses had to be derived from the work. She maintained that patients were to have been obtained through the ordinary ethical channels. She had never inquired whether any of the circulars had been posted or left, or whether advertisements had been inserted in the Press. She had never looked at the register of patients, but knew it was used for making accounts with patients and giving receipts. On examining the register she declared that she could account for all the patients shown in it. Mr. Woodside's capital was to have gone to found the new clinic. She had been prepared to wait for her salary until matters improved, and Mr. Woodside had so far not received any of his salary. She had expected to obtain sufficient patients to cover all the outgoings.

In answer to the President, witness admitted that a passage in the circular relating to unqualified practitioners did not come from the notes of her lecture. She again pleaded ignorance of the article card submitted to him before it was issued and had approved it, as he had seen the brochures issued by other firms and saw nothing objectionable in it. He had nothing to do with the card index, though he had seen it since this inquiry had begun. No distinction had been made between different classes of inquirers and patients. 60 to 70 per cent. had been introduced by their ordinary medical advisers; 217 doctors were associated in various ways with the Institute. Most of the remainder came into touch through personal recommendation. All patients were treated under the witness's own supervision. One of his objects in joining the Institute had been to spread knowledge of the treatment inside the profession. There was a society with a journal. There was a separate company for supplying drugs and apparatus with which witness had nothing whatever to do; it had been housed elsewhere at his insistent request. In answer to the President, he admitted that the two concerns had some common members. If the Council considered after inquiry that he ought to sever his connexion with the Institute, he would do so at once. He had, in fact, already tendered his resignation, but it had not been accepted, since the chief director had not yet returned from abroad.

In reply to cross-examination, the witness maintained that he saw nothing wrong in sending out the cards, in so far as they had been sent to patients and inquirers. He would not have sanctioned the issue of cards to such ancient inquirers as Mr. Coulson. The sending of Mr. Coulson's card had, he admitted, been improper. It had not occurred to him to admit this in his reply to the Council's warning notice. It had been on this account that he had tendered his resignation. He could not explain the presence of several cards in the index with no entries on them but addresses and numbers. When an inquiry came in, a card was made out with the name and address and filed away; any answers were recorded on the appropriate card. He did not, however, keep this index. No stereotyped letters were ever sent out. Asked why, if the cards had been intended for patients and inquirers, the points of the change of staff and reduction of fees had not been stressed, and why it should be necessary to include details such as the date of foundation, he replied that he had not gone into these questions when the cards had been produced. The only question raised had been whether it was right to send them out, and he had glanced through the draft and said "Yes." He had always understood that it was in order to notify private patients of change of address or the acquisition of a practice, but not to give the fees or describe the treatment. He did not regard an inquirer as a patient, or entitled to notification of change of practice. Many physicians in charge of reputable institutes sent new particulars to former inquirers; he was not in a position to say whether or not this was proper. He agreed that it had been improper to send the card to Mr. Coulson, but could draw no time limit after which an inquirer became "ancient." He had not realised the risk of cards going out broadcast; this would have been grossly unprofessional. He was not a business man, and it had never come to his notice that the Institute's articles allowed it large powers of advertising. The Institute made no profits and probably never would; it had been started from philanthropic motives. The object of such publicity as there had been was to establish the venture inside the profession and if possible to make it self-supporting. Publicity to the Institute could, of course, hardly help benefiting the company providing apparatus.

He had thought Miss Ash's inquiry a perfectly genuine one and had not remarked that she had not given the name of anyone as recommending the Institute to her. It was not always done. It had never occurred to him that she had received the notification from an improper source; it might well have reached her from a doctor. The safeguards against advertising had been the verbal undertakings of the other directors when he had joined the Institute. He had not inquired into what had happened before he had joined. He had, however, not had his stipulation recorded in the minutes. Apparently the precautions he had taken had not been sufficient in the case of Mr. Coulson, but the error might have been avoided with a little vigilance. In answer to the President, he said that the company had lost something under £2000 in the last completed year. Mr. Hamilton had neither made any profits nor done anything but put money in. Major Collison only countersigned cheques. To the Legal Assessor, he admitted never having taken pains to ascertain the objects of the company of which he was a director, or whether it was registered. Questioned on items of £1600 and £199 for development expenses in the balance-sheet, he said they must have been expended on legitimate advertising, but did not know what form that took.

The Legal Assessor read an extract from the memorandum of the company mentioning as one of its objects—

> "To adopt such means of making known the products of the company as may seem expedient, and in particular by advertising in the press, by circulars, by purchase and exhibition of works of art or interest, by publication of books and periodicals, and by giving prizes, awards and donations."

The witness observed that if he had known of this he would never have sanctioned it. He had refrained from inquiry because of his complete confidence in his fellow directors. The concern had been incorporated as a limited company to limit Mr. Hamilton's liability.

Major W. E. Collison testified that no advertising had been done in other than medical journals. The treatment had been invented in Germany, and the physician in charge had been a German. The index cards, of which Mr. Coulson's had been one, had been taken over when the present company had been formed. They had never been used before the reorganisation, and there had been no follow-up system. When the fees had been reduced, Dr. Corbet had instructed the clerk to send out notices to inquirers.

Cross-examined, he was uncertain whether respondent or himself had given those instructions. One to two thousand cards had been issued. A certain amount of advertising and circularising had been done in the days of the German physician.

The Council found the charges proved to their satisfaction, but postponed judgment for a year, subject to the usual provisos.

THURSDAY, MAY 30TH.

Alleged Canvassing for Patients.

The Case of Jacob Lenten, registered as of 124, Station-road, Hadfield, Manchester, L., L.M. 1926, R.C.P.Irel., L., L.M. 1926, R.C.S. Irel., who appeared before the Council on the following charge:—

> "That, being a registered medical practitioner, you have canvassed for the purpose of procuring patients for yourself, and in particular (1) in or about December, 1928, canvassed one, James Henry Taylor, and (2) in or about December, 1928, canvassed one, John Robinson, panel patients of the late Andrew Paterson Walker for whom you had acted as locum tenens. And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect."

The complainants were Mrs. Walker and Mr. J. W. Struthers, M.B. They were represented by Mr. H. E. Kingdon, counsel, and the respondent was accompanied by Mr. J. Lustgarten, counsel.

In opening the case, Mr. Kingdon related that on Nov. 7th, 1928, the respondent had acted as locum tenens to Dr. Andrew Walker. Dr. Walker had died on Nov. 23rd, and the respondent had continued to act at the request of Mrs. Walker. The practice had not been sold to him, but to Dr. Struthers, and the solicitors of the late Dr. Walker had written to respondent asking him to introduce the new-comer to the patients. Not only had Dr. Lenten refused to do this, but he had left behind him no list of patients on the day-book, and had marked no appointments for dates after Dec. 15th, with one exception. The respondent's statutory declaration contained a significant observation: "I believed that Mrs. Walker and her solicitors really intended to sell the practice to me, and consequently I had no letter to the Editor of the *Daily Record*, and had received a reply, obviously in a stock form, beginning, "Dear Sir, or Madam—," saying that the letter had been forwarded to the London doctor, who was desirous of getting a Glasgow doctor to deal with sufferers in Scotland, and that the applicant would hear from this second doctor in due course. The fact that the clerk did not purport to be resident in Scotland showed that the letter was a stock one. Statutory declarations by Dr. James Neal and Mr. F. D. Whitwell, the clerk, were put in.

Mr. Frampton, on behalf of the respondent, said that his client had committed the offence charged. There could be no doubt that he had been associated with or had acquiesced in the publication of two of the articles. The third had been merely a report of the proceedings at the Mansion House, and Dr. Brown could have had nothing to do with it. Nevertheless he, counsel, could not agree with the views of Mr. Hempson. Dr. Brown had devoted a good deal of his time to research work, and believed, rightly or wrongly, that his method was a cure for many maladies. Mr. Frampton asked whether a medical man was not entitled to announce a cure, so long as he did not announce his name with it. The Asthma Research Council had submitted ten cases to him in August of last year, and he had reported in November. The newspaper had published a letter from a patient, recording the result of treatment by "a London doctor," and had asked if there were really a cure for asthma. The newspaper had got into touch with Dr. Brown through a press-cutting agency. He had written enjoining secrecy, and at the request of the editor had treated the inquirer for a fortnight. As a result of the publication of this case 120 persons had written to the editor asking to be put in touch with Dr. Brown. Of these he had treated 23 free of charge. Dr. Brown had perhaps been mistaken in his view that if he withheld his name there could be nothing to identify him with these articles. He had been making arrangements to transfer all the Scottish patients to local practitioners, and had offered to demonstrate his method to any member of the profession. The clerk who had visited him had said that he was prepared to pay, and so a fee had been named.

Mr. Frampton referred to the blunder which had led to the erasure of Dr. Brown's name in 1924 for publishing a signed article in *John Bull*, and gave an undertaking on his behalf to refrain in future from communicating with the lay press.

The Council found the charges proved to their satisfaction, and directed that the name of Dr. Haydn Brown be erased from the Register.

The Case of William Mulhall Corbet, registered as William Corbet, of 66, Finsbury Pavement, London, E.C. 2, M.B., B.Ch. 1915, N.U. Irel., who appeared before the Council on the following charge:—

> "That, being a registered medical practitioner; (1) you have associated yourself with and/or been employed by The British Institute of Inhalation Therapy, an institution which advertises for the purpose of obtaining patients by means of a printed card describing you as the 'Physician in Charge' and giving the method of treatment and the fees and the hours of treatment; (2) you have acquiesced in such advertising for the purpose of obtaining patients to your own professional advantage. And that in relation to the facts so alleged you have been guilty of infamous or disgraceful conduct in a professional respect."

The complainants were the Medical Defence Union.

Dr. Corbet appeared in answer to his notice, accompanied by Mr. B. M. Cloutman, counsel.

In opening the case, Mr. Hempson said that the respondent was physician in charge of the Institute. On Dec. 19th, 1928, Mr. S. Coulson, a clerk in the employment of the British Medical Association, had received a printed card headed "British Institute of Inhalation Therapy; Physician in Charge, Dr. William Mulhall Corbet." The work of the Institute and the treatment were described, and a scale of fees set out. A covering letter stated that Mr. Coulson had made inquiries about the Institute in 1924. The wording of the card showed that it was not merely sent out to persons who were patients of the Institute and who had made inquiries, or there would be no need for the detailed information it contained. It was not within the bounds of professional propriety to "follow up" inquiries in this way. Mr. Hempson had instructed his clerk, Miss E. I. Ash, to write a letter drafted by himself to Dr. Corbet; in it she had represented that she was contemplating a course of treatment but wished to know what the fees were, as the question of expense was important. The respondent, in reply, had not inquired how she had come to hear of the Institute; he had treated it as a normal inquiry from a person who had received a circular. He had stated that the usual fee was three guineas for a first consultation and two or one for subsequent visits. No clearer case of a medical man attracting patients by means of circulars had ever come before the Council. It was reprehensible that a person who, four years before Dr. Corbet had been associated with the Institute, had been a mere inquirer, should be put on a list and systematically followed up with persuasions to undergo treatment.

Miss Ash's statutory declaration was put in, Mr. Cloutman offering no objection.

Dr. James Neal testified to his statutory declaration, and based his case entirely upon the card received by Mr. Coulson. He considered the card an absolute advertisement to attract the lay public. The President ruled out of order questions put by Mr. Cloutman to extract witness's opinion of methods employed by other institutions. Witness said that the name on the card was that of a doctor who had had nothing whatever to do with Mr. Coulson. He had made no inquiries as to the conduct of this particular Institute. Re-examined, he stated that it was not usual to state fees on any notification, and that he himself would not have regarded an inquirer such as Mr. Coulson was alleged to be as his patient.

Mr. S. Coulson testified to his receipt of the card, which had been left at his house like an ordinary advertisement. He had made no inquiries either in 1924 or at any other time, and had not invited the notification in any way. Confronted with the record card of the Institute, which bore his name and address and a reference number, with notes suggesting that a series of letters had been sent to him, he stated that he had never received a communication from the Institute before.

Dr. Corbet, giving evidence on his own behalf, stated that he had first heard of the Institute four years before at a medical dinner, and had soon afterwards visited it and became interested in its work. He had installed inhalation apparatus in his own surgery. In 1927, when he was considering a closer association with the Institute, he had visited the Registrar of the Council together with one of the directors, Mr. Douglas Hamilton, who had financed the company and had spent £16,000 to £20,000 on it, but had not profited by it. He had later made enquiries about the professional conduct of the Institute, which he had ascertained to be entirely satisfactory. It was not conducted for profits, and he had never seen any advertisements of it in the lay press. In April, 1928, he had succeeded the German physician in charge at £1400 per annum. The agreement had been a purely verbal one. He had also been appointed a director. In reply to a question by the Legal Assessor, he said that he did not know whether the Institute was a limited company, or whether it had any articles of association. He had been given one hundred shilling shares as a qualification, and had never made a profit; his holding was merely a question of status. He had desired to be a director to be able to keep an eye on the medical proceedings. The other members were Mr. Douglas Hamilton, Mr. Gavin Hamilton, and Major W. E. Collison. As a result of a decision to appoint an English physician and reduce the fees, this card had been prepared for circulation to patients and inquirers. He admitted to the President that the name of the new physician in charge was the only indication of the change. Twenty-five per cent. of the patients were treated free. Witness had had the with individual States. To do this would require fresh legislation in this country, similar to the Medical Act (1886), Amendment Act, 1905, which made it possible to arrange reciprocity with individual Provinces in Canada. Some 13 of the United States require all practitioners to be naturalised, and a decision against the validity of this provision in Nebraska would presumably hold good against these States as well. Nevertheless, there is no near prospect of British practitioners in the United States obtaining the same facilities as those available in other countries.

Royal College of Physicians and Surgeons of Canada.

The Executive Committee received from the Dominions Office a copy of the Act of the House of Commons of Canada by which this College was recently incorporated. The Act was passed in response to a petition from the Canadian Medical Association. The College consists of all those who, when the Act came into force, were professors of medicine, surgery, gynæcology or obstetrics in a Canadian University. A Provisional Council is to be convened, within six months of the passing of the Act, by the General Secretary of the Canadian Medical Association. This will consist of all persons present who are entitled to become Fellows of the College, and their duty will be to elect a Council of Officers for four years. The Council may, during the first two years, admit as Fellows without examination any duly qualified persons resident in Canada who have given evidence of high ability in medicine. They may also admit at any time, without examination, persons practising in Canada who possess a diploma or fellowship equal to those of the College, and may make such honorary Fellows as they think fit. Candidates for examination must be licensed to practise in a Canadian Province, and must have been qualified three years. The College is allowed to hold real estate to the annual value of fifty thousand dollars.

Qualification of Foreign Graduates.

The South African Medical Council had written to the General Council asking for reassurance that no licensing body in this country admitted a foreign medical graduate to its final examinations until he had undergone education and training equivalent to that required within the Union. (A British qualification entitles its holder to registration in most parts of the Dominions, including South Africa.) In its reply the Executive Committee stated that the Council had no direct power to make rules governing the training and examination of students. If their resolutions and recommendations were not adopted by the licensing bodies, they could only make representations to the Privy Council; without special authorisation from the Privy Council, they could not refuse to register a qualification. Licensing bodies *had full power to recognise training and examinations* undergone in the Dominions and foreign countries. The Council, moreover, pointed out that in recognising qualifications obtained in the Dominions—e.g., in South Africa—they had no powers of visitation or inspection, and granted recognition solely on documentary evidence. In these circumstances, there was no need for the South African Medical Council to apprehend that any students would be qualified without course of study and examination equivalent to that required in this country.

A SANATORIUM IN THE ISLE OF MAN.—A tuber*culosis sanatorium is to be established in the Isle of Man in* a building erected about 30 years ago by the Ramsey Corporation which was formerly used as a hospital for infectious diseases.

CONGLETON WAR MEMORIAL HOSPITAL. — Lord Moynihan recently opened an extension of this hospital which includes three emergency wards and accommodation for the staff. He is reported as saying he had never seen a hospital better fitted for its work, so well planned and furnished, or in such perfect surroundings.

LOCAL GOVERNMENT REFORM AND VOLUNTARY HOSPITALS IN SCOTLAND.

DISCUSSION AT ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

THE President of this Society, Dr. JOSHUA FERGUSON, took the chair at the annual general meeting held on May 3rd, when an address was given by Dr. J. PARLANE KINLOCH on the Effect of Local Government Reform on the Voluntary Hospitals in Scotland. *He said that at the present time the whole medical* organisation of the country was in a state of transition. His department was attempting to formulate a comprehensive scheme, and in doing so it was taking steps to consult with the medical profession in the four great centres of Scotland. Any opinions which he might express were not to be taken as final, or as having Government sanction. With regard to finance, the whole position with regard to expenditure on health services had been reviewed in 1926 by the Royal Commission on National Health Insurance. We were now spending so much on these services as compared with our trade competitors that there was no case for increasing the contributions by employers, workers, or the Treasury until the whole health administration of Britain had been overhauled.

Coöperation between Statutory and Voluntary Hospitals.

With regard to the hospitals, three types of institution had to be considered: (1) the great voluntary hospitals; (2) the public health hospitals; (3) the poor-law hospitals. Accepting the view of the Insurance Commissioners that the health services of the country must be reorganised within the existing financial commitment of the Treasury, it followed that the voluntary hospitals must be maintained at their present level and, if possible, expanded. The Government contribution could then be used to fill up gaps in the existing hospital service and to round off the hospital system. It had been decided that the poor-law hospital system should be reformed, since, except in a few areas, the system was inferior in quality; and these hospitals must be brought up to a higher level all over Scotland. The reconditioning and reequipment of poor-law hospitals, and the change in their conditions of administration would be effected with the cöoperation of the voluntary hospitals, whose position would be safeguarded.

The Local Government Act laid it down that the local authority must submit, and have approved, a complete health scheme for its area, including child welfare, antenatal, and maternity services, medical inspection of school-children and of children of pre-school age, the prevention and treatment of infectious diseases, including tuberculosis and venereal diseases, and the treatment of general diseases in the reconditioned poor-law hospitals. These services would be augmented in certain directions. For example, it was proposed to provide medical treatment for school-children. To deal with these requirements they might increase the number of whole-time medical officers, or incorporate the practitioners within the public health service. The former was a bad solution in Dr. Kinloch's opinion, and he strongly urged the importance of bringing the practitioners into the scheme. If this was to be attained there must be organised action by the medical profession itself.

The National Health Insurance service had not been properly correlated so far with the public health services, but the administration of both services had now been centralised in the new Scottish Health Department. Extension of medical benefit to dependents was recognised as desirable, but there was available for such a purpose a sum of only 5 million pounds per annum. To carry out the scheme properly it would require 12 millions per annum.

It was proposed, therefore, to apply the whole of the funds at present available to the provision of a general practitioner service, while the whole cost of specialist services would fall to be met by the local authorities. The relation of this scheme to the voluntary hospitals and the medical teaching schools must be such that the medical schools embraced the whole. The teaching of medicine must be developed more on the preventive side. There had been some progress in this direction in connexion with the teaching of midwifery. There should be no difficulty about developing medical education along these lines, but there must be no hard-and-fast rules to prevent research work from being carried on in the statutory hospitals. The medical curriculum must be modified in some way.

The Staffing of Statutory Hospitals.

It was important to prevent competition between the voluntary and the statutory hospitals. They must have the same staffs for both. He suggested that members of the visiting staffs of the voluntary hospitals should be ex officiis consultants within the statutory hospitals and that the routine consultant work in the statutory hospitals should be undertaken by the assistants from the voluntary hospitals' staffs, acting under the supervision of their own chiefs as consultants. There was not enough money to pay a big staff of specialists. For this reason it was not proposed to interfere with the present status and privileges of the " chiefs " in voluntary hospitals. At present they had a certain say in the admission of patients and so forth, and it was now proposed to continue this privilege with certain modifications. By a system of allocation of cases the voluntary hospitals would be kept full, the superintendents and the medical officer of health reviewing the waiting list from day to day. The normal mode of admission of patients would be from the central waiting list, but if any particular case was wanted by a surgeon it would go to his wards, and would not appear on the general list. There would thus be a new organisation from the centre outwards.

The present referee system must be replaced by one in which local referees were increasingly employed and the regional referees were connected with the consulting teams in the various hospitals. These regional referees would act as a link between the medical officer of health and the voluntary and statutory hospitals on the one hand, and the general practitioners on the other hand. It was essential to put a stop to the present excessive medical certification of disablement. This would be possible only when there was an adequate consulting service.

There were three important sections in the new Bill relating to hospitals: (*a*) Section 14, giving power to transfer poor-law hospitals to the public health hospital service; (*b*) Sections 27 and 28, the vital hospital clauses; and (*c*) Section 65, requiring a definite standard of efficiency in the hospital service.

Expansion of the Medical Schools.

The larger public health areas defined by the Local Government Act would permit of more efficient health services within each of these areas, but the most important aim was to have the health services of these new and enlarged local authority areas orientated towards the medical schools. In other words, the whole tendency was to evolve a regional hospital and medical service scheme out of the new local authority medical service scheme. For this purpose Scotland naturally fell into four main areas supplying the four medical teaching schools. From the point of view of the Central Department of Health such a regional system was in process of being developed in connexion with the National Health Insurance service.

So far as the medical teaching schools were concerned it would be an easy matter to undertake that the teaching hospitals were supplied with a suitable admixture of cases. If, however, this were regarded as the solution of the teaching problem, then the medical schools must be content to be miniature medical schools. The real solution of the problem was for the medical schools to expand and embrace the statutory hospitals of their areas. Under such an arrangement and without interference with the management of the voluntary and statutory hospitals, the teachers in the teaching hospitals would have access for teaching purposes to the statutory hospitals and their assistants would largely be employed in providing the actual specialist medical and surgical services required by the local authority hospitals. Under such an arrangement there would be a copartnership of the university authorities, the authorities of the voluntary hospitals, and the authorities of the statutory hospitals.

Discussion.

Dr. A. S. M. MACGREGOR thought that it would be long before all the contemplated schemes came into operation. There must be gradual progress and evolution. In his opinion no proper scheme of medical treatment could be made without extension of benefits to the dependents of insured persons. He agreed with Dr. Kinloch that the interests of the voluntary hospitals as medical training schools must be paramount. The great benefit of the new proposals was that they removed the poor-law system and opened up a whole field of disease to be dealt with in an organised way.

Prof. E. P. CATHCART spoke of the difficulty of altering the medical curriculum as at present constituted; he did not think it possible to do so without lengthening it.

Prof. J. H. TEACHER expressed his hearty sympathy with Dr. Kinloch's proposals to improve the facilities for teaching. He pointed out that in Glasgow, at least, an important reform of the curriculum in harmony with the views of Dr. Kinloch was already in force—namely, the scheme which had been initiated by Prof. Munro Kerr in connexion with the teaching of midwifery. The scheme would economise the student's time and would emphasise the preventive side of medicine.

Dr. J. B. MILLER considered that the proposals outlined by Dr. Kinloch were a charter for the general practitioner of the future. The National Health Insurance Act was ostensibly an effort to raise the health of the people, and the bringing in of dependents was a necessary development of this idea.

Dr. J. FERGUSON SMITH said that an important part of the work of the voluntary hospitals was done in the out-patient departments, and that no scheme which failed to realise this was likely to be satisfactory. He asked what provision was to be made for the support of the younger consultants. There were already probably twice as many men and women required to do the work of the hospitals as could make a reasonable living from the practice of their specialties, and if the new statutory hospitals drew off any appreciable fraction of those who now obtained special treatment in private, the position would be aggravated.

Dr. JOSHUA FERGUSON and Dr. JAMES TODD also took part in the discussion.

Reply.

Dr. KINLOCH said that he must remind them that the extension of medical benefit to dependents was still in the future. If funds were diverted to specialist service there would be nothing available for the provision of benefits for dependents. This was the reason for bringing in the local authority. He wished to make clear the intention that the voluntary hospitals should control their own affairs and that the statutory hospitals should be managed by the local authority. The consultants would remain in the same relation to the voluntary hospitals as at present, and would, in addition, join the staffs of the statutory hospitals, where they would be working under the conditions existing in those hospitals.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Consumption of Sea Fish.

THE amount of fish eaten in Germany is small, the average quantity consumed being 17 lb. per head per annum, as compared with 50 lb. in England, whereas the consumption of meat is about the same in the two countries. The Minister of Food lately took the chair at a meeting in Berlin, intended to popularise sea fish as part of the diet. A member of his Ministry said that the transport of fish from the shore to the kitchen is organised under the best hygienic conditions, and that the German fishing fleet is prepared to meet all demands. The kinds of fish principally found in German waters are rich in lipoids, cholesterol, lecithin, and vitamins. Calcareous substances, phosphorus, iron, and iodine are present in them too, and it has been observed that the incidence of goitre increases with distance from the sea. Fish is easily digestible and this applies also to dried fish, which are rather liked in Germany. There are no fish diseases which may prejudice the health of the consumer, and fish cannot be dispensed with in the diet of convalescents, or of patients suffering from gastro-intestinal diseases, gout, diabetes, and nervous affections. It is a pity therefore that the consumption of fish is not yet as general in Germany as in other countries.

Anthrax from Goat-hair.

Six of the workers in a brush factory some time ago developed anthrax, five of them dying from the infection, which was traced to goat-hair imported from China. The manager of the factory was prosecuted for manslaughter through negligence, because he had allowed the hair to be handled though he had been informed by the importer that it had not yet been disinfected. The district court gave a verdict of not guilty, in view of medical evidence that disinfection was not an absolutely reliable protection against anthrax. On appeal, however, the High Court quashed the verdict and sentenced the man to six months' imprisonment. This court held that the defendant had acted with gross negligence, since disinfection would have destroyed most of the bacilli.

Statistics of the Medical Profession.

This year's statistics show that the number of members of the medical profession residing in Germany, the Saar District, and the City of Danzig is 48,507, of whom 2376 are women. Twenty-eight per cent. of the profession describe themselves as specialists, showing an increase of 7 per cent. over the corresponding figure last year, whilst the number of medical men and women in general has increased by 2·5 per cent. On an average there are 12·4 medical men to each 10,000 of the population in the large cities as against 5·5 in the smaller towns and in country districts. The number of medical women has increased by 25·6 per cent., the majority of the additions being to the ranks of the specialists in diseases of children. 1535 medical men and 140 medical women are under 25 years old; 768 medical men but only 5 medical women are over 70, women having been admitted to qualification only for the last 30 years.

Radium Treatment of Exophthalmic Goitre.

Prof. Gudzent, of Berlin, describes the results of radium treatment of exophthalmic goitre. A dose of 100 mg. of radium-element is applied in 6 tubes for 24 hours and the treatment is sometimes repeated after ten weeks' interval. In 83 per cent. of the cases the goitre was reduced. The thyrotoxic symptoms disappeared in as many as 94 per cent. The disease responds rather slowly; toxic symptoms disappear first, the patients regain their sleep, and become less nervous; later, tachycardia, exophthalmia and finally the hypertrophy of the thyroid gland are diminished. Prof. Gudzent believes that thyrotoxicosis is curable by means of radium and that only in cases where this method has proved useless should an operation be performed. In ordinary cases of goitre he holds operation to be indicated.

Contributions under the Insurance Act.

According to recent statistics a workman earning 1750 M. a year has to pay 9·01 per cent. of his wages for health insurance. If he earns 2500 M. his contribution amounts to 8·3 per cent. It must be noted, moreover, that the employer has to pay a third of the health insurance and the whole of the accident insurance policy of his employees. Employees who are not workmen earning 1800 M. pay 8·8 per cent. of their salaries; those earning 3000 M. pay 8·3 per cent., and those earning 3600 M. 8·2 per cent. Persons with a small income have thus to pay more in proportion than those with a higher one.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

An Eastern Bureau of Health.

THE international aspects of disease in relation to quarantine were discussed in the Section of State Medicine of the recent Calcutta Congress, and the printed report is now available. The Public Health Commissioner for India recounts the systematic attempt now being made to coördinate international information of disease, and explains how some of the functions of the health section of the League of Nations, created in 1923, have come to overlap those of the original International Bureau at Paris, which has been in existence since 1907. A progressive extension has been made possible by successive grants from the Rockefeller Foundation, and one of the most outstanding events has been the establishment four years ago of an Intelligence Bureau at Singapore. The February meeting of the advisory council was attended by delegates from the Dutch East Indies, various British colonies and dependencies, China, French Indo-China, Japan, the Japanese colonies, Siam, and British India. Information of the occurrence of infectious diseases in the major ports is cabled weekly, on a fixed day, by each country to Singapore, where it is collated and broadcast in code for the benefit of the several Asiatic administrations. India picks up the broadcast at the Himalayan wireless station near Simla, and the public health department sends it on to the chief Indian ports, while abbreviated messages are also re-broadcast for the information of shipping in the Arabian Sea and Indian Ocean. In the same way the details are received by the other countries concerned, so that each has exact information every Friday regarding the state of infectious diseases in the principal ports of Asia to the number of 150. Appropriate measures can thus be taken against arrivals from infected ports. The increasing interest of the health organisation of the League of Nations in international hygiene is shown by the arrangements now in progress for the Malaria Commission of the League to visit India in the coming autumn.

Osteomalacia in India.

In the section of gynæcology at the same Congress, Dr. A. C. Scott, of the Women's Medical Service, speaking about osteomalacia in India, remarked that in her experience the disease was very prevalent, and estimated that in the areas most affected it accounts for more than 17 per cent. of the fatal cases of abnormal midwifery which come to women's hospitals. She considered that the chief causes were damp, dark dwellings, lack of sunlight, a deficiency of vitamin A in the diet, and bad hygiene in general; it followed that the disease was preventable. Dr. Scott's inquiry showed that the distribution of osteomalacia is very irregular, Kashmir and the Bombay presidency

CANCER OF THE COLON.

To the Editor of THE LANCET.

SIR,—I cannot agree with some of Mr. Flint's remarks, for I think Mr. Grey Turner is perfectly correct in preferring the oblique incision over the colon on the left hand side to the paramedian incision. After considerable experience of the oblique incision I have come to the conclusion it is far the most satisfactory. The rectus is dissected out of its sheath and displaced towards the middle line. This incision gives very free access to the colon and enables mobilisation of the splenic angle to be quite readily and easily carried out should this be required. With a paramedian incision mobilisation of the splenic angle is difficult. I have never seen post-operative hernia follow this incision, and in my experience it is one of the most satisfactory incisions as regards after-results as any used in the abdominal wall.

In regard to the blood-supply of the colon, in my opinion necrosis following anastomosis is always due to bad blood-supply, and I have actually seen this happen in the past on more than one occasion. More particularly is this the case in the common situation for growth towards the lower end of the sigmoid flexure. I agree with Mr. Flint as to the safety of Paul's operation, but he fails to mention two serious objections to it: (1) that it involves undergoing two, if not three, operations; and (2) that it most invaribly leaves a weak scar with liability to tiresome hernia.

I am, Sir, yours faithfully,

London, June 3rd, 1929. J. P. LOCKHART-MUMMERY.

SPRUE AND CŒLIAC DISEASE.

To the Editor of THE LANCET.

SIR,—In connexion with Dr. Thaysen's article in your issue of May 25th (p. 1086) on the differentiation of these two diseases, it may be of interest to recall that Dr. A. C. Hampson and myself demonstrated by the graphic method (Guy's Hospital Reports, April, 1924) that the blood in sprue showed the same megalocytic changes as in Addison's (pernicious) anæmia. At the same time we examined the blood of several cases of cœliac disease, though at the time unfortunately only one or two cases were available; in these we found no corresponding blood changes. These last results were never published. There would thus seem to be a simple and effective method of differentiating the two diseases, though admittedly further work is needed on these lines.

I am, Sir, yours faithfully,

J. W. SHACKLE, M.R.C.S., L.R.C.P.

Guy's Hospital, S.E., May 30th, 1929.

EPHEDRINE AND EPHETONINE.

To the Editor of THE LANCET.

SIR,—In the report of a discussion on the Action and Use of Ephedrine (THE LANCET, May 18th, p. 1036) I am credited with the statement: "In Germany ephedrine had been synthesised and with a mixture of dextrose placed upon the market as ephetonine." This has obviously been wrongly reported, no doubt from the resemblance of dextro and dextrose. The statement I actually made was to the effect that ephetonine is a compound of dextro- and lævo-rotatory ephedrine, manufactured synthetically.—I am, Sir, yours faithfully,

Oxford, May 30th, 1929. J. A. GUNN.

HOSPITAL COÖPERATION IN DEVON.—A conference of representatives of hospitals in Devon has been held at Exeter to consider the situation created by the Local Government Act. The outcome was the appointment of a Committee, consisting of an equal number of representatives of large and small hospitals and medical men, of whom three are to be general practitioners.

Public Health Services.

SCHOOL MEDICAL SERVICE.

—	No. on roll.	Aver. E.S. attendance.	Routine inspections.	Specials and reinspections.	Per cent. of defects.*

Leicester ..	31,271	27,565	10,347	30,089	14·59

E.S. = Elementary school.

* Excluding dental defects and uncleanliness.

Hull.

Dr. W. A. Daley, in his introduction to the detailed report of Dr. J. Morrison, shows that the coördination of the public health work has gone so far as to include even the port sanitary medical officers. There are now in Hull four senior assistant medical officers of health dealing respectively with: (1) tuberculosis; (2) maternity and child welfare; (3) school medical service; (4) port sanitation and infectious disease, each available to come to the aid of another in times of pressure. The institutions belonging to each department are at the service of the others—e.g., the clinics, sunlight apparatus, and disinfecting station.

Much progress has been made in developing facilities for treatment such as X rays for ringworm, while the East Hull Clinic, the open-air school, and an orthopædic hospital are in preparation; a sight-saving class and an open-air class are already working. The increasing recognition of the good work done at the clinics is shown by the rise in total attendances during the year from 148,132 to 229,893. In pursuance of a definite policy a stand is being made against the treatment of casual dental cases at the clinics and since the parents have to obtain and usually pay for emergency treatment they are coming to realise the value of routine conservative work which largely obviates its necessity. Light treatment given at the Infant Welfare Centre to school-children is mainly afforded by the mercury-vapour and carbon arc lamps. Dr. Morrison states that while the number of cases so far treated (52) is too small for final conclusions, the treatment of definite diseases is on the whole disappointing as regards cure and the benefits obtained seem to be mainly attributable to the general tonic effect. He adds, however, that these results with school-children are in marked contrast to those obtained with cases from the other two departments in whom it was found that active rickets and some forms of tuberculosis, notably lupus, did remarkably well. The orthopædic clinic has been almost overwhelmed by the results of last year's epidemic of anterior poliomyelitis.

Dr. Morrison has made an important study of the distinction between the dull and the backward children. The dull are found to be nearly as defective in general intelligence (measured by the Stanford Binet tests) as in educational attainments. They are a large and important class, never able to attain an average level of education, which should be dealt with by special methods. The backward, on the other hand, have far higher innate intelligence and their school failure is attributable rather to extrinsic factors such as ill-health, bad sight or hearing, or to lack of suitable educational facilities. With them may be grouped the cases of delayed development who can recover lost ground—a small number in Dr. Morrison's experience.

Mr. Meadon Baker, the organiser of physical training, states the governing factor that will lead to the desired goal of good posture is the teachers' personal attitude to the physical work. If the teacher shows real faith by persistent effort, good posture can be obtained, and by daily exercises the commonest types of deformity, round shoulders and flat chests, can be almost eradicated.

Sheffield.

Dr. Thomas Chetwood writes that as his report is framed on set lines, it must largely consist of statistics, adding: "Figures alone give only an imperfect picture of the work that has been done and require some explanation." A few lines later he quotes Sir George Newman: "If when the reader turns to study these dull records of the school medical service he will come with understanding, he will discover the hidden secret of an unseen reform which is silently but certainly changing the prospects and hopes of the English people." It seems all too true that the mass of facts here set forth has precluded some of the interesting observations to which Dr. Chetwood has made us yearly look forward; but at the same time they do reveal what an immense amount of work is being done and the progress that is being made. For example, the clinics have grown until it can almost be said that the accommodation is adequate, and the latest clinic on the Manor Estate Dr. Chetwood is able to describe as "the best that I have yet seen anywhere in England."

The number of routine examinations made during 1928 was nearly 5000 more than in 1927. The general condition of the children as shown by their physique, nutrition, and cleanliness tends steadily to improve; interesting anthropometric tables show that the improvement in height and weight has brought them more than up to the new standards of the Board of Education. Attendances at the clinics go on increasing, but in one aspect this is not so satisfactory. Additional evening clinics are now held for children suffering from toothache, but it is stated that parents consent to extraction but fail to appreciate the value and importance of sound conservative treatment and that many of the children who come to the "toothache" clinic are those whose parents have previously refused routine dental treatment. In some parts of England the evils of such a proceeding have led to reduction of facilities for treatment of "casuals" with added emphasis on routine conservative work.

A great step forward has been taken with the orthopædic scheme which is now awaiting the appointment of an orthopædic surgeon to be complete. Mr. H. A. Cole, chief superintendent of physical training, gives a critical survey of his work in Sheffield. He stresses the importance of good posture, any deviation from which means a strain upon one or more organs, and states that in classes where attention is paid to posture there is a brightening up in alertness of both body and mind. Games played on open spaces, he says, have both an immediate value as an antidote to cramped homes and school conditions and a preventive of ailments which is economically better than remedial treatment. The indirect gain from the wider outlook obtained by contact with other schools fosters the social amenities on which the fabric of civilisation is built.

Leicester.

Dr. A. Warner explains the increase in work at the clinics as due in part to an arrangement with the county council by which the aural clinic is more fully utilised, and partly by the greater number of dental cases, due to the appointment of an additional dentist and the establishment of a clinic in a school. He believes the chief obstacle to securing more general dental treatment to be the reluctance of parents to spend money and time in getting to the clinics and waiting there. If this is correct, the solution will be found in establishing dental clinics at the schools so that the children can, with the parents' consent, be taken direct from the classroom. In one such example 100 per cent. of those needing dental treatment were actually treated.

Mr. J. A. Keen, the aural surgeon, gives the records of some 17 children treated by the Zünd-Burguet method with exact measurements of the auditory acuity. The work was done in his private consulting-room at his own expense. The scheme for the treatment of out-patients' cripples and for the use of ultra-violet light has now received the sanction of the Board of Education and the buildings are likely to be proceeded with at once. A day open-air school is planned and good work has been done by two special classes run on the lines of an open-air school. The Mablethorpe Summer Camp, which is a voluntary institution, was used for two months last autumn as a residential open-air school, and Dr. Warner says he cannot remember any previous year in which the children appeared to benefit so much.

The organisers of physical training, Mr. R. G. Lean and Miss Jean Bennett, state that physical education aims at the physical, mental, and moral development of the individual and is thus an integral part of general education—and we might add closely related to school hygiene. Its association with obsolete forms of drill and meaningless manœuvrings may readily stifle the real spirit of education, and continued efforts are being made to give teachers the right concept of the work by special courses of instruction. Closely related to this work is that of remedial exercises, which is continuing to give good results. Dr. Warner has conducted a special inquiry on the influence of the home on the nutrition of the child, and compared 100 children from good homes with a similar number from poor homes. He found unmistakable evidence that the improved home conditions of group A have already had a beneficial effect on their general physique and nutrition, with definitely less evidence of rickets and chronic catarrhal conditions so often the precursors of definite ill-health.

Another unusual inquiry is that of Mr. Keen into the auditory ossicles from the specimens collected at mastoid operations. Many new facts are brought to light, one of them being the observation that the dimensions of these structures do not vary with age; they are already full size at birth.

INFECTIOUS DISEASES IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 25TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 298 (last week 362); scarlet fever, 1778; diphtheria, 875; enteric fever, 46; pneumonia, 1300; puerperal fever, 53; puerperal pyrexia, 93; cerebro-spinal fever, 18; acute poliomyelitis, 8; encephalitis lethargica, 23; dysentery, 8; ophthalmia neonatorum, 108. No case of cholera, plague, or typhus fever was notified during the week.

The largest incidence of small-pox at the moment is in London (Poplar, 14 cases; Stepney, 20); South Shields, 13; West Ham, 28; Leigh (Lancs), 13; Stoke-on-Trent, 18; Swindon (Wilts), 9; Merthyr Tydfil, 10.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on May 28th–29th was as follows:—Small-pox, 307 under treatment, 10 under observation (last week 332 and 12 respectively); scarlet fever, 1411; diphtheria, 1569; enteric fever, 13; measles, 132; whooping-cough, 717; puerperal fever, 27 (plus 9 babies); encephalitis lethargica, 111; poliomyelitis, 2; "other diseases," 58. At St. Margaret's Hospital there were 18 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 5 (1) from enteric fever, 81 (3) from measles, 5 (1) from scarlet fever, 63 (11) from whooping-cough, 21 (3) from diphtheria, 53 (10) from diarrhœa and enteritis under two years, and 51 (12) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to Wimbledon. Another death from small-pox provisionally assigned to Rochdale should have been reported in the return for the week ended April 13th. Four more deaths provisionally classified to small-pox are now reported for the month of April and assigned 2 to Gravesend (Kent) and 1 each to Sale (Cheshire) and Caerphilly (Glamorgan). No great town reported more than 3 deaths from influenza except Birmingham with 4. Liverpool reported 16 deaths from measles, Sunderland 16, Birmingham 11, and Leeds 10. Manchester reported 9 deaths from whooping-cough;

Leeds 5, and Birmingham 4. Diarrhœa claimed 6 deaths each in Birmingham and Manchester and 4 in Liverpool. The number of stillbirths reported during the week was 270 (corresponding to a rate of 45 per 1000 births), including 56 in London.

DEATHS FROM SMALL-POX.

The fatal case of small-pox which occurred in Lincoln in the week ended April 13th was that of a woman, aged 36 years, who was a passenger on the *Tuscania*. It is understood that she had intended to travel from Liverpool to a destination in Wales, and notified the Liverpool Port Sanitary Authority to that effect; on leaving the ship however, she changed her mind, stayed one night in a hotel in Liverpool, and travelled to Lincoln on April 3rd. She became ill on the 4th or 5th, and was seen soon after by a private medical practitioner, who called in the deputy medical officer of health on the 9th, when she was removed to Lincoln Isolation Hospital. The initial symptoms from the 6th to the 8th are understood to have been severe, and a prodromal rash appeared on the 9th. On that day Dr. D. C. Lamont, medical officer of health, tells us that the patient had a vivid erythematous rash on the face, neck, shoulders, and upper portion of the front of the thorax. Numerous cutaneous hæmorrhages were to be seen all over the body with the exception of the abdomen, and two or three papules on the palm of a hand. She was drowsy and restless, and at times semi-conscious, temperature remained at 105° F. On the 10th "lobster rash" was more pronounced and the face swollen, but the rash had not extended in area. Two vesicles on the side of the abdomen had become umbilicated, and the papules on the hand had reached the early vesicular stage. The hæmorrhages which involved practically the whole of the trunk and all the limbs were purpuric in type, but the face and neck remained practically free. At noon on this day the patient was transferred to the Nottingham Small-pox Hospital, where she died about mid-day on April 11th. The diagnosis was hæmorrhagic or black small-pox with a prodromal "lobster rash," the true small-pox eruption being limited to about five vesicles. Dr. Lamont adds that there were two small vaccination vesicles present on one arm, each smaller than a threepenny-piece. The patient had been vaccinated successfully in infancy and again on board ship on (?) March 31st.

The death from small-pox assigned to Stoke-on-Trent in the return for the week ended April 20th was that of a child, 7 years of age, who was suffering from broncho-pneumonia. Dr. A. Wotherspoon, medical officer of health, informs us that the child's condition was hopeless on admission to hospital. The certificate was filled in: (1) broncho-pneumonia, (2) small-pox.

The fatal case at Woolwich in the week ended May 18th was that of a boy 9 years of age; the rash appeared on May 2nd and became confluent in the vesicular stage. Dr. J. Macmillan, medical officer of health, states that the source of infection was not definitely traced, but there are grounds for believing that it was associated with the Gravesend cases. The cause of death as given on the death certificate was "small-pox; never vaccinated."

Medical News.

Society of Apothecaries of London.—At recent examinations the following candidates were successful in the undermentioned subjects:—

Surgery.—W. T. Ellis, Manchester and Charing Cross Hosp.; A. Freitag, Charing Cross Hosp.; J. D. B. Games, St. Bart.'s Hosp.; W. St. A. Hendricks, St. Mary's Hosp.; L. G. E. K. Lewis, Middlesex Hosp.; and B. J. Niall, London Hosp.

Medicine.—F. W. Crossley-Holland, St. Bart.'s Hosp.; A. Freitag, Charing Cross Hosp.; K. E. Gallaher, Manchester; and K. M. Seedat, Charing Cross Hosp.

Forensic Medicine.—P. S. Balachandran, Middlesex Hosp.; A. Freitag, Charing Cross Hosp.; and K. E. Gallaher, Manchester.

Midwifery.—A. Campbell, Edinburgh; R. H. El Sawy, St. George's Hosp.; B. L. Fishout, Cardiff; A. Freitag, Charing Cross Hosp.; C. Parthasarthe, Birmingham; and A. Scher, Basle and London Hosp.

The Diploma of the Society was granted to the following, entitling them to practise medicine, surgery, and midwifery: F. W. Crossley-Holland, A. Freitag, and K. E. Gallaher.

University of Aberdeen.—The Senate has recommended to the University Court that Lord Beaverbrook's gift of £1000 be devoted to the purchase and the installation of X ray apparatus in the Anatomical Department of the University.

University of Cambridge.—It is authoritatively stated that in desiring the residue of his estate to be applied in perpetuity for the promotion of education in chemistry, biochemistry, physical science, and other allied subjects, the late Mr. John Humphrey Plummer expressed his wish that a professorship or professorships, each of the annual value of £1200, should be established in the University. The trustees are advised that the estate should yield an income of about £10,000 a year.

University of London.—The degree of D.Lit has been conferred on Mr. F. A. P. Aveling, D.Sc., University Reader in Psychology, for a Thesis on The Psychological Approach to Reality.

University College.—It is announced that the examination for two Goldsmid entrance exhibitions (which entitle the holders to the final course for a registrable medical qualification) has been deferred until July 19th. The subjects are anatomy, physiology, and general pathology, and candidates must apply to the Secretary of the College by July 6th.

University of Leeds.—At the next degree ceremony in July the honorary degree of D.Sc. will be conferred on Dr. T. Wardrop Griffith, professor of medicine at Leeds from 1910 to 1925, and previously professor of anatomy from 1887.

Epsom College: *Sir Walter Buchanan Scholarship.*—The Council will shortly award this scholarship, of about £38 a year. It is primarily intended for the sons of deceased or prematurely invalided officers of the Indian Medical Service, but failing any such candidates, it may be granted to the sons of legally qualified medical men of wholly British parentage in necessitous circumstances who have practised medicine for at least five years in India. Forms of application may be had from the Secretary, Mr. J. B. Lamb, 49, Bedford-square, London, W.C.1.

London Jewish Hospital Medical Society.—Sir Humphry Rolleston will open a symposium on Some Diseases of the Jews, at 3 P.M. on Thursday, June 13th, at the London Jewish Hospital, Stepney Green, E.

Research Defence Society.—The annual general meeting of this Society will be held at 11, Chandos-street, Cavendish-square, W., on Wednesday, June 12th, at 3 P.M., with Lord Lamington in the chair. Prof. A. V. Hill will deliver the Third Stephen Paget Memorial Lecture, entitled Enemies of Knowledge.

Indian Medical Service Dinner Fund.—The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant, Piccadilly-circus, London, on Wednesday, June 19th, at 7.15 P.M. Further information is obtainable from the joint Hon. Secretary, Sir Thomas Carey Evans, 31, Wimpole-street, W.1.

Australian and New Zealand Medical Association in England.—The summer dinner of this Association will be held at the Trocadero Restaurant, Piccadilly, on Friday, June 14th, at 7.45 for 8.0 P.M. Mr. F. F. Muecke will preside, and Mr. Sampson Handley and Prof. F. R. Fraser will be the official guests of the Association. All medical visitors from Australia and New Zealand, whether members of the Association or not, are invited to be present, and guests may be brought. Communications should be addressed to Mr. P. J. Jory, 26, Queen Anne-street, London, W.1.

South African Medical Association: Annual Congress.—The scientific meeting was opened at Port Elizabeth on May 13th by the Hon. A. P. J. Fourie. Dr. A. J. Orenstein inducted Dr. R. M. Leith into the Presidential chair. In doing so he observed that it could be said with truth that a country got the medical profession it deserved. Not only did the enlightenment of a country react in a subtle way on the medical men practising in it, but the work of progressive and altruistic practitioners could be so hampered by ill-conceived legislation, and by the apathy of public bodies as to reduce its potentiality for public service to a lamentably low level. Dr. Leith spoke of the ability of the medical profession to instruct and enlighten a public which was becoming increasingly interested in health matters, and ready to learn. But there was need, he said, for the profession first to educate themselves more on the preventive side. The student had been taught to regard the diagnosis and treatment of established disease as the important thing, and prevention had not always been sufficiently stressed in their training.

Dr. C. H. Durrant, Chief Medical Officer, St. Kitts-Nevis Medical Service, has been appointed an official member of the Legislative Council of the Presidency of St. Christopher and Nevis.

MANCHESTER'S WATER-SUPPLY.—In order to increase Manchester's water-supply a huge dam is to be constructed at Hawes Water in the Mardale Valley of Westmorland to add to the length and depth of the lake at a cost of about £12,000,000. Subject to the approval of the City Council, the Waterworks Committee have sanctioned the commencement forthwith of preparatory works. Five years will be required for completion of the scheme.

NATIONAL PHYSICAL LABORATORY.—The report of this laboratory for 1928 shows that its work has expanded considerably during the year. Numerous X ray protective materials such as lead glass and lead rubber have been tested and the X ray departments of many hospitals have been inspected. There are, it is stated, many indications that the publication of the recommendations of the X Ray and Radium Protection Committee, together with the facilities provided by the laboratory, have resulted in marked improvements in the standard of protection attained by British makers of X ray apparatus. During the year a constant voltage generator has been installed in the Radiology Department. The details of this machine are given in the report and are interesting as showing the trend of modern X ray generator design. In 1928 the unit of X ray intensity was defined, but much experimental work must be done before an ionisation chamber is evolved which satisfies the conditions laid down at Stockholm. Preliminary investigations have been undertaken at the laboratory, and these have yielded important results, in fact, attempts have already been made to express the barium platino cyanide dose in "r" units. The executive committee calls attention to the large amount of work relating to fundamental standards of measurement which has been done by the various departments. A section of the report devoted to definitions *of the units and standards employed at the laboratory* bears witness to the high degree of accuracy achieved in physical measurements.

INTERNATIONAL CONFERENCE ON HEALTH OF THE SEAMAN.—The announcement that the Second Conference on the Health and Welfare of Merchant Seamen will take place at Geneva on Oct. 7th, 8th, and 9th requires some supplementary information for the benefit of those who have not followed the movement of which this Conference is only one phase. Some five years ago Dr. Harald Engelsen, of the Norwegian Red Cross Society, submitted to the Board of Governors of the League of Red Cross Societies a far-reaching scheme for promoting the health and general welfare of the merchant seamen on both national and international lines. In 1926 the first Conference on the Welfare of the Seaman, known as the Oslo Conference, was convened by the Norwegian Red Cross Society and the League of Red Cross Societies, a unanimous decision being taken to appoint a Standing Committee which would ensure continuity and coördination of the policies adopted at this Conference. This Standing Committee has met on several occasions in Paris during the last three years, and its labours have been so fruitful that the time has seemed ripe for calling a second Conference, in order that the many forces available for the benefit of the merchant seaman may be coördinated on sound lines. This Conference is convened under the auspices of the Norwegian Red Cross Society, the League of Red Cross Societies, the International Unions against Venereal Disease and Tuberculosis, and the International Association of Mercantile Marine Officers. The British representatives mentioned in the provisional agenda are Sir John Sandeman Allen, who will deal with the general situation in home ports; Mr. Leonard Bowden, who will speak on welfare work and social insurance; Dr. W. M. Willoughby, who will discuss the problem of tuberculosis; and Dr. R. M. F. Picken, who will deal with venereal disease, all in connexion with the merchant service. The subject of ships' libraries will be discussed by Mr. A. Mansbridge in coöperation with Mr. G. Stenersen of Norway. For further information application should be made to the General Secretary of the Conference, Dr. F. Humbert, the League of Red Cross Societies, 2, Avenue Velasquez, Paris, VIII.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Albemarle-street, W.

THURSDAY, June 13th.—4.30 P.M. *The following papers will be read:* F. M. L. Sheffield: Chromosome Linkage in Œnothera, with special reference to some Fl. Hybrids. (Communicated by Sir John Farmer, F.R.S.) Grace Briscoe and Winifred Leyshon: Reciprocal Contraction of Antagonistic Muscles in Peripheral Preparations—using Flashing Neon Lamp Circuit for Excitation of Nerve. (Communicated by Sir Charles Sherrington, F.R.S.) W. S. Stiles: The Scattering Theory of the Effect of Glare on the Brightness Difference Threshold. (Communicated by Sir John Parsons, F.R.S.) T. Moran: Critical Temperature of *Freezing—Living Muscle. (Communicated by Sir* William Hardy, F.R.S.) E. C. Smith: The Formation of Lactic Acid in Muscles in the Frozen State. (Communicated by Sir William Hardy, F.R.S.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

WEDNESDAY, June 12th.—2 P.M. and 6 P.M., SURGERY. Provincial Meeting at Sheffield. Lunch can be obtained on the train. From 2 P.M.–5 P.M., Operations, Clinical Cases and Pathological Specimens at: (1) the Royal Infirmary; (2) the Royal Hospital. Also from 2 P.M.–5 P.M., there will be a demonstration of animal experiment to show the relation between diet and disease at the Field Laboratory. Tea will be provided and dinner for those who wish it later in the evening. A return train to London will be arranged so that Members can dine on it.

FRIDAY, June 14th.—5 P.M., OPHTHALMOLOGY. Annual General Meeting: Election of Officers and Council. Papers: Mr. E. Maddox: Demonstration of the Cheiroscope. Miss M. Dobson: Velanoskiascopy, a Control in the Correction of Astigmatic Defects.

RESEARCH DEFENCE SOCIETY, 11, Chandos-street, Cavendish-square, W.

WEDNESDAY, June 12th.—3 P.M., Annual General Meeting. Prof. A. V. Hill: Enemies of Knowledge. (Stephen Paget Memorial Lecture.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, June 11th.—5 P.M., Dr. H. H. Dale: Some Chemical Factors in the Control of the Circulation (last Croonian Lecture).

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, June 10th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Ward Visit. 2 P.M., Mr. Bishop Harman: Eye Department.

TUESDAY.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, June 10th.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, June 10th, to SATURDAY, June 15th.—MEDICAL SOCIETY, Lecture Room, 11, Chandos-street, Cavendish-square, W., M.R.C.P. Course of Lectures, on Tues. and Frids. at 8.30 P.M. Tues., Dr. Bernard Myers:

Leeds 5, and Birmingham 4. Diarrhœa claimed 6 deaths each in Birmingham and Manchester and 4 in Liverpool.

The number of stillbirths reported during the week was 270 (corresponding to a rate of 45 per 1000 births), including 56 in London.

DEATHS FROM SMALL-POX.

The fatal case of small-pox which occurred in Lincoln in the week ended April 13th was that of a woman, aged 36 years, who was a passenger on the *Tuscania.* It is understood that she had intended to travel from Liverpool to a destination in Wales, and notified the Liverpool Port Sanitary Authority to that effect; on leaving the ship however, she changed her mind, stayed one night in a hotel in Liverpool, and travelled to Lincoln on April 3rd. She became ill on the 4th or 5th, and was seen soon after by a private medical practitioner, who called in the deputy medical officer of health on the 9th, when she was removed to Lincoln Isolation Hospital. The initial symptoms from the 6th to the 8th are understood to have been severe, and a prodromal rash appeared on the 9th. On that day Dr. D. C. Lamont, medical officer of health, tells us that the patient had a vivid erythematous rash on the face, neck, shoulders, and upper portion of the front of the thorax. Numerous cutaneous hæmorrhages were to be seen all over the body with the exception of the abdomen, and two or three papules on the palm of a hand. She was drowsy and restless, and at times semi-conscious, temperature remained at 105° F. On the 10th "lobster rash" was more pronounced and the face swollen, but the rash had not extended in area. Two vesicles on the side of the abdomen had become umbilicated, and the papules on the hand had reached the early vesicular stage. The hæmorrhages which involved practically the whole of the trunk and all the limbs were purpuric in type, but the face and neck remained practically free. At noon on this day the patient was transferred to the Nottingham Small-pox Hospital, where she died about mid-day on April 11th. The diagnosis was hæmorrhagic or black small-pox with a prodromal "lobster rash," the true small-pox eruption being limited to about five vesicles. Dr. Lamont adds that there were two small vaccination vesicles present on one arm, each smaller than a threepenny-piece. The patient had been vaccinated successfully in infancy and again on board ship on (?) March 31st.

The death from small-pox assigned to Stoke-on-Trent in the return for the week ended April 20th was that of a child, 7 years of age, who was suffering from broncho-pneumonia. Dr. A. Wotherspoon, medical officer of health, informs us that the child's condition was hopeless on admission to hospital. The certificate was filled in: (1) broncho-pneumonia, (2) small-pox.

The fatal case at Woolwich in the week ended May 18th was that of a boy 9 years of age; the rash appeared on May 2nd and became confluent in the vesicular stage. Dr. J. Macmillan, medical officer of health, states that the source of infection was not definitely traced, but there are grounds for believing that it was associated with the Gravesend cases. The cause of death as given on the death certificate was "small-pox; never vaccinated."

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful in the undermentioned subjects:—

Surgery.—W. T. Ellis, Manchester and Charing Cross Hosp.; A. Freitag, Charing Cross Hosp.; J. D. B. Games, St. Bart.'s Hosp.; W. St. A. Hendricks, St. Mary's Hosp.; L. G. E. K. Lewis, Middlesex Hosp.; and B. J. Niall, London Hosp.

Medicine.—F. W. Crossley-Holland, St. Bart.'s Hosp.; A. Freitag, Charing Cross Hosp.; K. E. Gallaher, Manchester; and K. M. Seedat, Charing Cross Hosp.

Forensic Medicine.—P. S. Balachandran, Middlesex Hosp.; A. Freitag, Charing Cross Hosp.; and K. E. Gallaher, Manchester.

Midwifery.—A. Campbell, Edinburgh; R. H. El Sawy, St. George's Hosp.; B. L. Fishout, Cardiff; A. Freitag, Charing Cross Hosp.; C. Parthasarthe, Birmingham; and A. Scher, Basle and London Hosp.

The Diploma of the Society was granted to the following, entitling them to practise medicine, surgery, and midwifery: F. W. Crossley-Holland, A. Freitag, and K. E. Gallaher.

UNIVERSITY OF ABERDEEN.—The Senate has recommended to the University Court that Lord Beaverbrook's gift of £1000 be devoted to the purchase and the installation of X ray apparatus in the Anatomical Department of the University.

UNIVERSITY OF CAMBRIDGE.—It is authoritatively stated that in desiring the residue of his estate to be applied in perpetuity for the promotion of education in chemistry, biochemistry, physical science, and other allied subjects, the late Mr. John Humphrey Plummer expressed his wish that a professorship or professorships, each of the annual value of £1200, should be established in the University. The trustees are advised that the estate should yield an income of about £10,000 a year.

UNIVERSITY OF LONDON.—The degree of D.Lit has been conferred on Mr. F. A. P. Aveling, D.Sc., University Reader in Psychology, for a Thesis on The Psychological Approach to Reality.

University College.—It is announced that the examination for two Goldsmid entrance exhibitions (which entitle the holders to the final course for a registrable medical qualification) has been deferred until July 10th. The subjects are anatomy, physiology, and general pathology, and candidates must apply to the Secretary of the College by July 6th.

UNIVERSITY OF LEEDS.—At the next degree ceremony in July the honorary degree of D.Sc. will be conferred on Dr. T. Wardrop Griffith, professor of medicine at Leeds from 1910 to 1925, and previously professor of anatomy from 1887.

EPSOM COLLEGE: *Sir Walter Buchanan Scholarship.*—The Council will shortly award this scholarship, of about £38 a year. It is primarily intended for the sons of deceased or prematurely invalided officers of the Indian Medical Service, but failing any such candidates, it may be granted to the sons of legally qualified medical men of wholly British parentage in necessitous circumstances who have practised medicine for at least five years in India. Forms of application may be had from the Secretary, Mr. J. B. Lamb, 49, Bedford-square, London, W.C.1.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—Sir Humphry Rolleston will open a symposium on Some Diseases of the Jews, at 3 P.M. on Thursday, June 13th, at the London Jewish Hospital, Stepney Green, E.

RESEARCH DEFENCE SOCIETY.—The annual general meeting of this Society will be held at 11, Chandos-street, Cavendish-square, W., on Wednesday, June 12th, at 3 P.M., with Lord Lamington in the chair. Prof. A. V. Hill will deliver the Third Stephen Paget Memorial Lecture, entitled Enemies of Knowledge.

INDIAN MEDICAL SERVICE DINNER FUND.—The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant, Piccadilly-circus, London, on Wednesday, June 19th, at 7.15 P.M. Further information is obtainable from the joint Hon. Secretary, Sir Thomas Carey Evans, 31, Wimpole-street, W.1.

AUSTRALIAN AND NEW ZEALAND MEDICAL ASSOCIATION IN ENGLAND.—The summer dinner of this Association will be held at the Trocadero Restaurant, Piccadilly, on Friday, June 14th, at 7.45 for 8.0 P.M. Mr. F. F. Muecke will preside, and Mr. Sampson Handley and Prof. F R. Fraser will be the official guests of the Association. All medical visitors from Australia and New Zealand, whether members of the Association or not, are invited to be present, and guests may be brought. Communications should be addressed to Mr. P. J. Jory, 26, Queen Anne-street, London, W.1.

SOUTH AFRICAN MEDICAL ASSOCIATION: ANNUAL CONGRESS.—The scientific meeting was opened at Port Elizabeth on May 13th by the Hon. A. P. J. Fourie. Dr. A. J. Orenstein inducted Dr. R. M. Leith into the Presidential chair. In doing so he observed that it could be said with truth that a country got the medical profession it deserved. Not only did the enlightenment of a country react in a subtle way on the medical men practising in it, but the work of progressive and altruistic practitioners could be so hampered by ill-conceived legislation, and by the apathy of public bodies as to reduce its potentiality for public service to a lamentably low level. Dr. Leith spoke of the ability of the medical profession to instruct and enlighten a public which was becoming increasingly interested in health matters, and ready to learn. But there was need, he said, for the profession first to educate themselves more on the preventive side. The student had been taught to regard the diagnosis and treatment of established disease as the important thing, and prevention had not always been sufficiently stressed in their training.

Notes, Comments, and Abstracts.

THE BICENTENARY OF THE BIRTH OF OLIVER GOLDSMITH, M.B. DUB. & OXF.

BY SIR WILLIAM HALE-WHITE, K.B.E., M.D., LL.D.,
CONSULTING PHYSICIAN TO GUY'S HOSPITAL.

GOLDSMITH is usually said to have been born on Nov. 10th, 1728, but some think that a rather later date is more likely, and a later date is given on the memorial in Westminster Abbey, so the present time is near enough for us to call attention to the bicentenary of his birth. He was a physician of whom our profession may well be proud, for he wrote the best comedy in our tongue, and Goethe said: "It is not to be described the effect that Goldsmith's 'Vicar' had upon me, just at the critical moment of mental development. That lofty and benevolent irony, that fair and indulgent view of all infirmities and faults, that meekness under all calamities, that equanimity under all changes and chances, and the whole train of kindred virtues, whatever names they bear, proved my best education; and in the end these are the thoughts and feelings which have reclaimed us from all the errors of life." All Goldsmith's writings are beautiful English, much of the "Vicar of Wakefield" has become part of our common speech. He was loved by everybody. Burke wept when he heard of his death, and Reynolds put aside his painting for the day.

Oliver Goldsmith

Wm Broughton

Oliver Goldsmith's signature, in the entrance book of the Royal Medical Society of Edinburgh, Jan. 13th, 1753. For this I am indebted to Dr. J. D. Comrie, lecturer on the History of Medicine, University of Edinburgh.

Medical Education.

No consecutive account of him as a physician has been published.* His father, a clergyman, first at Pallas, then at Lissoy, near Athlone in Ireland, was so poor that, although his elder son Henry had gone to Trinity College, Dublin, as a pensioner, Oliver was sent as a sizar, he had an unhappy time there. He attended some anatomy lectures and took his A.B. degree on Feb. 27th, 1749, after which he returned home. It was discussed whether he should be a lawyer or a parson; he tried to go to America, but went for a walk while his ship, at Cork, was waiting for a wind, which sprang up suddenly, and the ship sailed before Oliver could get back to it. The M.B. degree of Dublin could not be taken after the A.B. until three years had elapsed, so the earliest date at which Goldsmith could take it was 1752. When he actually took it is not certain; Percy says when he was about 20—*it must have been before 1763 for, in an agreement* with "Dodsley," written by Goldsmith in that year and now in the British Museum, he calls himself M.B. Clarke thinks he most likely took it between 1756 and 1763. It will be seen later there is no doubt he did take it. His father had died while he was at college, but his uncle, the Rev. Thomas Contarine, who had married his father's sister, gave him much of the necessary money to study medicine at Edinburgh, where he entered as a medical student in the autumn of 1752. In the class rolls of Prof. Munro is the entry that Oliver Goldsmith joined the class for anatomy at the end of October, 1752, and again at the end of October, 1753, in each case paying three guineas.

He writes[1] to his brother-in-law, Daniel Hodson, saying that during the day he has to attend lectures, at night he is in his lodging with hardly any society but a folio book, a skeleton, his cat, and a meagre landlady. He pays 23 pounds a year for diet, washing, and lodging, which is the cheapest to be got in Edinburgh; he reads hard, which he never could do if the subject was displeasing. The letter concludes: "Direct me to Surgeon Sinclair's in the Trunk Close, Edinburgh." This was a short street in old Edinburgh, going between the High-street and the open space *around the old physic garden. After he has been in Edinburgh* some seven months we find a letter from him to his uncle Contarine, telling that except for knowing a few who attend Munro's lectures, he is a recluse. "I shall give you the Professors' names and, as far as occurs to me, their characters, and the first as most deserving is Mr. Munro, Professor of Anatomy. This man has brought the science he teaches to as much perfection as it is capable of, and not content with barely teaching anatomy he launches out into all branches of physic, where all his remarks are new and useful. 'Tis he, I may venture to say, that draws hither such a number of students from most parts of the world, even from Russia; he is not only a skilful physician but an able orator, and delivers things in their nature abstruse in so easy a manner that the most unlearned may, must understand him; Plumer, Professor of Chemistry, understands his business well, but delivers himself so ill that he is but little regarded; Alston, Professor of Materia Medica, speaks much but to little purpose; the Professors of Theory and Practice say nothing but what we may find in the books laid before us and speak in so droneing and heavy a manner that their hearers are not many degrees in a better state than their patients." After giving this impression of the Edinburgh teachers, he says he shall go to Leyden; he clearly enjoys his studies, for—"I read a science the most pleasing in nature so that my labours are but a relaxation and I may truly say the only thing here that gives me pleasure."

The Royal Medical Society,[2] an ancient students' society in Edinburgh which still exists, admitted Goldsmith as a member in its sixteenth session, for his signature with ten others appears among those who were admitted on Jan. 13th, 1753 *(see figure). Some of his biographers infer that he was* distinguished by not having to read a paper on his admission, but this is not so, for members read their papers some time after admission. He was remembered favourably by the celebrated Black, and we know that several of his fellow students conceived a regard for him. Everything goes to show that at Edinburgh he worked hard at medicine, was interested and happy in it. He relaxed, for he took a *month's trip into the Highlands; he observed the people* when he wrote his famous "description of this unfruitfull country" to his cousin, Robert Bryanton, and he "spent more than a fortnight every second day at the Duke of Hamilton's, but it seems they like me more as a jester than as a companion; so I disdained so servile an employment; it was unworthy my calling as a physician."

His expenses in Edinburgh were paid by his uncle Contarine, his sister Mrs. Hodson, and his brother Henry; he lived honourably within his means; he "was obliged to buy everything since I came to Scotland, shirts not even excepted." His tailor's bill for the year 1753 was what Forster calls[3] "the not very unmoderate sum" of £9 11*s.* 2½*d.*; it included hose and hats, and shows that he liked sky-blue and claret colours. His letters indicate grateful affection for the kindness of his relatives, and in the last letter he sent to his uncle before leaving Edinburgh, he says: "As I shall not have another opportunity of

* Since writing this I learn that Dr. T. P. G. Fitzpatrick has recently given a lecture in Dublin on Goldsmith's Connexion with the Medical Profession.

The Differential Diagnosis of Splenomegaly with the Treatment of the Diseases Concerned. Frid., Dr. L. S. T. Burrell: Bronchiectasis, Abscess of Lung, and Empyema.—QUEEN MARY'S HOSPITAL, Stratford, E., Wed. at 2.30 P.M., Dr. A. A. Osman: Debility in Children and Adults. No fee.—ROYAL EAR HOSPITAL, Huntley-street, W.C., Thurs., 2 P.M., Mr. E. A. Peters: Aural Demonstration. No fee.—ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, W.C. Course in Ophthalmology. Every afternoon. Clinical work and lectures.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Course in Gynæcology. Afternoons and some mornings. Operations and lectures. Two weeks' Course.—VICTORIA PARK HOSPITAL, E. Special Course in Diseases of the Chest for two weeks. All day course, lectures, special demonstrations, and operations.—Further particulars from the Fellowship of Medicine.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, June 10th.—5 P.M., Prof. R. Chambers (New York): Some Aspects of the Protoplasmic Membrane. (Free Public Lecture.)

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

MONDAY, June 10th, 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Neurological Complications of the Acute Specific Fevers.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Mr. Donald Armour: Head Injuries.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Purdon Martin: Hysteria.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Sir Percy Sargent: Cervical Ribs.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.

WEDNESDAY, June 12th.—4.15 P.M., Clinical Meeting. There will be a discussion on Neurological Diagnosis in Children, followed by demonstration of cases of interest in the wards. Tea served at 4 P.M. All practitioners are cordially invited.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

TUESDAY, June 11th.—3.30 P.M. (at the Jessop Hospital): Prof. Phillips: The Early Diagnosis of the Cervix.

FRIDAY.—3.30 P.M., Mr. Cobb: Complications of Middle-ear Disease.

Appointments.

BROWN, R. CHRISTIE, M.S. Durh., F.R.C.S. Eng., has been appointed Obstetric Surgeon to the City of London Maternity Hospital.

WILSON, ARTHUR J., M.D. Edin., Honorary Physician, Coventry and Warwickshire Hospital.

King Edward VII.'s Convalescent Home for Officers, at Osborne, I.O.W.—WALLACE, Sir CUTHBERT, M.B., B.S. Lond., F.R.C.S. Eng.; GASK, G. E., F.R.C.S. Eng.; CHOYCE, C. C., M.D., Ch.B. Edin., F.R.C.S. Eng.; CARLING, E. R., M.B., B.S. Lond., F.R.C.S. Eng.; WILLCOX, Sir WILLIAM H., M.D. Lond., F.R.C.P. Lond.; MILLER, C. H., M.D. Camb., F.R.C.P. Lond.; FLETCHER, H. MORLEY, M.D. Camb., F.R.C.P. Lond.; and PURVES-STEWART, Sir J., M.D., C.M. Edin., F.R.C.P., have been appointed to the Consulting Staff.

Vacancies.

For further information refer to the advertisement columns.

Birkenhead County Borough.—Res. Asst. M.O. £450.

Birmingham, City Hospital for Infectious Diseases, Little Bromwich.—4th Asst. M.O. £300.

Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.

Bootle, Borough Hospital, Derby-road.—Hon. Dental Surgeon.

Bristol General Hospital.—Hon. Clin. Assts.

Buxton, Devonshire Hospital.—Asst. H.P. At rate of £150.

Cambridge, Addenbrooke's Hospital.—Res. Anæsthetist. Also H.P. At rate of £180 and £130 respectively. Also H.S. At rate of £130.

Coventry and Warwickshire Hospital.—Hon. Asst. P. Also Res. H.S. £125.

Derby, Derbyshire Hospital for Women.—H.S. £150.

Dewsbury and District General Infirmary.—H.S. £200.

Dreadnought Hospital, Greenwich. S.E.—H.P. and H.S. Each at rate of £110.

Dublin, Dr. Steevens' Hospital.—Res. Surgeon.

Dudley Guest Hospital and Eye Infirmary.—H.S. Also Asst. H.S. £175 and £150 respectively.

Dunedin, N.Z., University of Otago and Dunedin Hospital.—Sen. Res. Surg. O. £500.

East London Hospital for Children, &c., Shadwell, E.—Res. H.S. At rate of £125.

Exeter, Devon Mental Hospital, Exminster.—Jun. Asst. M.O. £300.

Exeter, Royal Devon and Exeter Hospital.—Asst. H.S. At rate of £100.

Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Res. Surg. O. At rate of £175.

Great Yarmouth General Hospital.—Jun. H.S. £100.

Grimsby and District Hospital.—H.S. £250.

Grosvenor Hospital for Women, Vincent-square, Westminster, S.W. Hon. Gyn. Surg.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S. Also H.P. Each at rate of £100.

Ilford Borough.—Asst. M.O.H., &c. £450.

Kensington, Fulham and Chelsea General Hospital, 194, Finborough-road, Earl's Court, S.W.—Res. Cas. M.O. At rate of £100.

Lancs County Council, High Carley Sanatorium, Ulverston.—Asst. Tub. M.O. £450.

L.C.C. Mental Hospital Service.—8th Asst. M.O. £300.

London Hospital, E.—Cardiographic Department. Paterson Research Scholar. £400.

London Temperance Hospital, Hampstead-road, N.W.—Cas. O. At rate of £120.

Lowestoft and North Suffolk Hospital.—H.S. £120.

Manchester, Ancoats Hospital.—Assist. Pathologist. £150.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Sen. Res. M.O. At rate of £125. Also Radiologist.

Manchester, Salford Royal Hospital.—H.P. Also 3 H.S.'s to Special Departments. Each at rate of £125.

M.A.B., Infectious Hospitals Service.—Jun. Asst. M.O.'s. Each £500.

M.A.B., Sutton, Surrey, Antitoxin Establishment, Belmont Laboratories.—Bacteriologist. £700.

Ministry of Health, Whitehall, S.W.—M.O. £600.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Res. M.O. £250.

Nottingham, Harlow Wood Orthopædic Hospital, near Mansfield.—Res. Surg. O. £250.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Oswestry, Shropshire Orthopædic Hospital.—Locum Tenens H.S.

Perth Royal Infirmary.—H.P. Also Jun. H.S. Each £75.

Princess Louise Kensington Hospital for Children, N. Kensington. Hon. Assist. Surgeon to Ear, Nose and Throat Dept.

Prison Medical Service, Home Office, S.W.—M.O. Class II. £350.

Queen's Hospital for Children, Hackney-road, E.—Surgeon to Ear, Nose and Throat Dept.

Rochdale Infirmary and Dispensary.—Jun. H.S. £175.

Royal Free Hospital, Gray's Inn-road, W.C.—Clin. Assts. to Special Depts.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. At rate of £100.

St. Andrew's Hospital, Dollis-hill, N.W.—Hon. Surgeon to Ear, Throat and Nose Dept.

Sheffield, Lodge Moor Hospital.—Res. M.O. £350.

Sheffield, Royal Hospital.—Residents. At rate of £80.

Sheffield Royal Infirmary.—H.S. £80.

Sheffield Union Hospital, Firvale.—Res. Asst. M.O. £250.

South Shields, Ingham Infirmary.—Sen. and Jun. H.S. £200 and £150 respectively.

Southern Rhodesia Medical Service.—M.O. £500.

Stockport Infirmary.—H.S. £175.

Sudan Government Medical Dept.—Two M.O.'s. LE720.

Swansea Hospital.—H.P. £150.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Tunbridge Wells and Counties General Hospital.—H.S. £160.

Warrington Infirmary and Dispensary.—H.P. At rate of £150.

Watford Peace Memorial Hospital.—Res. M.O. At rate of £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Grimsby (Lincs).

Births, Marriages, and Deaths.

BIRTHS.

EDMOND.—On May 29th, at The Crescent, Shrewsbury, the wife of William Edmond, F.R.C.S., of a daughter.

HOLMWOOD.—On May 26th, at Aldermaston, Berks, the wife of L. S. Holmwood, M.R.C.S., of a daughter.

LAWRENCE.—On June 1st, at a London nursing home, the wife of Dr. R. D. Lawrence, of Harley-street, of a son.

SANSOME.—On May 31st, at Sandwell House, West Bromwich, the wife of T. Heywood Sansome, M.B., Ch.B., of a daughter.

THOMSON.—On May 24th, the wife of Dr. Hugh Thomson, Musgrave Hall, Penrith, of a son.

WILSON.—On May 28th, at Frognall-lane, Hampstead, N.W., the wife of Dr. R. McNair Wilson, of a son.

MARRIAGES.

LAWSON—BLUNDELL.—On June 3rd, at St. Pancreas Church, N.W., Donald B. C. Lawson, M.B., Ch.B., to Catherine Mary, only daughter of Mr. and Mrs. Robert C. Blundell, of Taviton-street, Gordon-square, W.C.

MICHAELIS—SCHWAB.—On May 28th, Theodore David Michaelis to Elisabeth Henrietta Schwab, M.D., B.S., daughter of Mr. and Mrs. S. M. Schwab, of Glenloch-road, Belsize Park.

DEATHS.

BOWES.—On May 28th, at Dormer Cottage, Devizes, John Ireland Bowes, M.R.C.S., in his 80th year.

BRANTHWAITE.—On June 2nd, at 16, Percival-road, Clifton, Bristol, Robert Welsh Branthwaite, C.B., M.D., D.P.H., Director of Medical Services, Stoke Park Colony, Bristol, and late Commissioner, Board of Control, aged 70.

KENNEDY.—On May 13th, at Alassio, William Willoughby Kennedy, M.A. Glasg., M.B. Lond., D.P.H. Camb., M.D. Lond., aged 66.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

court of tumble-down houses and many lines of clothes hanging out to dry. The keeper of this wretched house—Goldsmith had but one chair—was taken by bailiffs, the lodger was in debt for rent, so the gay suit bought for the examination was pawned and the four books for review were pledged for a loan from a friend. Directly this was done a note from Griffiths arrived, demanding repayment, and Goldsmith wrote to him a letter, "the most interesting of all the Goldsmith papers that have been preserved to our time."

During the next few years his chief work was writing, but he saw a patient or two, for in a beautiful essay called "The Indigent Philosopher,"[4] written in 1762, he tells that he had just returned from the funeral of his friend, Sir William Abner. "I attended him as his friend and Physician during his last illness. I soon saw that he was dying, and was glad of it. He was leaving a world unfit for him."

In 1765 Reynolds told Goldsmith that it would be a good thing if he had a regular calling and was both a physician and a man of letters, consequently he dressed up in purple silk small-clothes, a handsome scarlet roquelaure, a full dress wig, a sword and a gold-headed cane, but the physician did not like it, for, said he, "here am I shut out of several places where I used to play the fool very agreeably." He tried practice for six months and had a patient, Mrs. Sidebotham; she, when her physician differed from her apothecary, sided against the physician, who thereupon left the house in high indignation. This appears to have been the end of his attempts to practise, although, as he was almost always known as Dr. Goldsmith, as Hawes calls him a brother practitioner, and as while in "Jupiter and Mercury" Garrick leaves out the doctor in speaking of Goldsmith as "this scholar, rake, Christian, dupe, gamester, poet," there is much about him as a doctor in Garrick's prologue to "She Stoops to Conquer," it is quite possible that he may have occasionally seen some patients for the rest of his life. This suggestion would also explain why he took his M.B. at Oxford. On Tuesday, Feb. 14th, 1769, Johnson, Percy, and Goldsmith went to Oxford, they dined at University College, Queen's, and Trinity, and *Jackson's Oxford University Journal* for Saturday, Feb. 18th, 1769, says: "Yesterday Oliver Goldsmith Esq., Bachelor of Physic of the University of Dublin . . . was admitted in congregation to the same degree in this University."[5]

Medicine in Goldsmith's Writings.

Be this as it may, Goldsmith certainly did not now greatly care for the profession of medicine, and he wrote so much on general topics that he cannot have had time for it; the catalogue of his books which were sold at his death contains hardly any on medicine, and the reader of his works will find few references to medicine, and nearly all that can be found are so vague that they might have been written by an author who was not a doctor. The parson and schoolmaster, but not the doctor, are described in "The Deserted Village," the only reference to him in "The Vicar of Wakefield" is in Chapter III.: "Physicians tell us of a disorder, in which the whole body is so exquisitely sensible, that the slightest touch gives pain." He is not mentioned in "She Stoops to Conquer," but in the intended epilogue Goldsmith wrote:—

"Doctors who cough and answer every misfortuner,
'I wish I'd been call'd in a little sooner.'"

In "An Enquiry into the Present State of Polite Learning in Europe," the only sentence that even suggests that the author is a doctor is in Chapter XII. "In an infirmary, the student who only attends to the disorders of a few patients is more likely to understand his profession than he who indiscriminately examines them all." "The Man in Black" is autobiographical, but there is no reference to medicine in it, nor is there in the rest of the "Citizen of the World," but in *The Bee*[6] we find in the article on Education this invaluable advice for children, "No luxurious dishes with high seasoning, nothing given to children to force an appetite, as little sugared and salted provisions as possible, though never so pleasing; but milk morning and night, should be their constant food . . . it corrects any consumptive habits." Modern research has indeed vindicated Oliver. In a review of "Philosophical Miscellanies on Various Subjects," by M. Formby,[7] Goldsmith shows that he has read some physiology, for the speaks of the secretion of sweat and the relation of the cerebrum to voluntary motion, and when writing of the inhabitants of different climates he also mentions the secretion of sweat.[8] In the Epilogue to "The Good Natured Man" (published in 1767) we find:—

"No no, I've other contests to maintain;
To-night I head our troops at Warwick Lane."

This refers to the fact that in 1767 the Licentiates of the Royal College of Physicians which was then in Warwick-lane, marched in a body to the College, demanding to be present at Comitia meetings. The President and Fellows locked themselves in, but the Licentiates hired a blacksmith to force the door and filled the College. Sir William Browne, the President, dissolved the Comitia.‖

There were two subjects, hydrophobia and quacks, about which Goldsmith wrote a good deal, no doubt because, being a physician, he was interested, but what he wrote does not show any special knowledge: it might have been equally well-written had he not been a doctor. It is difficult for us to conceive the fearsome, justifiable dread that our ancestors had of hydrophobia, always fatal and the most terrible of deaths, as I know from having seen persons die of it. Medical writings of the eighteenth century are full of cases and of supposed cures. Dogs were killed by hundreds. Goldsmith tried hard the humane task of alleviating the horrible fear, chiefly by pointing out that the bite of a dog often did not kill. This was true, for the dog might not be mad, and if he were, the bite was usually harmless when through the clothes, for they absorbed the poisonous saliva, thus:—

"And while they swore the dog was mad
They swore the man would die
But soon a wonder came to light
That show'd the rogues they lied
The man recover'd of the bite
The dog it was that died."

In letter Sixty-Nine of the "Citizen of the World" he ridicules the fear of mad dogs, and in the "Progress of the Arts in Switzerland"[9] he says "as we have been, frequently of late, teized with cures for the bite of a mad dog," and he goes on to say that pimpernel tea has been recommended, he describes how to make it, but expresses no opinion.

We have seen in a letter to his uncle, written from Edinburgh in 1753, that he speaks scornfully of quacks. They flourished in his time like weeds. They are ridiculed and satirised in letters Twenty-four and Sixty-eight of the "Citizen of the World": a doctor Rock§ is especially castigated. Inasmuch as James Powder was then considered a quack remedy, the general outcry against quacks was inflamed by Goldsmith's death and that of a Mr. Scawen.

He seems to have known some of the notable men in the medical profession, for he wrote humorous verses in reply to an invitation to dinner with George Baker, who became President of the College of Physicians, discovered the cause of lead colic, and did a large fashionable practice. His nephew, Mrs. Hodson's son, came to London and, on the advice of his uncle Oliver, studied medicine; his uncle wrote a letter introducing him to William Hunter, the original is in the possession of the Royal College of Surgeons. The uncle reported to Mr. Hodson that the student made good progress and that he had obtained for him the post of full surgeon in India. Katherine Balderston prints the following short note of Goldsmith's: "Dr. Goldsmith presents his compliments to Dr. Mackenzie, he will be at home this day till three, or at any other time the doctor shall appoint. Or he will wait upon him at Southwark. He is engaged to dinner every day for this six or seven days." I have tried, as others have done, to find out who this Dr. Mackenzie can have been, but I have not succeeded.

Thanks to Ronald S. Crane there has recently been brought to light the remarkable fact that Goldsmith[10] introduced Auenbrugger's discovery of percussion to England immediately upon the publication of his book in Vienna in 1761. Goldsmith gives an admirable abstract of the book, and concludes: "Such are the outlines of this new discovery; whether it may be of use to society or not, there is no necessity for me to pretend to determine, only this may be observed, that the lungs are often in the most healthy state, found to adhere to the pleura, and in such a case, I fancy the sound would, in that part, deceive the practitioner; however, I shall not pretend to set up my conjecture against his experience." Auenbrugger's discovery of percussion had to wait several years before it was generally recognised, this was not the fault of Goldsmith, and it is pleasant to think that an Englishman noticed it immediately, even before Roziere de la Chassagne, to whom the credit is usually given.[11]

Death of Goldsmith.

John Forster tells us that in 1762 Goldsmith was not well and went to Tunbridge and Bath, that he was severely ill in 1772 with strangury from which he obtained relief by James' powders, about which he became a bigot. He arrived in London in the middle of March, 1774, having recovered from a recurrence of his disease, but on March 25th he took to his bed in his chamber in Brick Court, where his bedroom was a closet without any light in it. This fatal illness led to so much controversy, that his loving friend,

---

‖ I am indebted to Dr. Arnold Chaplin for this information For a full account of the dispute, see "Medicine in England During the Reign of George III.," by Arnold Chaplin, M.D., London, 1919.

§ For an account of Rock see "The Quacks of Old London," by C. J. S. Thompson, London, 1928.

William Hawes,[¶] the apothecary, called in to attend him, published a pamphlet, "An Account of the late Dr. Goldsmith's Illness so far as relates to the Exhibition of Dr. James' Powders," by William Hawes, Apothecary, London, 1774. He dedicated it to Sir Joshua Reynolds and Edmund Burke. In the dedication he says: "I have reason to believe some persons have formed very unjust and uncandid notions respecting my conduct in the affair." Hence the pamphlet. Hawes tells us that Goldsmith sent for him at 11 P.M. on Friday, March 25th, 1774. The patient had violent, intensive frontal headache, no pain elsewhere, no shivering, a moist tongue, pulse 90. He told Hawes that he had taken two ounces of ipecacuanha wine as a vomit, and that he desired to take James' powder. Hawes said he thought this would do harm and suggested an opiate. Goldsmith was obstinate, and Hawes remarks on the difficulty of treating a brother practitioner. The argument lasted half an hour, Goldsmith would not give way, so Hawes had to say that the taking of the James' powder would be without his approbation, and he suggested calling in Dr. Fordyce; this led to more argument, but finally Goldsmith consented. Fordyce went the same night and by the time he reached Goldsmith's chambers the patient had already taken two or three doses of the powder, which had operated as a purgative and emetic. Fordyce disapproved of the taking of the powder.

Hawes went to see Goldsmith the next (Saturday) morning and was told he was dozing, and so did not go up to him, but called in the evening, when he found him very ill with great diarrhœa and vomiting, and his servant said that Goldsmith had continued to take James' powder; he was much reduced and his pulse was very quick and small. Goldsmith said to Hawes, in a low voice, "he wished he had taken my friendly advice last night." He seemed to have neither spirits nor strength to speak more. The same evening Dr. Fordyce called on Hawes and said that Goldsmith had done himself such injury by taking James' powder that he proposed to call in Dr. Turton. At 8 A.M. on Sunday morning Hawes went again and found the patient much worse, very weak, much vomiting and diarrhœa; with Goldsmith's consent he sent for Turton. Drs. Fordyce and Turton met at the time appointed to assist at a consultation, which was continued twice a day till the patient died on April 4th, 1774.

After Goldsmith's death paragraphs appeared in the papers[**] ascribing it to James' powders; this aroused replies in the *Morning Post*, which published accounts of his illness from Mary Ginger, wife of the head porter of the Inner Temple, who attended on him for the last five years of his life; Sarah Smith, the nurse who nursed him in his fatal illness and John Eyles (his servant), all of whom declared that the patient had much less James' powder than Hawes states and that he was very angry with Hawes because he had sent powders which were not James' powders. Mary Smith says that at the funeral Hawes said that James' powder was the occasion of death. A letter from Sal. Glauberi attacks Hawes in such wretched taste that I instinctively distrust the writer; he is answered temperately by another correspondent. Francis Spilsbury,[12] who, although he defends the use of quack medicines and abuses Hawes, concludes that Goldsmith's death was "owing to an undeniable and demonstrated injudicious use of James' powder," and later on he says: "Therefore I will not deny that to them (James' powders) the death of Dr. Goldsmith may be imputed." Reading the available documents, the impression given is that there is not sufficient evidence to determine the primary illness, that death was much accelerated by antimony poisoning,[††] that Hawes' is a fair account; that probably the proprietors of James' powder were afraid that Goldsmith's death would lessen the sale of the powders, and that Hawes was trusted by Goldsmith's friends for, after the death, Reynolds and Burke honoured him with the management of the disposition and sale of Goldsmith's furniture and books, and Maurice, Oliver's brother, warmly thanked him for all that he had done.

[¶] A greatly respected, able man, physician to the London Dispensary. He did much work on the resuscitation of the apparently drowned, he founded the Royal Humane Society, and published "An Examination of the Rev. John Wesley's Primitive Physic." See Gentleman's Magazine, 1808, lxxviii., 1121.

[**] The copy of Hawes' pamphlet in the Royal Society of Medicine Library has some of these newspaper cuttings bound up with it.

[††] Kenrick, one of Goldsmith's enemies, actually suggested that he committed suicide by taking the powder.

DIAGNOSIS OF MENOPAUSE.

To the Editor of THE LANCET.

SIR,—Most medical practitioners agree that the signs and symptoms usually associated with the menopause are so vague that a sharply defined diagnosis is often impossible. In my own experience I have found certain signs to be definitely associated with the menopause, and I should be grateful if other investigators could inform me if they have observed them. In certain cases the condition of the hands has arrested my attention; on examination they appear to be painted with red pigment on the palmar aspects—on the fingers near their tips, the radial aspects of the thumbs on the terminal phalanges, the thenar and hypothenar eminences, and above the creases on the wrists. In other words, the condition can be imitated by placing the palmar aspects of the hands lightly (and as if by accident) on a table smeared with "wet paint" and immediately withdrawing them. The condition is transient, while the usual pressure signs mark it as vascular.

I am, Sir, yours faithfully,

Dublin, May 29th, 1929. JOHN V. RYAN M.B., B.Sc.

ON GOAT KEEPING.

THE British Goat Society's Year Book for 1929 is now in its ninth annual issue and contains much useful information for keepers and breeders. There are several contributions by medical men. Dr. W. Ker Bell has an interesting note on Goats' Milk and the Value of its Calcium Content, while Mr. F. E. Corrie, B.Sc., discusses the value of the iodine content of milk both to the goat and the drinker of its milk, such content being controlled by the food supply. Dr. R. T. Leiper, F.R.S., Director of the Institute of Agricultural Parasitology, deals with the Internal Parasites of the Goat, pointing out that the worm infestations accumulate in the animals not by multiplication inside but by the addition of new parasites to the feeding grounds of the goat due to accumulative droppings. "If one could find a drug" says Dr. Leiper, "which would at a single dose remove all the parasites from the inside of the goat, the animal would again become infected very soon from the young stages in the grass in its paddock." Speaking of the two aspects of the Institute's work, prevention and treatment by new methods, Dr. Leiper sees in their coöperation the ultimate relief of suffering. Among other articles of interest are the Constituents of Food and their Fate in the Animal Body by Mr. A. B. Orr, M.R.C.V.S., Goats' Milk as a Food by Mr. J. C. Urquhart and Mr. F. Knowles, and the Mechanics of Digestion by Mr. H. Stainton, F.R.C.V.S. The annual, which is well illustrated, contains the rules and regulations of the British Goat Society, a list of judges for the year, and the names and addresses of members. It can be obtained from the hon. secretary, Mr. Thomas W. Palmer, 10, Lloyd's-avenue, London, E.C.3., price 1s. 6*d*.

THE NON-FRENCH WINES.

WHILE France is par excellence the country which produces the most satisfactory as well as the most beautiful wines known to us, many claim that Germany, with its hocks and moselles, offers at least as high and delicate an invitation to the palate as anything that Bordeaux or Bourgogne can give, while Portugal and Spain make claims of high character on different grounds, and the wines of Italy, especially as drunk in Italy, have qualities of their own which win them many admirers. Mr. Shand, who has already written on food and wine generally, and an excellent book upon French wines,[1] now introduces us to a category of the wines of Portugal, Spain, Germany, and Italy, and also of Switzerland, Austria, Hungary, and the new state of Czecho-Slovakia, and, lastly, of the British Empire. He sets out under each wine its claims and its qualities, and in many cases the mass figures of its production, giving the reasons for his judgments and also much useful information of a general character. A valuable glossary is added. The book will be found a practical work of reference and will also help doctors in advising patients as to their diets.

Croonian Lectures

ON

SOME CHEMICAL FACTORS IN THE CONTROL OF THE CIRCULATION.

Delivered before the Royal College of Physicians of London

BY H. H. DALE, M.D. CAMB., F.R.C.P. LOND., F.R.S.,
DIRECTOR OF THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH.

LECTURE II.*

LOCAL VASODILATOR REACTIONS.—HISTAMINE.

(Delivered on June 6th, 1929.)

HISTORICAL.

I THINK it will be helpful to appreciation of the present position of the evidence on the physiological significance of histamine if I very briefly sketch the history of our knowledge of that substance from the beginning.

Histamine, which can be regarded chemically as the amino-acid histidine deprived of a molecule of carbon dioxide, was first made synthetically, as a chemical curiosity, by Windaus and Vogt.[1] The first hint of its physiological interest was obtained when Barger and I[2] were seeking for a principle in certain ergot extracts, which we had recognised by its potent stimulating property on the muscle of the isolated uterus, associated, apparently, with a pronounced depressor action, when administered intravenously to a cat, Barger isolated a small quantity of this substance in pure form; and the fact that Ackermann[3] had simultaneously shown that certain bacteria decarboxylate histidine, helped us to identify our substance from ergot as the base now known as histamine. When Laidlaw and I[4] came to investigate its action in detail, the remarkable resemblance between its effects in different species and those which, in the same species, had then recently been described as characteristic of the anaphylactic shock, soon became clear. It became clear also that, in each species, the corresponding physiological complex was produced by various organ extracts and products of protein digestion, in which the presence of unknown "depressor principles," lowering the mammalian arterial pressure by an incompletely analysed reaction, had long been recognised. The presence of such a "depressor" substance, in addition to the specific pressor principle, had been observed in pituitary extracts by Schafer and Vincent.[5] Oliver and Schafer[6] had obtained a "depressor" action with extracts of thyroid gland, Mott and Halliburton[7] with extracts of brain and nervous tissues, Vincent and Sheen[8] with extracts of liver, muscle, and various glandular organs. The substance first suspected as the cause of this activity was choline, and we shall see later that a choline action does contribute largely to the total vasodilator action of certain organ extracts, and has its own special physiological interest. Vincent and Sheen, however, finding that the extracts which they were examining retained a large part of their depressor action after atropine had been administered, rightly concluded that choline was not the chief agent responsible.

At the time when Laidlaw and I were investigating the action of histamine, the action of Bayliss and Starling's secretin was in the centre of physiological interest. This extract of the intestinal mucosa, like other organ extracts, had been found by them to contain a powerfully depressor substance, distinct from the hormone of pancreatic secretion. The opportunity was taken of investigating this depressor agent, and Barger and I[9] actually obtained at that time, from an extract of intestinal mucosa, a small quantity of pure histamine. The significance of this, however, was far from clear. On the one hand, the amount isolated represented only a very small proportion of the activity of this type in the original extract; and, on the other hand, the histamine had been obtained from such a source that contamination with intestinal contents, in which histamine would certainly be produced by bacterial action, could not be excluded. The observation, in any case, remained for some years an isolated one; and such evidence as accrued in this interval was on the whole against the identification with histamine of the unknown depressor principle, the so-called "vasodilatin," so readily yielded, to simple extraction with water or alcohol, by most of the organs and tissues of the animal body. On the one hand it had been observed, for example by Stern and Rothlin[10] working with the spleen, that the principles occurring in natural organ extracts, while admittedly resembling histamine closely in their action, were apparently destroyed by chemical treatment to which pure histamine was completely resistant. On the other hand, by the time that Laidlaw and I resumed, about 1917, the physiological analysis of the action of histamine, in conjunction with Prof. Richards, of Philadelphia, the production of the "anaphylactoid" effect by intravenous injection of various substances had become familiar; and many of these had not the remotest chemical connexion with histamine. Such effects had been produced, for example, by salvarsan, by colloidal carbohydrates such as agar-agar, and by solutions of the heavy metals when these various agents were injected intravenously. We felt ourselves *driven to admit that community of the resulting* symptom-complex could provide no reason for inferring community, or even similarity, of chemical structure. As Laidlaw and I[11] wrote at that date: "The existence of these points of community, in the action of substances so utterly unrelated chemically as histamine and certain metallic ions, forbids any assumption that the production of similar effects, by unknown constituents of some organ or tissue, indicates the presence therein of histamine itself, or of any substance chemically related to it." I think we were right in deprecating such an assumption on the evidence then available; but, in the light of present knowledge, it is clear that we had not given proper weight to one possibility—namely, that the substance extracted from animal tissues might indeed be histamine, and that the metallic ions and the various colloids might produce similar effects on injection, by causing liberation of histamine by injury of the cells containing it.

The first definite claim to the chemical identification of histamine as the essential depressor constituent of a number of animal organs and tissues was made by Abel and Kubota[12] in 1919. Their evidence, unfortunately, failed to carry complete conviction. They actually isolated histamine salts from two of the many tissues investigated. One was the pituitary body. In this case the significance of their finding was complicated by two circumstances. Even the small quantity of histamine which they obtained was far too large to represent the depressor constituent of really fresh pituitary substance, and they wrongly supposed that they had obtained, and identified as histamine, the essential oxytocic principle of the posterior lobe. It was impossible to avoid the suspicion that the material which they used had undergone some putrefactive alteration. The other tissue was the gastro-intestinal mucous membrane, in which case their observation, substantially confirming the earlier one by Barger and myself, was open to the same criticism as ours had been. Abel and Kubota's work reopened the question of the presence and physiological significance of histamine in the living tissues; their conclusions, as more recent work has shown, were substantially correct; but the evidence left these conclusions open to doubt, and they met with no general acceptance.

---

* Lect. I. appeared last week.

HISTAMINE AS A NORMAL CONSTITUENT OF MANY TISSUES.

The opportunity for the renewed activity of my own laboratory in the direct investigation of the depressor constituents of tissue extracts was created by circumstances having no immediate relation to our earlier work on histamine. Somewhere about the year 1926 interest arose, in more than one centre of investigation in Canada and the United States, in claims made for the injection of extracts prepared from the liver as a specific treatment of morbidly high arterial pressure. Dr. Best, of Toronto, who was due to spend some months in my laboratories, brought with him samples of the liver extract then being prepared and used in Toronto for the purpose mentioned, and showed us the method by which, at the time, the activity of the different batches of this extract was being physiologically controlled. We were not directly concerned with the therapeutic value of this liver extract. Samples of it were used, in carefully controlled therapeutic trials carried out in Sir Thomas Lewis's wards, by Dr. Iris Harmer, who failed to find evidence of genuine therapeutic value; and I think it may be assumed that this treatment has not justified the high hopes at one time entertained by its advocates. Our problem, however, was to discover, if possible, the chemical nature of the substances producing the immediate depressor action, which was being used in the laboratory as an index of the value of this extract; and our opportunity was created by the expectation of its value in therapeutics, which, for the time being, made it available on a large scale. Dr. Best and I had the advantage of coöperating with my chemical colleagues, Drs. Dudley and Thorpe.[13]

In the vasodilator activity of this extract we easily recognised two different factors—an action resembling that of choline, affecting the stronger arterioles, and an action resembling that of histamine, confined to the minute vessels and capillaries. We could make an artificial mixture of choline and histamine, indistinguishable in its action from the liver extract. Yet, on the chemical side, the properties of the principles producing these effects were difficult to reconcile with these physiological identifications. The principle acting like histamine, in particular, appeared to have some chemical properties quite unlike those of histamine. At several stages we had almost concluded, as have other workers with organ extracts, that it could not be histamine itself. We were only saved from this error by observing that, when histamine was added to the extract, its chemical behaviour showed similar anomalies; it now behaved like the natural vasodilator principle rather than like itself in plain watery solution.

Not to trouble you with details, I may say at once that we eventually isolated, from these alcoholic extracts of perfectly fresh liver, both choline and histamine; and we obtained them, not merely in sufficient quantities for complete chemical identification, but in such amounts, in relation to the activities of the original extract, as to make it unnecessary to suppose that any other more complex or unidentified principles contributed to the depressor, vasodilator action. Having reached this, at the time, unexpected conclusion concerning the liver extract, we turned our attention to the lung. I had long known that this organ yielded an extract having a peculiarly intense depressor action. We now found that the choline component in this action was relatively very weak. Almost the whole of the activity was of the histamine type, and we had comparatively little difficulty in isolating the histamine, again in such quantity as to make it unnecessary to suppose that any other more complex substance contributed to the activity of the original lung extract. Table I. shows the figures obtained, for the histamine contents of the liver and lung extracts, at different stages in the purification, by physiological estimates at all stages except the last, where the value given is the actual weight of histamine base contained in the pure dipicrate which was isolated. There is no ground for suggesting that the loss at any one stage is so disproportionately large as to indicate removal of a different active substance, or that, in any case, it is greater than was to be expected in the separation of a small quantity of the active base from a relatively enormous quantity of other materials.

Best, Dale, Dudley and Thorpe: Jour. Phys., 1927, lxii., 397.

Being able now with some confidence to assume that a histamine-like action of an organ extract was due to histamine itself, we could make a rapid survey of a number of organs, making extracts under standard conditions, and assaying them for histamine by the physiological method. Table II. shows figures obtained in this way and published by Dr. Thorpe.[14] Some of these estimates, particularly those made on the spleen, need revision in the light of more recent knowledge as to the intensity of the choline-like action which certain extracts may exhibit. In general, you will notice the relatively enormous histamine content of the lung, and the low position in the scale of skeletal muscle. The fact that, nevertheless, histamine was actually isolated and identified among the mass of basic constituents which muscle yields to extraction, is greatly to the credit of Dr. Thorpe's skill and tenacity. More recently Dr. Dudley has isolated histamine from spleen extract, again in sufficient quantity to account for the activity of this type shown by the extract.

Data mostly from Thorpe: Biochem. Jour., 1928, xxii., 94.

We were also able to test a question of great physiological interest—namely, whether the histamine which we thus extracted from a tissue, such as that of the lung, was present during life or formed rapidly after the death of the cells. We found that a lung taken from a living, anæsthetised animal, and frozen immediately in strongly cooled alcohol before mincing, yielded as much as the other lung, left for an hour or two in the dead body before removal. Best has recently shown that sterile autolysis of the tissue at body temperature is actually accompanied by the disappearance of histamine, through some action of which the nature is yet unknown. Histamine had evidently as good a claim to be regarded as a normal constituent of the living cell, as had any other substance which similarly conservative methods could extract. It must either preexist during life, or be formed in the very act of cellular death.

HISTAMINE AND LEWIS'S H-SUBSTANCE.

Our chemical investigation, having arrived at this point, obviously began to have an important bearing on the conclusions which Lewis and his colleagues were reaching independently. They had evidence that the living cells of the skin, when subjected to irritation or injury, liberated a substance with an action remarkably like that of histamine. We had shown that the cells, of all the organs which we had examined, yielded histamine itself to the simplest and most conservative methods of artificial extraction, and that all this histamine had apparently existed, in some form, in the living cell. The suggestion was obvious that the substance liberated by the living but injured cell, Lewis's H-substance, was histamine itself, not newly formed in response to the stimulus, but already existing in the cell-interior, and only becoming active on liberation. We had not indeed, and have not yet, obtained chemically identifiable histamine from skin; the technical difficulties of disintegrating the freshly separated, living skin, in sufficient quantity for such chemical work, have not yet been overcome. Harris,[15] however, in Lewis's laboratory, had no difficulty in proving that the skin of man and other mammals, extracted by processes similar to those which we used for other tissues, yielded a substance physiologically indistinguishable from histamine. Measurements in comparison with pure histamine solutions, with the use of such different physiological reactions as the depressor action on the cat's arterial pressure, the stimulant action on the isolated uterus of the guinea-pig, and the whealing effect on the skin of the human subject, gave concordant values. Harris also tested the question of the pre-existence of this substance in the skin cells, or its new formation on injury, by estimating the amount of the histamine-like substance present in normal cat's skin, and in a symmetrical, originally equal area rendered œdematous by scalding. The scalded skin had lost the H-substance in comparison with the normal; so that the result was in complete conformity with our own evidence, that the histamine extracted from a tissue exists preformed during life, and is not produced by post-mortem change.

So far the indications seemed to be all in favour of the identification of the substance released from living cells, in response to injury, with histamine, which can be so easily extracted from them by procedures involving their death. Lewis, in his book, while acknowledging the many points in favour of such an identification, prefers to refer to the substance liberated during life as the H-substance—a name designed to leave the question of identity open, while recognising the many suggestive points of analogy. It must be admitted that *complete* proof of the identity could only be obtained if the H-substance could be trapped, in œdema fluid or in blood or lymph leaving an injured area, in sufficient quantity to make its chemical isolation practicable. The difficulty, however, of such an enterprise would be not merely the sufficiently formidable one of quantity. H-substance, by common consent, is normally present inside the cells of the tissue. When we have attempted to extract it, we have invariably obtained histamine. If H-substance is not histamine, therefore, it is a substance which immediately yields it, when the simplest and least injurious procedures which we can devise are applied to its extraction from the cells, and its isolation for chemical study. We have no reason to expect that, when it had been liberated from the cells, H-substance would be more stable under such treatment; so that, even if chemically recognisable histamine were obtained from extra-cellular H-substance, the fact would add but little to our knowledge, and leave the question of identity almost as open as it is at present.

Accepting this lack of complete chemical evidence as, for the time being, inevitable, I think we should do well to beware of exaggerating its importance. Strictly speaking, we have as good chemical evidence of the presence of histamine in the cells of the body generally, and of its liberation from them under certain conditions, as we have of the existence of adrenaline in the suprarenal medulla, and of its secretion as such into the blood. All that we really know, in the latter case, is that adrenaline can be extracted from the gland, and isolated from the extract by suitable chemical procedures; and, further, that something, indistinguishable from adrenaline in action, is liberated into the blood leaving the gland when the splanchnic nerves are stimulated. Chemical evidence has not excluded, and is unlikely to exclude, the possibility that adrenaline may exist in the cell, and be secreted into the blood, not as free adrenaline, but as some more complex "A-substance." We assume, and I think rightly, that adrenaline is itself the physiological agent; and the real difficulty, in making the analogous assumption with regard to histamine, has arisen, not so much from the small gaps in the chemical evidence, as from the doubt as to whether histamine would fulfil all the physiological requirements.

Difficulties in the Identification.

One of the difficulties, which appears to have weighed with Lewis, is the relatively long persistence of some of the effects attributed to liberation of the H-substance; whereas we should expect that a substance so diffusible as histamine, as we know it in watery solutions of its pure salts, would be carried rapidly away in the blood stream. It is not easy to appraise the true significance of this apparent discrepancy. Direct evidence as to its meaning is not available; but there are not wanting indirect indications, such as the pronounced tendency of histamine to enter into loose combinations with colloidal substances, especially at certain reactions, which may well prove to have a bearing on the apparent behaviour of the H-substance. In circumstances altering the physiological condition of the cell-substance, histamine might be liberated, in one case free, in another loosely combined with products of large molecular weight and low diffusibility; on the other hand, changes in the neighbourhood of its liberation might greatly influence the tenacity of its adsorption by the tissues with which it comes into contact. It should be remembered, in this connexion, that the H-substance does not always give this appearance of low diffusibility, or close restriction of its action to the locality of its liberation. The subject of factitious urticaria owes his abnormality, according to Lewis, to the readiness with which the H-substance is liberated from the cells of his skin, in response to relatively mild mechanical stimulation. In such a subject Lewis found that the simultaneous production of wheals over a large area of skin was quickly followed by a distant dilator reaction of the small vessels of the blushing area on the face and neck, entirely comparable to that produced by introduction of a suitable, small dose of pure histamine into the general circulation. H. Kalk[16] has recently published observations to demonstrate that stimulation of the skin, in subjects of dermatographism, is followed by secretion of an acid gastric juice. This would indicate, not only that the H-substance may be quickly absorbed in significant amount from the site of its liberation, but that it shares yet another of the characteristic activities of histamine—namely, that on the gastric secretion.

While, therefore, some of the phenomena connected with the H-substance are not easy to reconcile immediately with the supposition that it is free histamine, there are others which would be equally difficult to explain, if it were supposed to be a much more complex and indiffusible body. If these difficulties alone were in question, it would seem rational, and entirely compatible with what we know of its properties, to suppose that histamine is the active constituent of the H-substance, and that the latter, according to the varying conditions of its liberation, may represent all grades of molecular association, from free histamine to relatively large and indiffusible complexes. The term "H-substance" would then no longer represent a hypothetical chemical entity, which might be histamine or something entirely different; it would represent a group of loose molecular combinations, of varying complexity, in which histamine may be liberated from cells during life, and to all of which it may impart its characteristic physiological actions.

I believe that such a conception would reconcile all the various facts yet available, concerning the natural tissue-reactions and the analogous effects of histamine, in man and the carnivora. I know of no other which would adequately account for the remarkable range of identities in action, and also for the minor apparent divergences in behaviour.

More serious difficulties arise, however, if we attempt to apply such a conception to all vertebrate animals. Laidlaw and I early pointed out that the rabbit, under ordinary conditions of experimental anæsthesia, failed to show the depressor, vasodilator response to small intravenous injections of histamine, which is so striking a feature of its effects on the cat, the dog, and the monkey; yet the rabbit does not lack the local vasodilator reaction to injury. Later evidence has weakened the significance of this contrast. Lewis observed that histamine would cause congestion and œdema of the rabbit's conjunctiva when locally applied, and Feldberg,[17] in my laboratory, demonstrated the general dilator response to histamine of the minute vessels of a rabbit under chloralose, and in the denervated ear of a rabbit without anæsthesia. There is not, accordingly, the sharp discrepancy which earlier evidence suggested, between the reactions of herbivorous and other mammals. It may be that the two effects of histamine described by Lewis—direct dilatation of minute vessels, and reflex dilatation of stronger arterioles—differ in relative prominence in different mammalian types. It should be noted that our chemical identifications of histamine in tissue extracts, needing large-scale work, have been carried out with organs from oxen and horses.

In the case of the frog, on the other hand, the lack of vasodilator action by histamine, which Laidlaw and I also first indicated, constitutes a genuine and complete discrepancy. Grant and Jones[18] have observed that the vessels of the frog's skin, and of the mucous membrane of its tongue, show local dilatation responses to injury or irritation, closely analogous to those seen in the skin of man. Histamine, on the other hand, whether locally applied or injected into the general circulation, produced no effects in the frog having any relation to these local dilator reactions, or in any way compatible with its participation in their production. Yet extracts from the frog's skin, similarly applied to the mucous membrane of its tongue, reproduced the vascular effects of mild injury as faithfully as human skin extract, or histamine, evokes the analogous response in human skin. Later they found that the wheal-producing extract from mammalian skin, when freed from excess of inorganic salts, was as inactive as histamine on the frog's mucous membrane. The frog-skin extract, on the other hand, contained a substance resembling histamine in its general chemical properties, and reproducing the various known actions of histamine on mammalian vessels and plain muscle, though with widely different relative intensities; it exhibited, in addition, the dilator action on frog's vessels, which histamine does not possess at all. The meaning of these results seems perfectly clear. So far from weakening the resemblance between the H-substance of *mammalian* skin and histamine, they add another and highly significant similarity, in the failure of both to dilate the vessels of the frog's tongue. The vasodilator principle of frog's skin, on the other hand, is clearly a different substance, though it appears to be a base akin to histamine in some of its chemical properties.

Viewed as a whole, the evidence seems to indicate histamine, in the mammals chiefly investigated, as a generally distributed constituent of the cells of the normal body, inert while it remains within the cell, but intensely active in producing local vasodilator reactions, when appropriate stimuli release it from the cell into the tissue fluid, either free or in molecular combinations of varying complexity. In other vertebrate types, such as the frog, some other basic substance, possibly allied to it, appears to replace histamine in distribution and function.

PROBLEMS OF THE PHYSIOLOGICAL SIGNIFICANCE OF HISTAMINE.

From such a conclusion a number of interesting physiological questions immediately arise. We may inquire, for example, whether the cells which are so exquisitely sensitive, to the presence of traces of histamine in the surrounding medium, themselves hold it inactive in their protoplasm; or whether, on the contrary, the cells from which it is released to produce its effects are of a different kind, and are themselves insensitive to its presence, in any relation to their walls. In the skin, which has been so much more completely studied in this connexion than other tissues, the evidence seems to be in favour of the latter alternative. Harris's experiments, in Lewis's laboratory, show that the histamine which can be extracted from skin is yielded chiefly, if not entirely, by the cells of the epidermis. There is no reason for supposing that the epidermal cells react to histamine in any way; so that the evidence is in favour of attributing the local vascular reactions of the skin to histamine liberated largely from cells which do not otherwise participate in the reaction. On the other hand, the endothelial and plain muscle cells, of the minute vessels concerned in the vascular reaction, form so small a part of the total mass of the skin tissue, that we cannot conclude from such evidence that they do not also contain histamine themselves. To glance for a moment at other effects of histamine than that on the minute blood-vessels, the activity which first brought it to my notice was its intense stimulation of the plain muscle of certain hollow viscera, particularly of the uterus and the bronchi. My colleagues and I have not chemically investigated plain muscle by itself, but some of Abel and Kubota's evidence suggests that it is relatively rich in histamine. If this is the case, its presence there indicates for histamine another type of physiological function; released by stimulus or injury from plain muscle, it will not only cause local vascular dilatation but play a part in exciting or maintaining the contractile reaction, either of the muscle cells directly injured, or of others in their immediate neighbourhood.

The fact that lung, the only tissue of those available for large-scale extraction which contains so high a proportion of endothelial cells, also contains by far the highest proportion of histamine among organs yet investigated, suggests, again, that endothelial cells must be rich in this base. It seems safe to conclude, however, that the histamine causing the evanescent vascular response to mild injury is largely a product of other cells in the neighbourhood of the reacting vessels.

The presence of histamine in so large quantity in the lung presents a physiological problem by itself. The facts that in the lungs alone there may be as much of this intensely active substance as of adrenaline in the suprarenal glands of the same animal, and that this organ, with its small intrinsic metabolism, has no obvious need for local variation of the diameter of its small vessels, naturally raises the question of an internal secretion of histamine from the lung, and its consequent function as a true hormone. There is no evidence of such a process, and it can only be recognised as a mere possibility. There is an alternative possibility, equally unsupported by any direct or adequate evidence, that the histamine, thus accumulated in the lung, may represent material which, having served its function elsewhere in more active tissues and escaped into the venous blood, has been caught on its way through the lung vessels, and held pending destruction by some method. Best's evidence of its disappearance in sterile, post-mortem autolysis would be compatible with such a possibility, but could hardly be regarded as significant evidence in its favour. The physiological significance of the histamine in the lung must still be regarded merely as a problem waiting for solution

Looking at all the evidence for the normal physiological functions of the histamine in various organs, I think that we may conclude that it is practically limited to actions in the immediate neighbourhood of its liberation. The very width of its distribution, in practically every organ and tissue investigated, might by itself be held to imply for it a function thus normally localised, as distinguished from a true hormone function through the blood stream. Such evidence as we have of this normal, local effect of histamine relates to its liberation by *stimuli injurious in their tendency, however mild in* degree. As to whether it is also liberated as a concomitant effect of normal metabolic activity we have no further evidence. On several previous occasions I have suggested that the liberation from the active cell of a substance acting like histamine on the minute vessels in its immediate neighbourhood should provide a perfect mechanism for the fine adjustment of the blood-flow to the fluctuating needs of small tissue units; but we have still no more than this teleological argument in favour of such a process. Taken by themselves, the facts yet available concerning the distribution of histamine in the body *give it no support; the passive lungs, with capillaries* widely open, are richest in histamine of all the organs yet examined, while the voluntary muscles, with their violent fluctuations of metabolism and of capillary patency, stand very low in the scale.

The few indications which we have of the action of histamine at a distance from the site of its liberation are not such as to suggest a hormone function in the true sense. I mentioned earlier its effect on the muscular coats of the hepatic veins, hitherto known and studied only in the dog. I think that we may reasonably suppose that histamine absorbed from the intestinal contents, through the branches of the portal vein, may bring this sluice-mechanism into play; but we could hardly class such an effect as a true hormone action. It is probable, in any case, that such a mechanism has more importance under pathological than under truly normal conditions. Similarly, the distant actions of histamine absorbed from urticarial wheals, as described by Lewis and by Kalk, should properly be classed not with the normal, physiological effects, but rather with the pathological phenomena, to which we must next turn our attention.

COTTAGE HOSPITAL FOR NEWQUAY.—A committee which was appointed to consider the subject reported that a well-equipped cottage hospital had become "a live necessity" for Newquay and the seven neighbouring villages included in the scheme. The population of the district is 14,000, which is greatly increased by visitors in the summer months, yet there is no hospital accommodation nearer than Truro, 14 miles distant. It has therefore been decided to proceed immediately with the building of a hospital, with accommodation for 22 patients, of whom four or five will be private patients. There will be a small ward for children.

Reflections upon
THE NEED FOR A DEPARTMENT OF CLINICAL PHYSIOLOGY.

BY LINDSEY W. BATTEN, M.B. CAMB., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, EAST LONDON HOSPITAL, SHADWELL; LATE CHIEF ASSISTANT, DEPARTMENT OF DISEASES OF CHILDREN, ST. BARTHOLOMEW'S HOSPITAL.

THERE must surely arise before long, at least in every university and preferably in every medical school, a department of clinical physiology; and it is to be hoped that its coming is not far distant, for the need becomes almost daily more clear. The department will have two functions—research and teaching.

RESEARCH IN CLINICAL PHYSIOLOGY.

It may be that, hidden away in the pages of obscure monographs, a fair amount of ascertained fact, bearing on the morphology, X ray anatomy, biochemistry, and physiology of the normal man, woman, and child (as opposed to the laboratory animal and the sick human subject) exists. Dogmatic statements assuredly abound. But it is certain that well-founded information on the limits of the normal in any of these fields is hard to come by, and as far as practical medicine is concerned it is only too clear that the limits of the normal are not known, and that much of the accepted teaching about it is wholly inaccurate. This fact is repeatedly demonstrated somewhat as follows.

A patient, complaining of subjective symptoms of ill-health, not too well defined, consults a physician (using this term in the broadest possible sense). The latter, according to the era in which he lives, his medical training and the bent of his mind, discovers an abnormality, a retroflexed uterus, a sagging transverse colon, ren mobile, costa cervicalis, hypo- or hyper-chlorhydria, hypo- or hyper-arterial tension, "curvature of the spine" (this physician lived some time ago), an alteration in the protein particles, and refractive index of the serum (this one is alive to-day), undue mottling of the pulmonary fields and increased hilus shadows, too many streptococci in the stools, excessive alkalinity or acidity almost anywhere, a positive von Pirquet, a deviating nasal septum, an excessive cutaneous reaction to milk protein, or one of a hundred other such "abnormalities" old or new. At the time he discovers it, however, it is, of course, new, and he proceeds to treat it secundum artem. The patient is cured. She goes home and tells her friends. They come, with symptoms more or less similar, the same abnormality is discovered in several cases, they are treated—they, too, are cured. What further need have we of witnesses? The facts are published, the condition receives a name, a surprising number of hitherto obscure symptoms are found to be due to it, cures abound, and in the slack season the Press spreads the glad news. It is not until months have passed and some cases curiously resistant to treatment have begun to appear that another physician, more sceptically minded, takes a hundred medical students, including the hospital's Rugby football team, and discovers the abnormality in, say, 20 per cent. After some acrimonious correspondence in the technical press the matter fades into obscurity, but within a year the whole unedifying story repeats itself with a new "abnormality," and there is no sign that the field is exhausted. Biochemistry is still in its infancy, endocrinology is a young child, bacteriology barely adolescent, and practitioners of all kinds are almost as unwilling as ever they were to admit that faith may make their patients whole. The odd thing about the whole matter is that only in this indirect and spasmodic fashion is our knowledge of the normal and its *boundaries increased. It is nobody's business to be* exploring, surveying, and charting this imperfectly mapped territory.

It is abundantly clear that dissecting-room anatomy and laboratory physiology are, regarded as handmaids to medicine, unprofitable servants. Only by a continuous study "in the round" of normal men, women, and children, employing all the methods of clinical medicine, can the bounds of the normal be defined, these erratic excursions be forestalled or curtailed, and medicine be given that scientific basis, which it is so prone to boast of possessing already. To pursue such a study should be the first work of a department of clinical physiology; to check, constantly and repeatedly on an ever-widening scale the accepted standards employed in clinical medicine, to record its results and to see that its records are easily accessible to any seeker after truth. It will investigate the reactions of human beings to changes in diet and environment, to exercise and rest; it will endeavour to classify into types (and yet will be slow to do so dogmatically); it will measure, photograph, and skiagraph. It will watch for the appearance in wards and clinics of new clinical methods, signs, tests, and "instruments of precision," and especially for the postulation of abnormalities of form or function to explain familiar groups of symptoms. No less carefully will it observe the laboratory work of experimental physiologists, and it will promptly initiate control experiments on large groups of normal subjects to try out as far as may be the value of each new discovery, whether in laboratory or clinic.

And who will be its subjects? For routine anthropometric work it will employ the material nearest to its hand, medical students, probationer nurses "child welfare" infants, antenatal women; none of these will be the worse for being weighed and measured, in the broadest sense of those terms. For ad hoc control experiments it should not be difficult, even in this age of "safety first," to find sufficient volunteers.

As the department grows in strength and importance it will no doubt extend its range, and with tact and good management it will find it possible to examine recruits for industry and the services, candidates for life insurance, school-children, and a large number of the general public curious about the state of their health. Its statistical department will be kept busy. The work will be costly, but possibly some income by way of fees for work done may be obtainable, and both labour and money will be well spent in the service of truth.

Of the head of the department exceptional gifts and qualifications will be required. To a capacity for clear thinking and a single-minded devotion to truth he must add educational experience of an unusual kind. He must have something more than a good working knowledge of both laboratory physiology and clinical medicine with a basis of broad culture generally denied to those who abandon too early the study of the literæ humaniores for that of the physical sciences.

THE DEPARTMENT AS A TEACHING CENTRE.

Thus far the department has been considered only in relation to research, but the need for it as a teaching centre is no less, and the practical value of its work will be perhaps even greater. The gap between physiology and clinical medicine has been often mentioned. The saying that the first duty of the ward-clerk is to forget his physiology is quoted as a piece of deplorable advice, thank heaven long out of date; it is hinted that the gap is rapidly narrowing, and that quite soon medicine will be so nearly a pure science that there will be no gap at all. It is always assumed that medicine, not physiology, is to be responsible for the bridging operations. In actual fact the gap is still wide, the antiquated advice trembles on the lips of many a clinical teacher. Medicine is in no danger of becoming a science, but will remain an art for many a long day to come, and it is at least possible that, in so far as the gap can be bridged, physiology must be the responsible pontifex.

It has been rightly decreed that knowledge of the normal must precede investigation of the pathological, and for this reason, presumably, anatomy and physiology are studied early in the medical curriculum; yet the conscientious student, having pursued the study of these subjects even to the point demanded by the examiners for "the primary fellowship," and fairly crammed his memory with facts, figures, and mnemonics, arrives in the wards completely ignorant, in a clinical sense, of the normal which he will be endeavouring for the rest of his life to distinguish from the pathological. He has not even heard of such a thing as physical or physiological types, he has not inspected and percussed even one chest, much less has he compared the clinical aspect of a long thin chest with that of a short and broad one; he has not listened to one normal heart when he should be familiar with normal hearts beating quickly, normal hearts beating slowly, and normal hearts murmuring at their pulmonary bases, to say nothing of hearts occult from observation in deep and well-covered chests. He has never seen the normal fundus oculi, the larynx, or the drum of the ear, and he is completely ignorant of the clinical aspects of infancy, childhood, adolescence, and senescence. He can answer difficult questions on the latest theories of colour-vision, renal secretion, and protein metabolism; he can tell you within one decimal point per cent. the composition of human milk; he knows how much gliadin there is in bread; he can draw a map of the cerebral convolutions and another of the otic ganglion; he knows the origin, insertion, and nerve-supply of a hundred voluntary muscles and can say what each one would do if it contracted all alone. He probably knows more facts than he ever knew before or ever will again and they are facts concerning the structure and functioning of the human body; yet of men, women, and children regarded as living organisms, progressing from birth to death, eating, working, playing, and sleeping, of their bodily needs and requirements and of the variety of types to be found among them he knows scarcely more than his cousin apprenticed to industry or trade. Quite literally he does not even know the look of them. At the very point at which his studies seemed about to bear fruit they break off short and he is given to understand that he has now finished with the normal and may proceed to study the pathological.

He goes then to the wards, to the casualty and out-patient departments, and is there confronted by patients suffering from a wide variety of complaints and diseases. By a kind of trial-and-error method he does learn by degrees and in part to distinguish the normal from the abnormal, the normal being, for him, that dull and disappointing condition of affairs in which nothing pathological can be discovered. In patches, as for example in the children's department, he is taught a little about the healthy subject, but though at intervals he may be urged to study the normal, he feels, naturally enough, that this is not now his proper task. He has enough to do in studying disease, besides, has he not learned his anatomy and physiology?

It is not until after he is qualified that this deficiency in his knowledge and experience comes home to him, perhaps not even then. If, as happened to a part of one generation, he finds himself inspecting and examining recruits, soldiers, and pensioners in large numbers and for long periods, his eyes are opened perforce. If he goes on to examine normal children at welfare centres and schools his conception of the normal widens again and its true boundaries begin to appear. The extreme difficulty of defining them with certainty and the importance and fascination of this task also becomes apparent.

But for the majority who are seldom or never called upon to inspect healthy subjects the case is different and the results of this deficiency in the curriculum are not far to seek. First, it is within the knowledge of most that unusual physical or physiological types do far too often escape recognition and are confused with the clinical picture of some serious disease.

exploring, surveying, and charting this imperfectly mapped territory.

It is abundantly clear that dissecting-room anatomy and laboratory physiology are, regarded as handmaids to medicine, unprofitable servants. Only by a continuous study "in the round" of normal men, women, and children, employing all the methods of clinical medicine, can the bounds of the normal be defined, these erratic excursions be forestalled or curtailed, and medicine be given that scientific basis, which it is so prone to boast of possessing already. To pursue such a study should be the first work of a department of clinical physiology; to check, constantly and repeatedly on an ever-widening scale the accepted standards employed in clinical medicine, to record its results and to see that its records are easily accessible to any seeker after truth. It will investigate the reactions of human beings to changes in diet and environment, to exercise and rest; it will endeavour to classify into types (and yet will be slow to do so dogmatically); it will measure, photograph, and skiagraph. It will watch for the appearance in wards and clinics of new clinical methods, signs, tests, and "instruments of precision," and especially for the postulation of abnormalities of form or function to explain familiar groups of symptoms. No less carefully will it observe the laboratory work of experimental physiologists, and it will promptly initiate control experiments on large groups of normal subjects to try out as far as may be the value of each new discovery, whether in laboratory or clinic.

And who will be its subjects? For routine anthropometric work it will employ the material nearest to its hand, medical students, probationer nurses "child welfare" infants, antenatal women; none of these will be the worse for being weighed and measured, in the broadest sense of those terms. For ad hoc control experiments it should not be difficult, even in this age of "safety first," to find sufficient volunteers.

As the department grows in strength and importance it will no doubt extend its range, and with tact and good management it will find it possible to examine recruits for industry and the services, candidates for life insurance, school-children, and a large number of the general public curious about the state of their health. Its statistical department will be kept busy. The work will be costly, but possibly some income by way of fees for work done may be obtainable, and both labour and money will be well spent in the service of truth.

Of the head of the department exceptional gifts and qualifications will be required. To a capacity for clear thinking and a single-minded devotion to truth he must add educational experience of an unusual kind. He must have something more than a good working knowledge of both laboratory physiology and clinical medicine with a basis of broad culture generally denied to those who abandon too early the study of the literæ humaniores for that of the physical sciences.

The Department as a Teaching Centre.

Thus far the department has been considered only in relation to research, but the need for it as a teaching centre is no less, and the practical value of its work will be perhaps even greater. The gap between physiology and clinical medicine has been often mentioned. The saying that the first duty of the ward-clerk is to forget his physiology is quoted as a piece of deplorable advice, thank heaven long out of date; it is hinted that the gap is rapidly narrowing, and that quite soon medicine will be so nearly a pure science that there will be no gap at all. It is always assumed that medicine, not physiology, is to be responsible for the bridging operations. In actual fact the gap is still wide, the antiquated advice trembles on the lips of many a clinical teacher. Medicine is in no danger of becoming a science, but will remain an art for many a long day to come, and it is at least possible that, in so far as the gap can be bridged, physiology must be the responsible pontifex.

of most that unusual physical or ph
do far too often escape recognition
with the clinical picture of some

diet. The amount of extract used was that stated by the makers to be equivalent to 8 oz. of liver. In most of the later experiments the following preparation was given in one dose daily before the mid-day meal. This material was prepared as follows:—

Eight ounces of fresh calf's liver was scraped on a plate so that the hepatic parenchyma was separated from the connective tissue and reduced to a finely divided condition. To this was added the juices of two oranges and two lemons with one ounce of port wine and one ounce of sugar. The whole was pressed through a single thickness of gauze. Sufficient water was added to give 8 fluid ounces.

A like amount of this preparation if administered in three equal doses daily before meals was as efficacious as when given in one dose. In one series of experiments the raw liver was administered with the juices of two tomatoes.

All the blood used in tests of coagulability was obtained by venepuncture, 0·5 c.cm. of blood being employed in each experiment. Very small quantities of blood should not be used, as they give a false impression of the rapidity of the coagulation of hæmophilic blood in bulk. The clotting was observed in clean test-tubes at the temperatures recorded. Evaporation was prevented. The coagulation times given in Tables I. and II., as well as those shown in the graphs, were observed with blood obtained 12 hours after the ingestion of hepatic tissue. The more rapid effects of administration are recorded in Table III. The tables and graphs show the times required for the "completion of clotting"—that is to say, the formation of a complete gel. The expression "commencement of clotting" implies the first visible departure of the blood from fluidity. In the experiments with cooked brain 8 oz. was substituted for the meat at the mid-day meal.

Summary of Cases.

CASE 1.—Boy, aged 14 years, who had been previously admitted to hospital for epistaxis and hæmarthroses. For 29 days 8 oz. of cooked liver was substituted for the meat of the midday meal, but on several days part of the liver was not eaten, on some occasions only 2 oz. being taken. From the twenty-ninth till the fifty-first day 8 oz. of cooked liver and one ampoule of Burroughs Wellcome and Co.'s dry liver extract were given on alternate days. The effects on the speeds of blood clotting are given in Table I.

TABLE I.—*Showing the Increased Speeds of Blood Clotting following the Ingestion of Cooked Liver and Liver Extract.*

Number of days of treatment.	Diet.	Blood-clotting times (in minutes).	
		At 18°C.	At 37·5°C.
0 (before treatment)	Ordinary.	74	66
8	Cooked liver.	71	64
14		66	56
21		42	34
29	Cooked liver and extract on alternate days.	—	—
36		38	23
51		34	14

After the fifty-first day the boy refused to take any adequate quantities of cooked liver and a diet which included 8 oz. of cooked brains with and without the addition of 1 oz. of cooked liver was given for 34 days. During this period the clotting times of the blood at 37·5° C increased from 14 minutes to 29 minutes, and on the thirty-fourth day 60 minutes was required for coagulation at room temperature. The ordinary diet was then substituted for 18 days, and the clotting times at 37·5°C. increased from 29 minutes to 42 minutes and coagulation at room temperature required 73 minutes. The regression thus nearly reached the original condition. Eight ounces of raw calf's liver with the juices of two oranges and two lemons was then given daily in the form already described, in addition to the ordinary diet. The effects on the coagulability of the blood are shown in Table II.

TABLE II.—*Showing Clotting Times after the Ingestion of Raw Liver with the Juices of Oranges and Lemons.*

A = Number of days of treatment.
B = Clotting times at 37·5 C. in minutes.

A.	B.	A.	B.	A.	B.
0	42	12	12	32	7
4	15	15	8	33	6
7	6	18	8	37	7
9	6	25	10		

The coagulation time at 18° C. on the 37th day was 21 minutes.

For 34 days the same amount of raw liver with the juices of two tomatoes, one ounce of port wine, and one ounce of sugar was given in addition to the ordinary diet. Six days after the commencement of this treatment the coagulation time at 37·5° C. was 5 minutes, but it subsequently increased. On some occasions clotting commenced at 37·5° C. in 6 or 7 minutes, but the completion of clotting was considerably delayed, 16, 19, 20, 21 and 22 minutes being noted. On the thirty-fourth day clotting at 37·5° C. commenced in 7 minutes and was complete in 10 minutes.

On the clinical side Dr. Trevor Jones reports:—

"The patient (admitted to hospital Nov. 10th, 1928) before liver treatment was instituted had long-standing hæmarthroses in both knees and in the left elbow. In March, 1929, when the coagulation time had been reduced to 6 minutes several attempts were made to break down the adhesions under gas anæsthesia. No fresh effusions occurred during these attempts. There was some absorption of fluid in the knees and movements of the joints and massage of the adjacent muscles have not produced fresh effusions. But the improvement in the mobility of the joints has not been marked in this case."

CASES 2 AND 3 (boys aged 7 and 9 years respectively).—The effects of treatment on the speeds of blood clotting are shown in Graphs 1 and 2. In these diagrams ——— represents "ordinary diet," - - - - - represents a diet including 8 oz. of cooked liver, ... show a similar diet partly rejected, ——— designates a diet including 8 oz. of raw calf's liver with the juices of two oranges and two lemons, and -·-·-·-· indicates a diet including 8 oz. of raw calf's liver with the boiled juices of two oranges and two lemons.

On the clinical side Dr. Trevor Jones reports:—

"CASE 2 was admitted to hospital on Jan. 25th, 1929, and liver treatment was commenced on Feb. 6th, 1929, when the patient had a marked hæmarthrosis of the right knee. This cleared up in 4 to 5 weeks, and he was allowed to play games. A fall produced an intramuscular hæmorrhage 4 to 6 inches long in the back of the thigh which was absorbed in two weeks, during rest in bed. Several cuts and abrasions have occurred which stopped bleeding normally without treatment. On two occasions he pulled out a loose tooth and the bleeding was also within normal limits. A tendency to bruise more readily than normal persons remains."

"CASE 3.—Admitted to hospital Feb. 15th, 1929, when he had several subcutaneous hæmorrhages and a conjunctival hæmorrhage which cleared up in a fortnight after treatment. He is now allowed to play boisterous games with other boys, and there has been no recurrence of hæmorrhages since the treatment but a tendency to bruising persists. Small cuts and abrasions stop bleeding rapidly without requiring treatment."

The immediate effects of the ingestion of hepatic tissue on the coagulability of hæmophilic blood are illustrated in Table III.

TABLE III.—*Showing the Speeds of Clotting of Hæmophilic Bloods at 37·5°C. after the Ingestion of 8 oz. of Raw Calf's Liver, given with the Juices of Two Oranges and Two Lemons.*

The Clotting of Shed Hæmophilic Blood by Thrombin.

Several years ago, Addis[14] stated that thrombin clots hæmophilic blood as rapidly as normal blood. Three years ago I tested the coagulant action of a thrombin (prepared at St. Mary's Hospital, London, and known as "protagulin") on the blood of Case 1, which then exhibited coagulation times of 48 minutes at 37·5° C. and 68 minutes at 18° C. The speeds of clotting were reduced by the addition of this hæmostatic to 9 minutes at 37·5° C. and 14 minutes at 18° C. The experiments were repeated with blood obtained by venepuncture from Cases 1, 2, and 3, when the clotting times at 37·5° C. had been reduced to less than 25 minutes by liver treatment. Two drops of a standard solution of protagulin were added to 2 c.cm. of blood in each experiment. In each case the whole of the blood firmly clotted at 37·5° C. in less than one and a half minutes and in two or three minutes at 18° C. Bleeding from small cuts was completely arrested in less than two minutes. It appears that this preparation of thrombin provides the means of arresting accessible hæmophilic bleeding when the speed of blood clotting at 37·5° C. is reduced below 25 minutes.

Ætiology.

The observations just recorded show that the daily ingestion of hepatic tissue increases the coagulability of hæmophilic blood and reduces the tendency to *spontaneous hæmorrhages.* The initial delay in the alteration of coagulability of hæmophilic blood when hepatic tissue is administered, the temporary regression during an early phase of the treatment in Case 2, and the effects produced by the discontinuance of liver diet suggest that a metabolic change is primarily involved, rather than direct action on the blood itself.

Although much attention has been given to the condition of the blood in hæmophilia, very few attempts have been made to trace the abnormality which leads to the production of blood which does not clot promptly when shed. More than a century ago, Nasse[25] suggested that in hæmophilia there is a defect in the growth of the blood and certain similarities in the condition of hæmophilic and embryonic bloods point in the same direction (Pickering and Gladstone[26]).

There are several indications that the liver produces bodies that are essential for blood clotting. Many facts point to the formation of fibrinogen in the liver, such as the loss of fibrinogen in the blood that follows hepatic injury or intoxication and that occurring after the establishment of an Eck's fistula or the occlusion of the hepatic blood-vessels (Foster and Whipple,[27] Doyon [28]), whilst the work of Nolf[29] indicates that prothrombin, which is also an essential factor in blood clotting, is likewise produced in the liver. There are also a considerable number of observations which suggest that products liberated by the lysis of erythrocytes are either the raw material of fibrinogen or stimulate the production of that body (Levi-Crailsheim,[30] Reymann,[31] Davide[32]). To this evidence is added the stimulation of erythropoiesis which, in certain conditions, follows the ingestion of liver, liver extract, and even the ash of hepatic tissues. It thus seems established that hepatic activity plays an important part in the production of blood.

Viewed in the light of these facts and inferences, the observations here recorded do not appear surprising. In hæmophilia it seems probable that the production of certain bodies which are essential for rapid blood clotting is either deranged or has not advanced beyond that found in an embryonic state. It also seems probable that material present in the liver of normal animals modifies the hepatic activity of hæmophilic persons and so leads to the production of blood which clots readily at body temperature.

My most cordial thanks are due to Dr. Basil Hood, the medical superintendent of St. Marylebone Hospital, for full facilities for work; to Dr. Trevor Jones for the clinical work and observations, also for much general help; and to Nurse S. Knowlton for rendering the preparation of raw liver palatable.

PNEUMOCOCCAL SEPTICÆMIA DURING THE PUERPERIUM.

A CONTRIBUTION TO THE PROBLEM OF THE SPREAD OF PUERPERAL INFECTION.

BY JOAN NIXON, B.Sc., M.B. LOND.,
RESEARCH ASSISTANT, OBSTETRIC UNIT AND BACTERIOLOGY DEPARTMENT;
AND
HEDLEY D. WRIGHT, M.D., D.Sc. EDIN.,
READER IN BACTERIOLOGY, UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.

THE occurrence of primary uterine infection with the pneumococcus is perhaps sufficiently unusual to warrant the recording of the two cases described below, but there is the additional justification that in one of them the infection was traced back to a source which does not appear to have been sufficiently considered in relation to the general problem of puerperal sepsis—the respiratory tract of one of the attendants.

The details of the two cases were briefly as follows:

CASE 1.—A. B., aged 30. Fourth confinement. During pregnancy she had been debilitated and had had a cough. The labour, which was apparently one month premature, began on March 2nd, 1929. The patient was attended in her own home by her doctor, who states that the case was quite normal except for the fact that he ruptured the membranes. The placenta was delivered after 15 minutes and was intact. Next morning (March 3rd) there was abdominal pain and the same evening the child died, the cause of death being unknown. On March 4th (second day) the morning temperature was 101·8° F. and the pulse rapid. The lower part of the abdomen was tender. Urine had been passed and there was no vomiting. In the evening the temperature was lower, but the abdominal condition remained unchanged.

On March 5th (third day) she was admitted to hospital and was very ill. The temperature was 101° F., the pulse-rate 140 per minute, and the respiratory rate 40 per minute. The lower part of the abdomen was rigid and tender and did not move with respiration. The uterus was large and tender, and there was tenderness on palpation of the vaginal fornices. No mass could be felt in the pelvis. The lochia were red and were not offensive. There were no lacerations of the perineum. A few scattered rhonchi were heard in the chest, but there was no evidence of consolidation. Prof. F. J. Browne diagnosed peritonitis and operated immediately. A large amount of pus was found free in the peritoneal cavity. The uterus, ovaries, and Fallopian tubes were superficially inflamed, but there was no localised inflammation. The peritoneal cavity was drained and the wound closed. After the operation the patient grew steadily worse and died at 4 P.M. on March 6th (fourth day).

Bacteriological.—At the time of operation cultures were made from the vagina, the uterine cavity, the peritoneal exudate, and the blood. These all yielded growths of pneumococcus type I. The culture from the uterus on blood-agar was pure and heavy, that from the vagina much scantier. The colonies developing from the blood averaged 18 per c.cm. Just before death a small amount of sputum was inoculated into a mouse from which pneumococcus type I. was also isolated.

Post-mortem.—There was a great deal of pus in all parts of the abdominal cavity. The uterus was large and it and its appendages superficially inflamed. The endometrium was inflamed and slightly necrotic, but there was no part of the placenta retained. In the left broad ligament was a small area of suppuration. The pelvic and uterine vessels were not thrombosed. The other abdominal organs manifested the changes associated with septicæmia and peritonitis. The right pleural cavity contained a small amount of pus over the most dependent posterior part of the diaphragm, which on its inferior surface was very severely involved in the peritonitis. A very small part of the lung in immediate relation to the small collection of pus was congested and slightly consolidated.

It was clear that the primary infection was in the uterus and the lung changes were secondary. In sections of the uterus pneumococci were found in large numbers in the material covering the endometrium and in the inflamed broad ligament and the peritoneum.

Source of Infection.—As this infection originated in a private practice it was not possible to examine any of those who attended the case. Just before the patient's death the infecting organism was found in her mouth, but it must remain uncertain whether this means that she had harboured the organism before her delivery or that it was there in consequence of the slight lung lesion resulting from the septicæmia.

CASE 2.—C. D., aged 30. Primipara. One month postmature. Narrow pelvis. The patient went into labour on March 17th, 1929, and was attended in her own home as a "district" case. The labour was a prolonged one, and during the next 48 hours five vaginal examinations were made. After 60 hours (March 19th) the membranes ruptured, and three hours later forceps were unsuccessfully applied. One hour later a further unsuccessful application of forceps was made, after which the patient was removed to hospital, and with considerable difficulty the child was delivered with forceps. There was a second degree tear of the perineum and considerable laceration of the left labium majus. There was very little hæmorrhage, but severe shock. Next morning (March 20th) the temperature was up to 100° F., and the pulse-rate was 126 per minute; 50 c.cm. of antiscarlatinal serum were given. On the second day of the puerperium (March 21st) the temperature was 103° F. and the pulse-rate 140. There was abdominal distension and slight rigidity, but no tenderness except over the uterus. The legs were slightly œdematous. On March 22nd (third day) the condition remained much the same, but there was some vomiting. The lochia were not offensive. The perineal wound was very œdematous and was beginning to slough. Examination of the lungs and heart revealed no abnormality whatever.

On the fourth day (March 23rd) it was recognised that this was a pneumococcal infection and 100 c.cm. of type I. antipneumococcal serum were given intravenously, and repeated on two subsequent occasions. There were no untoward effects, but neither this nor the local treatment nor intravenous injections of metarsenobillon had any beneficial influence, and the patient died on March 24th (fifth day). The chest was repeatedly examined for signs of inflammation, but entirely without result.

Bacteriological.—Cultures from the vagina were made immediately after the patient's admission and before delivery. There had been some bleeding as a result of manipulations outside the hospital, so that the vaginal secretions were possibly considerably diluted. No pneumococci were obtained, but only a few staphylococci (*albus*) and diphtheroid bacilli. On March 21st (second day) cultures were made from the vagina and the blood—owing to the amount of perineal laceration a culture from the interior of the uterus could not be made. The vaginal culture yielded a heavy growth of pneumococcus type I. and a few colonies of *Bacillus coli*. The blood yielded two colonies per c.cm. of pneumococcus type I. On March 23rd (fourth day) cultures from the cervix and from the interior of the uterus grew diphtheroid bacilli and large numbers of pneumococci type I. On the same day a small amount of sputum and saliva was inoculated into a mouse, from which pneumococci (group IV.) were isolated, but *none of the type infecting the patient* (type I.)

An autopsy on this case was refused so that evidence as to the exact nature of the case is incomplete. But in view of the failure of special attempts made to find clinical evidence of a pulmonary lesion and particularly of the absence of the infecting organism from the saliva and sputum it seems quite evident that the infection was primarily a genital one and not in the respiratory tract.

Source of the Infection.—Altogether 11 individuals had had some association with the case, and the mouth and throat secretions of all of them were inoculated into mice to see if any of them were carriers of type I. pneumococci. Of the 11 who attended the patient at various times four had made vaginal examinations in the early stages and two of these had applied forceps unsuccessfully; one other had completed delivery of the child with forceps in hospital. The other six had not apparently had any close association with the case. Of these six one was a carrier of pneumococcus type III. and two others of pneumococcus group IV. (serologically heterogeneous group). Of the remaining five individuals two, who had only made vaginal examinations, had no pneumococci in their mouths; the third who had examined the patient several times was a carrier of group IV. pneumococci; the fourth, who had completed the delivery in hospital, was not a carrier, but the fifth who had made the second attempt at forceps delivery in the patient's home yielded a pneumococcus of type I. It was subsequently learned that he had been suffering during this period from a severe "cold." Fourteen days after the first examination no pneumococci could be found in his mouth secretions, so it appears that he was not a permanent carrier of the organism. It seems to us highly probable that the infection was transmitted from this individual to the patient, and it is worth noting that although masks are worn by those in attendance upon cases delivered in this hospital they are not used in cases on the district and were not used for this case.

There was no direct connexion between these two cases. The attendant who appears to have been implicated in the spread of the infection did assist at the operation on the first case and developed his "cold" three days later. It is just possible that he may have been infected at that time, but it seems much more probable that his infection was associated with the epidemic of respiratory disease which prevailed at the time.

Discussion.

Primary pneumococcal infection of the genital tract during the puerperium has been recorded in several papers published prior to 1912. These cases are reviewed by Bondy and they will not be further discussed here except to note that in some of them the bacteriological information is incomplete. Since that date cases have been recorded by Monckeberg, Seymour, and McCord. We have not been able to find any record of the type of pneumococcus occurring in such cases. In primary pneumococcal peritonitis occurring in children McCartney and Fraser found type I. pneumococci eight times and type II. twice.

In the recorded cases the source of the infection is not very often considered. Foulerton and Bonney state that two of their cases occurred in the practice of one doctor at about the same time, and Monckeberg reports that the midwife attending his case was suffering from tonsillitis and pneumococci were grown in large numbers from the lesion in her throat. He considers the midwife was the source of the infection, but there is no information as to the serological grouping of the organisms.

There is at present a healthy interest in the subject of puerperal infection coupled with a certain reasonable dissatisfaction with our recent lack of progress and a marked display of energy in an attempt to make good these deficiencies. There is at the same time some danger of misdirection of much of this energy on account of a lack of clarity in conception of the nature of this disease. It is too widely believed that all sepsis in the puerperium is due to the hæmolytic streptococcus. Recent work makes it quite evident (Bryce, Armstrong, and Burt-White) that much of the minor sepsis, probably what the older clinicians called sapræmia, is due to other organisms, and our own experience is exactly similar—of 22 cases which occurred in this hospital in 1928 only six were due to the *Streptococcus pyogenes.* The two cases herein described, while not in any way influencing the conclusions drawn from such statistics as those of Kinloch, Smith, and Stephen and much previous work that the severe cases are nearly always streptococcal, do still further emphasise the necessity of adequate bacteriological study of each case as a preliminary to the study of its origin. Our first case contributes nothing to the solution of the problem of the spread of infection, but in the second case we think there is no reasonable doubt that the organisms came from the upper respiratory tract of one of her attendants who was suffering from a mild infection of that area. It must be admitted that the infecting organism is an unusual one, but this was valuable because it admitted of such definite identification, and this is just what is so difficult with streptococci. But it seems highly probable that streptococcal infections may be transmitted in just the same way as has been suggested by Meleney and his associates for an epidemic in New York and by Kinloch and his associates in Aberdeen. Meleney seems to regard this type of infection as a simple transmission from a carrier, but the Aberdeen group discuss the subject as part of the much bigger problem of droplet infection in general. The New York workers have adopted as preventive measures the wearing of masks at all times when the patient is being examined or treated, and the exclusion from the staff of all proved carriers of hæmolytic streptococci. Kinloch and his associates deprecate the use of masks and stress the importance of minimising the risk of infection by increasing the amount of floor space per bed. We are inclined to think that this mode of spread is a special case of droplet infection in that the general infectivity of the community is important in so far as it increases the infectivity of the attendants. In our case it was not the carrier of a pneumococcus who transmitted the infection but the one individual who himself was suffering from an infection. McKinlay failed to find any direct statistical relationship between the incidence of streptococcal diseases in general and that of puerperal septicæmia. Our cases occurred during a period of epidemic respiratory disease at a time when pneumonia due to type I. pneumococcus was occurring with some frequency. Whether coincidentally or otherwise hæmolytic streptococci tend to increase in numbers in throats that are inflamed. Inflammation of the respiratory tract is such an obvious potential source of danger that it would seem incumbent on those dealing with midwifery cases who are suffering from such affections either to abstain temporarily or at any rate to take such precautions as will minimise the risk. The wearing of masks is at least worth consideration.

After the adoption of surgical aseptic methods in the practice of midwifery serious puerperal sepsis became much less common, but since this first preliminary decline occurred the incidence has remained at a fairly steady level. This may be a reflection of the efficiency of the aseptic technique of the obstetrician. On the other hand, it may be due to the neglect of precautions of a particular kind against some frequently present possibility of infection. We think that the respiratory tract is such a source, and that precautions against infection from this source should be carefully taken.

Future investigations will, we hope, yield us more exact knowledge of the relative importance of this and other factors in the establishment of puerperal [illegible]is.

[illegible] are [illegible]ebted to Prof. F. J. Browne for permission [illegible]se cases and for the opportunity of [illegible]em.

[illegible] at foot of next column.)

EXCRETION OF THE CONSTITUENT IONS OF SULPHUR WATER.*

BY DAVID BROWN, M.D., B.Sc. LOND.,
PHYSICIAN TO THE ROYAL BATH HOSPITAL, HARROGATE;
AND
ARNOLD WOODMANSEY, M.Sc.,
ANALYST TO THE HARROGATE CORPORATION.

BEFORE this work nothing was known about the elimination of the imbibed ions during a course of sulphur-water treatment by internal application. Even now it is impossible to say which channel—fæces, urine, or sweat—eliminates the actual constituents of the sulphur water when these are identical with those of normal excreta. Barium is the only constituent dealt with that is found in sulphur water and not in the body, and this, while presenting interesting features, is anomalous because it so readily forms insoluble compounds.

Conditions of Experiment.

Four experiments (denoted A, B, C, and D) were carried out on three subjects who, in their usual condition of health, were placed on fixed dietaries, suited to the appetite and inclination of each: (*a*) for four days (pre-sulphur period) to obtain the basal quantities of ions excreted before sulphur water was administered; (*b*) for four days (sulphur period), during which sulphur water was taken in place of an equal volume of plain drinking water; (*c*) for four days (post-sulphur period) when sulphur water was stopped and plain water resumed.

Fixed conditions of work, exercise, rest, and—as far as possible—sleep were observed. The fæces, urine, and sweat were quantitatively analysed for barium, manganese, calcium, magnesium, potassium, and sodium. In Experiment D sulphur as sulphate was also determined. In B and C chloride was estimated in the urine. In C the total urine nitrogen and basal metabolism were determined and the daily weight taken. Blood pressure was observed in B and C.

For details of the method of sweat collection (which we believe original) and for the full tabulated results reference must be made to the original paper in the Proceedings of the Royal Society of Medicine.

Results.

In C there was marked purgation, and the diuresis, observed in the earlier experiments on the same subject when living on a non-purin diet, was not observed. On the contrary, there was a lessened volume of urine—5630 c.cm. in the sulphur-water period, as against 6325 c.cm. for the pre-sulphur or basal line period. The average amount of solids, calculated from the specific gravity and compared with that of the basal line period, was increased by about 30 per cent. (31 g. as against 22·5 g.), falling to just below the basal line in the post-sulphur stage. This increase denotes increased metabolism.

In B, which was not associated with purgation, but rather with moderate constipation (there being no

---

* Summary of a paper read before the Section of Balneology and Climatology of the Royal Society of Medicine on Jan. 10th, 1929.

action of the bowel on one day), the diuresis was moderate, about 6 per cent., but the amount of solids in the urine was not markedly increased.

In *D*, where there was no considerable purgation, but from time to time looseness of bowels, there was an 8 per cent. increase in the volume of the urine in the sulphur period with an increase of 3 g. per diem in the excreted solids. In the post-sulphur period this diuresis continued with 10 per cent. reduction in the amount of solids passed. This result was thus intermediate between that where purgation was present and that where comparative constipation obtained.

Total nitrogen of the urine in C also showed an increase, as in the earlier experiments (on non-purin diet), but the short duration of the sulphur period probably did not allow this to develop to the amounts previously observed, so that it only rose 2¼ per cent. (instead of from 5 to 8 per cent.).

EXPERIMENT C.—*Total Nitrogen (Kjeldahl).*

Days		
1 to 4	Average daily excretion of N	16·1 g.
5 to 8	„ „	16·5 g.
9 to 12	„ „	16·1 g.

Average increase in daily excretion of N, 2¼ per cent.

The basal metabolism, taken by Dr. Geoffrey Holmes before the subject rose in the morning, showed no essential change. The blood pressure, taken by Dr. Wilfrid Edgecombe in B and C experiments, remained stationary (130 syst., 88 diastolic). Weight during Experiment C, the observations being made at the same hour of day and under same conditions, was as follows:—

Pre-sulphur period, loss	5¾ oz. daily.
Sulphur period, loss	8 oz. „
Post-sulphur period, loss	1¼ oz. „

The total loss was just under 4 lb. for the whole experiment.

Analysis of Results.

All the metallic ions taken in the ingested sulphur water were supposed to be eliminated during the sulphur water period, and were in each case deducted from the results of the sulphur water periods before the calculations were made of + or − excretion of the ions. This was done in order to apply the most unfavourable conditions in calculating the obtained results of plus excretion of ions.

Barium.—Never totally recovered. None in urine or sweat; blood (?). From the fæces 20 per cent. was recovered in Experiment A; 26 per cent. in B; 80 per cent. in C, and 61 per cent. in D.

Manganese.—Mainly in fæces and urine, and there was excess excretion in three cases out of four.

A— 30 per cent. retained
B— 20 „ excreted in excess.
C—300 „ „ „
D— 4 „ „ „

Calcium.

	(1)	(2)	(3)
A	16+	84+	50+

D	89+	17+	53+

There was general retention of Na ion during the sulphur period. The + excretion in three cases out of four during the sulphur period of Ca, K, and Mn ions suggests + metabolism of compounds containing these ions. The deficient excretion of the Mg ion is probably only due to the method of calculation, which supposes all ions of sulphur water to be excreted during the sulphur-water period. Possibly the + secretion of K ion is accompanied by replacement of this ion by the retained Na ion.

Thus, during the sulphur period: Managanese excretion, calcium excretion, and potassium excretion were increased in three experiments out of four, and magnesium excretion and sodium excretion were decreased in three experiments out of four, and four out of four respectively. During the post-sulphur period the percentage results were about equally divided between plus and minus, except that the retained sodium tended to be excreted and the excretion of magnesium was increased in two experiments out of four. The total percentage excretion in the sulphur and post-sulphur stages when taken together show nothing conclusive except a net retention of the sodium during the combined stages.

In Experiment D (the only one thus investigated) the percentage excretion of total sulphur was markedly increased, over and above that combined in the sulphur water—namely, 89 per cent. during the sulphur period and 17 per cent. during the post-sulphur period, an average excess of over 50 per cent. on the combined periods.

This sustained elimination of sulphur seems to us very noteworthy, considering the importance to life and health of sulphur-containing amino-acids (especially such an essential body as cystein and the recently discovered auto-oxidisable constituent of the cell-glutathione), as so far nothing has been known of the effects of sulphur water on the sulphur metabolism of the body. It will be noted that by all three avenues (bowel, kidney, and skin) the elimination of total sulphur was markedly increased. This result probably has a distinct clinical bearing. Dr. F. C. Eve, of Hull, has pointed out that in some cases of arthritis neutral sulphur of the urine is increased up to eight or ten times the normal amount. As is well recognised, neutral sulphur is that part of the sulphur of the urine which is least oxidised and probably comes direct from tissue breakdown.

Our results throw no light on the question of the ultimate origin of the increased sulphur output, but only point to increased breakdown of sulphur-containing substances either forming part of the food or coming from the tissues. Further experimentation on the relative quantities of total neutral, ethereal, and inorganic sulphur would appear a promising line of research if combined with accurate observation on the excretion of total nitrogen and urea.

The Possible Modes of Action of Sulphur Water.

1. The simplest theory is that it acts as a common drench, the effect being due to osmosis. This idea is negatived by the results and the problem is shown to be one of metabolic change.
2. Body ferments may be released by the removal (by oxidation) of the products of their own activity. In B (with constipation) the excretion of Ca, Mg, K, and Na is minus, whereas in C (with purgation) this excretion is plus.
3. Direct stimulation of the tissue ferments.
4. The retention of sodium has no doubt an important bearing. That Ca and K excretions are both increased shows the far-reaching effect on general metabolism.

Barium was only found in the fæces and to the average extent of only 50 per cent. The excretion of barium was largest during the sulphur period, and thereafter showed a rapid falling off. Hence we must conclude that a considerable but variable amount of barium is retained in the body tissues, probably in a nearly insoluble state, and perhaps fed gradually to the tissues.

We claim to have established that as the results of drinking sulphur water—

1. An increase of metabolism takes place.
2. The action of manganese in sulphur water probably provides the catalyst necessary for the stimulation of body ferments including possibly xanthine oxidase.
3. Barium of sulphur water has so far not been found in the general circulation; on the average 50 per cent. is retained. Whether this is slowly fed to the tissues, or is locked up in the intestinal mucosa, and thence gradually excreted, or whether it is lodged in the liver and then gradually fed to the tissues, is uncertain. In consonance with pharmacological experiments with pure preparations, the avenue of excretion, if any, seems to be the bowel.
4. There is distinct retention of sodium in the body with an increased extrusion of calcium and potassium. This agrees with results obtained by other experimenters using pure sodium preparations. There

must be a consequent modification of the crystalloid containing fluids of the cell.

5. The sulphur metabolism of the body is increased by 50 per cent. and this increase, by analogy with known effects of iron on free cystein and glutathione, may be due to the presence of manganese in sulphur water.

6. The chlorine ion is extruded from the body with greater ease than the sodium ion.

7. The percentage increases in excretion of chlorine were greatest by the bowel. The increased percentage excretion of sodium was greatest in the urine, except where there was great purgation.

8. The excretion by the skin of calcium, magnesium, sodium, and potassium was increased about 70 per cent. above the normal. This should be remembered in connexion with the skin disorders treated at our spas, and in relation to the use of preparations of calcium employed in the ordinary treatment of such cases.

9. During constipation the excretion of all ions (except sodium by urine and fæces) was decreased. Purgation increased the metabolism most.

The plus excretion of the ions in sulphur water was an entirely unexpected result, especially the plus excretion of manganese. The retention of barium in some position almost, if not entirely, outside the blood stream was also unanticipated. The retention of sodium in the general tissues was vaguely known, but, so far as we know, there were no definite figures proving its extent. The plus excretion of calcium and potassium might have been foretold from reading the literature on hypertonic injections of sodium chloride. The effects on excretion of the various ions by the skin appear to us to be very striking.

We place the possible methods by which sulphur water acts in the following order:—

(1) The more rapid removal of waste products when formed.

(2) The probable stimulation of the body ferments (possibly also of xanthine oxidase and sulphatase) by manganese, a constituent of sulphur water.

(3) An alteration in the cell fluids consequent on the absorption and retention of the sodium ion.

(4) Possible increase of permeability of the cell to sulphur-containing bodies.

(1) may be only a consequence of (2), (3), and (4).

We are unable at present to suggest a definite and satisfactory part for barium in the increased metabolism which follows ingestion of sulphur water in clinically suitable quantities.

Clinical and Laboratory Notes.

A NOTE ON INTENSIVE IONISATION.

BY W. S. WHITCOMBE, M.D. BRUX., L.S.A. LOND.

IONISATION, ionto-phoresis or kataphoresis—whichever name is preferred—can be administered from the anode or from the kathode of a galvanic current.

With the kations I am not concerned. It is from the negative pole only that high doses (100–200 milliampères) can be given, and I have suggested the term "intensive ionisation" to designate this therapeutic measure which is capable of producing very remarkable results in the treatment of the various forms of chronic arthritis, neuritis, and fibrositis. The smaller doses (15–30 milliampères), which I understand are given at the various spas and electrotherapeutic institutions, are not sufficiently powerful to influence such diseases to any appreciable extent.

The output of ions from the applicator depends entirely upon the quantity of electricity (Coulombs) passing through the body; and the voltage must be strong enough to overcome the resistance of the body. The anions of the electrolyte are then carried by their electrical charge through the tissues towards the anode. What becomes of them? Physicists, like Sir Oliver Lodge, think that they are arrested on their way by the denser tissues, muscle, bone, and fibrous structures, and that their electrical charge then leaves them as deposits of nascent ions. That substances such as iodine, chlorine, and the salicylic radicle in the nascent state are very powerful germicides is beyond dispute; chlorine gas, the hypochlorites, and iodine are, of course, freely employed as antiseptics. If, then, by means of galvanism, we can drive their nascent ions into diseased areas, surely such a procedure is of the highest value?

At a demonstration which I gave at the Royal Society of Medicine on March 15th, I showed by a simple experiment the dissociation, by galvanism, of a solution of iodide of potash, whereby starch material at the anode was iodised to a deep blue colour after the passage of the current from the kathode, four inches distant. To prove the repulsion of the iodine from the electro-negative pad I enlisted the help of Mr. W. H. Martindale, Ph.D., who kindly analysed the electrolyte solution of potassium iodide on two occasions before and after treatment. His analysis showed that about 2½ grains of pot. iod. were lost by a pad of 63 square inches surface soaked in the electrolyte solution. A physicist can easily calculate the number of million nascent ions of iodine, representing one grain of potassium iodide, discharged from the kathode; one atom of iodine being estimated at 53 electrons.

Considering the proximity of the body fluids (lymph and blood) to the epidermis, how is it possible to doubt the passage of these nascent ions into the tissues? I believe that they, in some part, enter into albuminous combinations with the sera of these fluids. How else can we account for the copper penny taste in the mouth and the iodine in the urine?

My immediate object is to give a detailed account of the process by which these high doses can be given safely and comfortably. This technique I demonstrated on a patient suffering from hip pain, at the Royal Society of Medicine. On that occasion a current of 145 milliampères at 80 volts was passed, for 25 minutes, from hip to hip, a distance of 17 inches. It was noticeable to all those present that, at the end of the treatment the skin showed merely a uniform blush, there was no sign of burning or blistering, and there was no discomfort. My technique is as follows:—

Pads composed of three layers of gamgee tissue, lightly quilted in a covering of lint, are made to the size and shape required. They are backed by a conductor material for which I suggest the term "galvani." This gauze is made of fine gold-plated copper ribbon wound round thread woven to a ¼ inch square mesh. At my request it is now stocked by Messrs. Schall and Son and by Messrs. Allen and Hanburys, so that it is easily obtainable. Safety-pin terminals connect up the current through rubber-covered cables.

There are eminent authorities on electrotherapeutics who do not admit the specific action of these nascent elements, and suggest that the effect of the treatment is due to metabolic changes in the tissues consequent on the galvanic current. They may be right, but what evidence exists to support this theory? There is a great deal of evidence on the other side. It is probable that we shall have to enlist the help of the bacteriologists to settle the matter, for if they can show that pathogenic organisms are destroyed by the ionisation of antiseptic chemicals such as iodine, and are not sensibly affected by the galvanic current alone, then the case is proved; also the biochemists might help us very considerably by examining the body fluids.

GENERAL ANÆSTHESIA BY THE INTRAVENOUS INJECTION OF ETHYL ALCOHOL.

By Julien D. Constantin, M.R.C.S. Eng.,
ANÆSTHETIST TO THE MILLER GENERAL HOSPITAL, GREENWICH, AND THE FRENCH HOSPITAL, SHAFTESBURY AVENUE.

In view of the premature and mostly inaccurate publicity given to the method of anæsthesia advocated by Dr. Miguel Garcia Marin, of the Military Hospital, Mexico City, it seems desirable to describe the method in detail.

Intravenous anæsthesia is not a new thing, but the use of ethyl alcohol intravenously had not, as far as I know, been reported until Dr. Marin's experiments became known.[1] The method consists in the administration, intravenously, of 90 per cent. pure ethyl alcohol in a solution of glucose. Dr. Marin has been experimenting for over four years, during which time he performed about 700 operations on animals before applying his technique to operations on human beings. Some 300 patients have now been anæsthetised successfully in this way for various operations.

Dr. Marin gives as his reason for using ethyl alcohol that it "dissolves lipoids and penetrates by endosmosis the protoplasm of the nerve cells, hindering their metabolism."

He claims that the adoption of the intravenous route does away with any risk of initial syncope through direct irritation of the mucous membrane. Further advantages of intravenous anæsthesia are: (a) No mask, or other appliances to the face or mouth, need be used during any operation to the head or face, which eliminates the possibility of infection from this source and also leaves a clearer field of action to the operator. (b) There is less danger of post-anæsthetic pneumonic complications. (c) The risks of fire during the use of thermocautery or diathermy are done away with. (d) The possibility of injury to the eyes from accidental contact with an irritating anæsthetic is avoided. (e) Perfect control of administration obtained (see below). (f) No material effect is noticeable on the blood pressure. There is an initial rise, but this is of short duration, and the blood pressure soon falls to normal again and remains normal.

It is claimed that, since ethyl alcohol is 137 times less toxic than chloroform, and since surgical anæsthesia can be obtained with a dose three to four times smaller than the lethal one, there must be a large margin of safety.

Technique.

The usual aseptic and antiseptic precautions, as for any other intravenous administration, should be taken. An ingenious apparatus has been devised by Dr. Rooul Ortiz, of Mexico, a collaborator of Dr. Marin, but a convenient, if not ideal, substitute may be found in the old Army 606 outfit, interposing a two-way stop-cock at the junction of the two outlet tubes.

Two sterile solutions are used, one in each container. They are: (a) an isotonic solution of glucose, and (b) a solution of pure ethyl alcohol and glucose—viz., 30 c.cm. of 96 per cent. ethyl alcohol in 70 c.cm. of a 25 per cent. solution of glucose. Any vein may be selected to suit the convenience of the anæsthetist or the surgeon. Once the needle is ascertained to be well inside the lumen of the vein, solution (a) is allowed to flow and a few cubic centimetres are injected; then the two-way tap is turned over to allow solution (b) to flow at a rate of not more than 10 c.cm. in 30 seconds. This rate is more or less maintained until anæsthesia has been induced. When anæsthesia is considered sufficiently deep, the tap can be turned off; or at the discretion of the anæsthetist more anæsthetic or isotonic solution can be given. The needle may be held in position during the administration by pieces or sticking plaster. The dosage is estimated from the body-weight of the patient (2 to 3 c.cm. of the 96 per cent. pure alcohol per kg. of weight), but one is seldom called upon to make use of the maximum allowance.

Results.

Induction may take from 2 to 15 minutes. There is no initial stage of excitement such as may occur with inhalation anæsthesia. Perfect relaxation is said to be a chief feature, the breathing being very quiet; and naturally this is of great assistance to the surgeon in all abdominal cases. The method should not be employed for infants or in cases of advanced pulmonary tuberculosis, but the 300 cases already operated on have included patients with definite cardiac lesions and also diabetics. Bright's disease is said not to be a contra-indication. One curious contention is made—namely, that alcoholics require a dose even smaller than the average temperate subject.

Surgical anæsthesia is reckoned to last an hour and a half, but may be prolonged, by giving more anæsthetic, up to four hours. The recovery is peaceful and there are no ill-effects, such as vomiting. The patient may even be fed if the nature of the operation so permits. There is a period of post-anæsthetic analgesia that may last three to four hours or more. During the experimental stage there were instances of hæmoglobinuria, but this trouble was soon eliminated when isotonic solutions of glucose were employed and the correct dilution of alcohol was adopted, thereby ensuring proper diuresis.

My acquaintance with this type of anæsthesia is so far limited to two cases, but I was greatly impressed by the results obtained.

The first case was that of a woman, aged 58, with a slight cardiac arrhythmia, who walked into the hospital a few moments before the operation for onychogryphosis, and, therefore, had had none of the preparation one would expect before an anæsthetic. Her weight was a little over 9 st. and it was reckoned that her allowance would be about 150 c.cm. of 96 per cent. ethyl alcohol. The induction took 13 minutes and was very peaceful, the anæsthesia being gradual and uneventful. The corneal reflex was slow in disappearing. Although the surgical part of the operation was relatively a small one, I had the opportunity of testing the relaxation of the abdominal walls by pressure, and everything seemed apparently as it should be, though I should hesitate to say whether the patient would have reacted to incision of the parietal peritoneum at that stage. The systolic blood pressure, taken just before the anæsthetic, was 130, and when anæsthesia had been induced it was still the same. The patient, seen two hours after the anæsthesia, although conscious to a certain degree, was somewhat inclined to be "fidgety" with her arms and incoherent in her speech; otherwise she seemed to be quite comfortable. She suffered from incontinence of urine once, three hours after the operation.

The second case was that of a man of between 50 and 60 years of age, who had an excision of an epithelioma of the upper lip with the diathermy "knife." The same solution as in the first case was again employed, and the total quantity of alcohol administered was 175 c.cm. The time of induction here was also 13 minutes, and again there was no excitement, the man being inclined to be talkative and apparently experiencing no distress or discomfort. In my opinion the operation was painlessly performed, and except for a few twitchings of the facial muscles, due to direct electrical stimulation, there was no movement of the body. The patient was conscious almost immediately after the operation, and an hour and a half afterwards he was sitting up in bed taking nourishment. He had not vomited, and he said he did not feel any nausea; he talked sensibly, but seemed to be somewhat "merry and bright," as after a mild potation.

I observed that in these two cases the respiration had a tendency to be perhaps too shallow, but there was immediately a distinct improvement whenever the tap was switched over to the isotonic glucose solution only. I point this out to show that great control is available during administration.

---

NOTE ON
INTRAVENOUS ANTITOXIN IN AN OUTBREAK OF SCARLET FEVER IN A PUBLIC SCHOOL.

By H. Stanley Banks, M.D. Glasg., D.P.H. Camb.,
MEDICAL SUPERINTENDENT, ISOLATION HOSPITAL AND SANATORIUM, LEICESTER.

Scarlet fever of a severe semi-septic type broke out among the boys of a public school in Leicestershire in February, 1929. The first nine cases were treated by ordinary expectant methods and without antitoxin. The course of the disease in these gave rise to much anxiety, and complications were frequent, as noted in the Table below.

Then occurred the worst case of all, a boy aged 13, who, when seen by me about the seventh day of the disease, had already a severely ulcerated throat, cervical glands enlarged and tender, double acute suppurative otitis media, and acute mastoid suppuration on one side. He was given 10 c.cm. scarlatinal antitoxin intravenously, unfortunately without effect at this stage. The sepsis developed into pyæmia with multiple purulent arthritis, involving incisions into the hip-joint, the elbow-joint, both ankle-joints, and the double mastoid operation. The serum was given too late in this case and the dose was too low for such a severe case.

The subsequent cases, 16 in number, were treated early in the acute stage with antitoxin *intravenously* according to the technique which I have previously described[1]. In these 16 cases the acute stage, though apparently of the same sharp type as the others, was arrested within 12–24 hours of the injection; further, no desquamation occurred and the complications were limited to one mild adenitis in a case who received his antitoxin on the fourth day of his disease, and one simple hordeolum. All 16 cases were allowed up within a week, and were discharged from isolation in about a fortnight's time.

All were boys between the ages of 12 and 18 years, except one master aged 49 years. All received their injections within the first four days of their disease, generally on the second or third day. There were no ill-effects noted from the serum administration, although one boy had a moderately severe rigor and two had hyperpyrexia for a few hours after the injection. In one case intravenous serum appeared to be contra-indicated owing to a history of hay-fever. In this case an intradermal test injection of 1 in 10 dilution of the serum was done and it did not produce any reaction. Accordingly, the usual dose, 10 c.cm. of serum was injected intravenously, and no ill-effect was noted.

The following Table gives particulars of the complications noted in this interesting series :—

Scarlet Fever Complications.

Nine cases not treated with antitoxin.

Suppurative otitis media with persistent otorrhœa	2	Dacryo-cystitis	1
Non-suppurative otitis media	2	Pneumonia	1
Albuminuria or nephritis about third week ..	7	Jaundice	1
Empyema of maxillary antrum and frontal sinus	1	Adenitis	7
		Nasal discharge	6
		Desquamation	9

Sixteen cases treated with intravenous antitoxin.

Adenitis	1	Hordeolum	1

The only case omitted from the Table is the severe case of pyæmia noted above, in which the serum was given too late to be effective.

The injections, with the exception of the first two, were given by Dr. Hubert L. Ellison, to whom I am indebted for detailed information as to the course of the outbreak.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

At a meeting of this Society, held at the rooms of the Medical Society of London, on May 31st, Dr. F. J. H. Coutts, the President, being in the chair, Colonel L. W. Harrison reviewed some of the

Experimental Work in Syphilis,

particularly that bearing on resistance to infection and reinfection. Referring to the well-known difficulty or impossibility of reinfecting a syphilitic soon after outbreak of the primary sore and to the long periods of latency after subsidence of early symptoms, he discussed the theory of Neisser, which is held also by Kolle and his school, that these phenomena are due not to immunity in the sense of active resistance but to "anergie," or mere tolerance of *Spirochæta pallida* by the tissues. Kolle and Schlossberger demonstrated complete natural "anergie" in mice, the spirochæte spreading through the tissues of these animals after inoculation and remaining there in a virulent state for many months without evoking any signs of disease. Numerous experiments have demonstrated a natural, partial "anergie" in rabbits, a proportion of which develop no chancre after primary inoculation but the spirochætes spread through their tissues, as proved by infectivity of the lymph glands and possibly the development of generalised lesions. Experiments show that "anergie" qua the development of a primary sore can be brought about in rabbits and human beings by treatment during the incubation stage which is insufficient to destroy the infection. Brown and Pearce and Kolle have suggested on the strength of animal experiments that in human beings, in certain circumstances of primary infection, no chancre may develop. Although the non-development of a chancre is common enough, no evidence has been produced which proves that mice, rabbits, or human beings can resist primary invasion.

Development of Immunity.

Colonel Harrison went on to discuss the development of immunity in an animal which has been infected for some time, and reviewed experiments by numerous workers to show that in the serum of man or an infected animal there has been demonstrated little evidence of antibodies to virulent spirochætes, though the serum of infected animals or of normal animals which have been treated with vaccines of *S. pallida* may act against cultural spirochætes. Sachs, Klopstock, and Weil found that, after inoculation with alcoholic extract of heart plus a foreign (pig's) serum, a rabbit becomes positive to Wassermann and flocculation tests, showing that these tests depend on antibody to lipoid. The views of F. Klopstock that the antigen is spirochætal lipoid and those of Torii that it is tissue lipoid were discussed, the evidence seeming to favour the views of Torii. Bergel has presented histological evidence that mononuclear cells, by virtue of lipolytic enzymes, break up the spirochæte into granules, but Bergel's views have not been supported greatly by other workers.

On the indirect evidence of acquired immunity, Kolle showed that in rabbits after the outbreak of the primary sore it becomes increasingly difficult to provoke by reinoculation a second primary sore until after the ninetieth day the reinoculation hardly ever succeeds. These experiments have been substantially confirmed by Chesney and Kemp, Uhlenhuth and Grossmann and others, but these workers do not support the inference of Kolle that failure to reinfect depends on the continued presence of the original spirochætes. They have produced evidence that rabbits can be cured by injections of arsenobenzol, as proved by non-infectivity of their glands, and yet, provided the original infection has lasted long enough, reinoculation provokes no chancre. Further, as showing that infection stimulated the *development of properties actively antagonistic to S. pallida*, in a certain proportion of the animals which present no chancre after reinoculation there is no spread of the virus to the tissues; thus in these animals there has developed in the course of the primary infection not merely "anergic" or "chancre immunity" but active immunity.

Resistance to Infection and Reinfection.

The immunity of rabbits resulting from infection may not apply to virus from another source; thus a rabbit originally infected with the Truffi strain of *S. pallida* may resist infection with the homologous strain but be reinfected by the Nichols strain and vice versa. This specificity of immunity does not occur in man, and some evidence has been produced, notably by Jahnel and Lange, that a syphilitic can resist infection with *S. pertenuis* of yaws. That immunity depends on interaction of the spirochæte and the tissues seems to be demonstrated by the experiments of Manteufel and Richter and others, which show that a rabbit inoculated intravenously *may develop no lesions and can then be superinfected* by intratesticular inoculation. Also Brown and Pearce showed that the more the development of the primary lesion was interfered with by treatment short of that required to destroy the infection and the fewer the number of primary lesions, the greater the certainty that generalised lesions would *develop. The fact that a number of animals whose* infections had lasted 90 or more days were left after sterilisation with only a chancre immunity has suggested to Chesney and Kemp the possibility that, in men who after apparently successful treatment have remained negative for many months and have then become serologically positive, the cause may lie not in relapse of the original infection but in reinfection without chancre. The effect of injury in breaking down "anergic" in rabbits qua development of lesions was demonstrated by Chesney and Kemp. In rabbits which had been treated late and then reinoculated with syphilitic virus into wounds in the back chancres followed in 50 per cent. of cases, which contrasts with the rarity of chancres following intratesticular reinoculation of rabbits treated late in the disease. Also, Chesney, Turner and Halley showed that, if rabbits with granulating wounds, or new scars of such, are inoculated intravenously, a route which does not commonly result in lesions, syphilomata developed in the granulating wounds, or in the scars, within periods closely approximating the average for incubation. Chesney, Turner and Halley related two human cases which demonstrated very clearly the tendency of syphilomata to develop in the sites of wounds or injuries. The slow development of chancre immunity in men has been demonstrated by Halley and Wassermann. These workers studied *the literature on 676 cases of reinfection, and, after* rejecting 447 as inadmissible, found in the remainder that 97·8 per cent. were treated first in the primary and secondary stages and that in practically all the first infection when first treated was less than 16 weeks old, while in 82 per cent. it was less than 8 weeks old. This suggests that when treatment is commenced soon after the sixteenth week a chancreless infection may follow reinoculation. Brown and Pearce have shown evidence that resistance to *S. pallida* is bound up with the activity of the endocrine system and the lymphoid tissues. They have also shown that animals exposed to light present a more effective response to infection than do those kept in the dark. Thus they show that the cure of syphilis is not merely a matter of a test-tube reaction between remedy and spirochæte.

Schamberg and Rule have shown, Colonel HARRISON continued, that in rabbits the artificial production of high temperatures by hot baths can prevent the development of syphilis after inoculation. Also, like Weichbrodt, who raised the animals' temperatures by putting them in an incubator, that artificially produced high temperatures favour the retrogression of syphilitic lesions. Experiments on syphilitic *men carried out by Schamberg and Tseng, who found* that the body temperature could safely be raised to 106° F., were not very conclusive.

Levaditi and colleagues have shown that bismuth and vanadium are prophylactically and therapeutically effective only so long as the amount of metal absorbed and incorporated in the tissues ("metallic *potential") is above a certain level and that this* level is more easily attained with the basic tartrate of bismuth (trépol) than with metallic bismuth in fine subdivision (neo-trépol). Thus trépol protected a rabbit against inoculation up to 152 days later while neo-trépol protected only two out of nine rabbits inoculated 73 days after the injection.

Discussion.

Dr. **DAVID LEES** agreed as to the value and significance of the patient's constitution in the results of treatment; but would like more details, and as to what were the best means of reinforcing a patient's resistance when it was low. Mono- and poly-glandular therapy had not given him assistance in this. He also remarked on the paucity of the experimental work done in this country on syphilis in comparison with that in other lands.

Dr. **H. M. HANSCHELL** supported the idea that the llama was very susceptible to syphilitic infection; in Peru it was not infrequent for drovers to attribute their syphilis to that animal. Some patients who *showed a poor response to antisyphilitic* measures reacted well as soon as a course of cod-liver oil was given. He was able to confirm several points in the paper from his own experience.

Dr. **H. C. SEMON** expressed scepticism on the conclusions which were drawn as to suprainfection in animals which had been treated, in that this *treatment had set up bismuth depôts, which at a* later stage might protect against further infections. The choice of the site of previous injury for the manifestation of syphilitic disease had a parallel in the case of psoriasis, which was often found on tattoo marks.

Discussion is to be resumed at the next meeting.

ROYAL SOCIETY OF MEDICINE.

SECTION OF LARYNGOLOGY.

RADIUM TREATMENT OF MALIGNANT DISEASE OF THE ŒSOPHAGUS.

THE summer meeting of this Section was held on June 7th, Mr. H. **BELL TAWSE** presiding.

Thoracotomy and Radon Needles.

Mr. **F. J. CLEMINSON** read a paper on Thoracotomy in the Treatment of Malignant Disease of the *Œsophagus by Radon. The mortality of œsophageal* cancer at the present time, he said, was almost 100 per cent. Attempts to remove the growth by operation nearly always resulted in the patient's death. The use of radium under œsophagoscopy had not more than an occasional cure to its credit. The results could thus hardly be worse and there was always a chance that a new technique might improve them. He had, therefore, attempted to treat cases by inducing collapse of the lung on one side, and then opening the thorax with a view to placing radon needles in the periphery of the growth. Radon was used to obviate the need of removing the source of irradiation after the exposure had been completed. After the patient had recovered somewhat from the operation the other side of the chest could be opened and the procedure repeated. He had treated three cases in this way.

The first patient was a nervous man aged 74, first seen in June, 1928. For three months he had had indigestion, with difficulty in swallowing, and had lost 7 lb. in weight. A skiagram showed an irregular stricture from the fourth to the sixth dorsal vertebræ. The appearance was regarded as strongly suggestive of malignant disease. Œsophagoscopy showed a growth in the upper margin of the œsophagus, 9½ in. from the incisor teeth. A small portion removed showed actively growing carcinoma, many of the cells undergoing active mitosis. Removal of the eighth rib gave a good view of the region. It was not possible to feel the growth, but 20 unscreened radon seeds, each containing 1·2 millicuries, were implanted by means of a curved needle and trocar, being distributed along the growth. The pleural cavity was mopped out with 1 in 1000 flavine, and the chest wall sutured without drainage. Seven to ten days after operation there was distinct improvement in swallowing, but convalescence was delayed by the formation of pleural effusion, possibly attributable to the fact that the radon seeds had not been screened. Fifty millicuries were then passed down the œsophagus in a platinum tube and left for 24 hours. Some weeks later the patient was found to have lost ground and was bringing up much sputum, but he could swallow such solid food as bacon and eggs. Eighteen weeks after the performance of the thoracotomy the man died, the symptoms indicating a tracheal-œsophageal fistula; an autopsy was not allowed.

The second patient treated had complained of the return of food five minutes after it was swallowed; when first seen he could take only fluids. X rays showed an irregular stricture at and below the level of the arch of the aorta. Malignant disease was diagnosed from a specimen removed. The technique of the operation performed was similar to that described above, except that the radon seeds were screened. On the fifth day the temperature was 101° F., and there was a moderate pleural effusion. Under medical treatment the temperature became normal and the effusion had cleared up by the twelfth day. Noticeable improvement in swallowing followed, but only for a few weeks; after six weeks a radiogram showed obstruction below the level of the aortic arch. The treatment was repeated, but death occurred four months after the thoracotomy. The autopsy showed carcinoma on the left side of the œsophagus, extending for 1½ in. Below the aorta was an opening into the mediastinal tissue which led to a peri-œsophageal abscess. The extent of the growth was 4 in. The abscess had allowed the radon seeds to escape.

The third patient was a man, aged 61, who had had dysphagia for five months. His stricture was at the level of the fourth dorsal vertebra. The left vocal cord was paralysed. The growth was a squamous-celled carcinoma. The case was dealt with on the same lines as the others, but he died five weeks after the thorax had been opened. Here also an opening in the gullet led into an abscess cavity. The growth was so extensive that it was not really a suitable case for radium therapy.

Mr. MUSGRAVE WOODMAN (Birmingham) also gave a communication on the Insertion and Use of Radon in Cancer of the Œsophagus. He said that the use of central large doses of radium had failed, because the radium was in contact with the central mass of necrotic tissue, and far from the growing edge of the tumour. Moreover, the presence of a mechanical appliance, such as a tube, led to the formation of a fibrous stricture. He favoured the use of radon needles, platinum-screened, which need not be removed. His cases had all been examined by X rays each month. In none of the cases had a needle passed into the mediastinum, nor had there been inflammatory reaction round them. None of the patients had shown a general reaction, nor had there been any immediate mortality. There was general improvement in swallowing afterwards. One patient, however, died of tracheal fistula three weeks after the insertion of the radon, and the post-mortem examination revealed two burns, both ulcerated, and one having perforated. He attributed the burns to an excessive concentration of radon. Three sections from a fatal case had been examined pathologically. The first, taken from a spot remote from the radon seeds, showed typical active epithelioma, the second, from a site fairly close to a radon seed, was more indolent and less malignant; while the third, quite close to a radon seed, showed definite regression and more evidence of fibrous tissue. He feared few patients would be found suitable for this treatment, since it was difficult to detect œsophageal cancer in an early stage, but he was hopeful that ultimately these growths would be brought under control.

Radon and Diathermy.

Mr. W. S. THACKER NEVILLE read a paper on Two Cases of Œsophageal Carcinoma Treated by Radon and Diathermy. He said that the treatment of carcinoma in this region when the cost of radium was prohibitive was a difficulty. In one patient he inserted a Souttar's tube, but it became blocked, and death occurred a few months later. In one case diathermy rendered a gastrostomy unnecessary, but it did not prevent secondary growths. This man lived for a year, and was able to swallow and to carry on his work as a blacksmith for eight months. Another patient had radon inserted into the growth, and lived for five months afterwards.

Dr. BROWN KELLY thought that at the present stage these measures could be looked upon only as palliative. The food given to patients should be soft and semi-liquid. He believed that in the future intubation would be used mainly for a persistent application of radium; he had found it unsatisfactory when the disease was at the ends of the gullet.

Mr. W. HOWARTH did not think the outlook in regard to the treatment of cancer of the œsophagus by radium was more hopeful now than when he began to study the subject in 1912, though access through the chest made its application more convenient. He had not tried radon. The main essential in the irradiation treatment of malignant disease was that every cancer cell should receive a lethal dose. This could only be achieved, he thought, by a combination of the external with the internal methods. Thoracotomy should be part of the treatment. Removal of a rib he did not consider necessary; by means of a rib retractor the intercostal space could be enlarged and an adequate view of the site obtained.

Mr. C. A. S. RIDOUT spoke of the advantage of doing preliminary gastrostomy, especially in producing a cleaner area and one to which radium could be more satisfactorily applied. If only these cases could be seen by the surgeon at an early stage he believed radium held out a great prospect of ultimate triumph.

Mr. HAROLD BARWELL emphasised the great importance of a proper spacing of the radon needles. In dealing with the œsophagus one did not know how far the growth extended outwards, and it was very difficult to know whether all the cancer cells had been killed.

Sir JAMES DUNDAS-GRANT contended that much could be done to relieve for a time the distress of these patients, though the chance of cure was still remote. He advocated the use of the radon introducers invented by Muir, of New York. He agreed with Mr. Ridout that benefit followed preliminary gastrostomy.

Dr. J. A. GIBB read a paper on

Referred Pain of Nasal Sinus Disease.

He emphasised the importance of a knowledge of referred pain, since microbic infections resulting in the formation of pus were liable to be overlooked. He drew attention to the relation between headaches and sinus disease, a nerve frequently implicated being the fifth. Very often pain of sinus origin was treated as mere headache.

The PRESIDENT referred to a case in which a woman complained of acute pain over the mastoid. The tympanic membrane was normal and there was apparently no ear disease. Opening and draining the sphenoidal sinus caused the immediate cessation of the pain. In another case he was called to open the mastoid, but found that the cause of the pain was not acute mastoid disease, but a carious upper molar.

Mr. W. T. GARDINER (Edinburgh) said that any patient who complained of a fixed headache, especially always in the same position, should be strongly suspected of having sinus disease. Tenderness of the scalp when brushing the hair was a suspicious symptom.

Mr. H. TILLEY reminded members of his demonstration before the Section of Otology of the

Society of the nerve path discovered by Fenton and Lasser, which was responsible for the conveyance of much referred pain.

Dr. **P. Watson-Williams** said he was called to see a boy aged 14, who had very severe pain in the ear following influenza, with the view of a mastoid operation. There seemed to be nothing wrong with the ear, so other advice was sought. The boy died and suppuration was found round an infected sphenoidal sinus. He did not think one could point to any particular area as the site of pain in these cases.

Dr. **Gavin Young** spoke of the close relation of the vidian nerve to the sphenoidal sinus; in some cases there were dehiscences in the roof of the vidian canal, so that there was only the lining of the canal and the mucosa of the sphenoidal sinus between the nerve and the sinus. Sometimes pain in edentulous patients arose from tooth stumps which had been left in the jaw at the time of extraction.

Mr. **W. S. Thacker Neville** read a contribution on

Morphine and Scopolamine Anæsthesia in Nasal Operations.

In it the author spoke of 461 cases which had been operated upon by him at Greenbank Hospital, Darlington, under morphine-scopolamine narco-anæsthesia. The operations did not include tonsillectomies. In 83 out of 150 cases specially analysed in the paper, the dose given was: morphia gr. ¼, scopolamine gr. 1/100, digitalin gr. 1/50, the last two being repeated in the same dosage within an hour. He detailed the procedure followed. For a Caldwell-Luc operation he injected locally novocaine and sod. sulph. He did not use this form of anæsthesia for children under 12. Of the 150 cases, 122 suffered no pain, 18 said they had slight pain, 8 had definite pain, and 1 required general anæsthesia. The average time which elapsed between the first dose and the commencement of the operation was 1 hour 12 minutes, the shortest time being 35 minutes. The average duration of the operation was 25 minutes, the longest operation taking 70 minutes. Respirations quickened during the operation, often the pulse-rate was 140 per minute. The systolic blood pressure was raised. It was usual for the patient to talk to the surgeon during the operation. After the operation the chief complication was vomiting; it commenced many hours after, and did not call for treatment. Two died out of the 461 cases, which were described is some detail.

Mr. **T. B. Layton** pointed out that the combination spoken of by Mr. Thacker Neville was not an anæsthetic, but a narcotic. He, the speaker, did not think any operation ought to be done on the nose under general anæsthesia if it could be done under local. Local anæsthesia would never answer for any operation which involved rough handling or much manipulation of tissue. The problem was largely a psychological one. Operation should not be attempted under local anæsthesia unless quiet could be ensured.

Considerable discussion ensued on the subject of general *versus* local anæsthesia.

Mr. **Harold Barwell** read a paper dealing with the

Treatment of Inflammation in the Maxillary Antrum and Frontal Sinus.

Mr. Barwell contended that the principles which ought to underline rational methods of treating suppuration in nasal sinuses had only been slowly appreciated. He considered that the essential need was to secure unimpeded drainage of the affected cavity into the nose. Packing only interfered with this drainage. Cure took place by regeneration of the epithelial lining, hence curetting did harm, as also did strong antiseptics. Small polypoid thickenings disappeared when the required drainage had been established, though it was well to remove any large polypi. For frontal sinusitis he now performed fewer operations than he did 15 years ago; the disease seemed to have become less virulent. Acute inflammation might be of any grade of severity, since the sinuses participated in the production of the secretion of any acute coryza. In all except the mildest cases of antral imflammation the cavity should be washed out. For this purpose he used normal saline solution tinged with tincture of iodine. For very thick discharge he first introduced one or two drachms of hydrogen peroxide. Supraorbital pain was often due to antral suppuration in cases which did not show any involvement of the frontal sinus. Acute frontal sinusitis rarely required external operation; this was only called for when there were signs of external abscess formation.

The paper was fully discussed.

Cancer of Vocal Cords.

Dr. **W. Jobson Horne** read a paper on Difficulties in Diagnosis and Fallacies in Statistics in reference to Cancer of the Vocal Cords. He said that cancer was diagnosed more often than it existed, and in the larynx the error was chiefly made concerning the vocal cords. But in his early days he did not remember to have seen a case in which cancer was overlooked when it did exist. He had noted an increasing number of cases within recent years of so-called intrinsic cancer of the larynx or of the vocal cords in women. In the statistics collected by the late Dr. William Hill and himself women patients ranged from 10 to 15 per cent. of the total, though this form of cancer was previously unrecorded in women. He wondered whether the altered incidence bore any relation to change of habits, such as smoking? The first disease to be eliminated in diagnosis was tuberculosis, and this, even at the present day, was often a difficult matter. High authorities had declared that no one need be ashamed of having made the mistake. Syphilis was another disease which must be eliminated before the diagnosis of cancer of the cords was made. Syphilis and cancer of the larynx had been associated in quite a number of cases, therefore the finding that the patient had a positive Wassermann reaction might be a hindrance rather than a help in diagnosis. Tuberculosis and cancer of the larynx were, however, but rarely associated in the same patient. With regard to the differentiation of innocent from malignant tumours of the cords, one type of tumour took the form of an excrescence or outgrowth on the cord; it might be sessile or pedunculated or condylomatous. The cord was mobile. Radium applications gave good results in its treatment. If this condition was malignant, the degree was so mild that thyrotomy showed 100 per cent. of permanent cures. In statistics this form of tumour should be kept separate. Sections from growths for diagnosis should always be cut at right angles to the cord, and should include actual cord substance.

Dr. **Horne** showed a number of photomicrographs on the screen to support his thesis.

The subject was discussed by Sir **James Dundas-Grant**, Mr. **T. B. Layton**, Mr. **R. A. Worthington**, Dr. **Andrew Wylie**, Mr. **M. Vlasto**, and Mr. **H. Tilley**.

Mr. **O. Popper** read a paper entitled Bloodless Tonsil Enucleation, and showed a guillotine of new design.

A number of clinical cases were discussed.

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of this Society on May 8th, with Dr. **Haig Ferguson**, the President, in the chair, a paper on

STILLBIRTH AND NEONATAL DEATH

was read by Dr. **Chalmers Fahmy** and Dr. **Elsie Crowe**. It was based, they said, on a study of 300 cases from the Royal Maternity and Simpson Memorial Hospital, Edinburgh. Of the total number, 248 fœtuses were born at, or near, full term, while 52 were definitely premature. In order to keep in prominence the clinical aspect of the investigation, the cases were classified according to the manner of delivery, the 248 fœtuses born at, or near, full term being grouped as follows :—

—	Still-born.	Neo-natal.	Macer-ated.	Total.
Spontaneous delivery (all vertex presentations) ..	47	16	28	91
Forceps	54	7	4	65
Breech	47	4	5	56
Cæsarean section	8	5	0	13
Craniotomy	23	0	0	23
Total	179	32	37	248

Dr. Fahmy and Dr. Crowe drew attention especially to *the frequency of intracranial hæmorrhage in cases of* normal spontaneous delivery. It would be seen, they said, that there were 47 stillbirths in the group of spontaneous delivery, all being vertex case presentations. Eleven of these deaths were due to intracranial hæmorrhage and 15 to asphyxia, whilst in 8 of the latter some intracranial hæmorrhage was also found. Acute anæmia was thought to be the cause of death in 4 cases, in each of which labour was complicated by antepartum hæmorrhage and no cause for death was found other than the pale and anæmic state of the fœtal organs. The history was given of a number of cases of easy labour in which death was due to intracranial hæmorrhage, and it was pointed out that in parous women the fœtal head might be driven through the pelvis, from brim to outlet, in a short space of time after rupture of the membranes, this rapid descent predisposing to hæmorrhage. Such a rapid passage of the head was not unlike that occurring during a breech delivery, which was recognised as a cause of cranial injury. The number of neonatal deaths in infants born at, or near, full term was 16 ; and of this number 7 were due to intracranial hæmorrhage. The association of intracranial hæmorrhage with asphyxia was noteworthy. Often it was hard to say which factor predominated but the two conditions were frequently found in combination. This pointed clearly to the necessity of treating asphyxiated infants with great gentleness, whether they were born white or blue. That infants born pallid should be treated as if in a condition of shock was well recognised, but the speakers did not think that equal care had hitherto been deemed necessary for those born with blue asphyxia. Such infants might be suffering from intracranial hæmorrhage as well as asphyxia, and methods of artificial respiration, such as Schultze's and Byrd's, should not be practised. Intracranial hæmorrhage was occasionally found with pulmonary disturbance in infants surviving only a few days, and it was possible that this hæmorrhage, by depressing the respiratory function, might predispose to partial atelectasis and also to patches of pneumonia.

Mr. D. STEWART MIDDLETON read a paper on

Ureteric Dilatation of Pregnancy.

Until a few years ago, he said, the dilatation of the ureters commonly associated with pregnancy had only been noted in post-mortem specimens, but pyelo-ureterography had now demonstrated that it occurred in about 85 per cent. of pregnant women. The right ureter was usually alone affected, but the condition might be bilateral, the left ureter becoming dilated much later in pregnancy. Mr. Middleton strongly favoured the theory that the ureters were affected by the factors acting on the uterine musculature throughout pregnancy—namely, muscular hyperplasia combined with diminished contractility. The greater dilatation on the right side might be accounted for by torsion of the uterus. During the puerperium the muscular hyperplasia would, of course, retrogress, and mobility would be re-established immediately after delivery. It was clear that the thickened ureter, already showing connective tissue hyperplasia and exposed to a good deal of trauma during labour, would sometimes become so far fibrotic as to cause ureteric stricture and thus perpetuate what was otherwise a temporary hydro-ureter. In Mr. Middleton's opinion acute pyelonephritis of pregnancy was due to chronic colonic stasis which allowed the absorption of *Bacillus coli* from the gut and ended by the infection of a vulnerable dilated ureter during excretion of these organisms from the blood via the renal tract. Raising the foot of the bed might have a beneficial influence by decreasing any tendency to pressure on the lower ureter by the lower pole of the uterus. Most cases of pyelitis responded to simple treatment, but in more serious ones the dilated ureter must be drained. It was now seldom necessary to induce abortion or premature labour for pyelitis. At the same time, steps should be taken to treat the stasis in the proximal colon wherein lay the origin of the infection.

Mr. Middleton attributed idiopathic hæmaturia of pregnancy to compression of the veins in the renal pelvis with a corresponding rise in the arterial tension. This would from time to time give rise, he said, to rupture of a small vessel. He gave details of four cases of hæmaturia during pregnancy and showed that catheterisation of the ureter and aspiration of the renal and ureteric residual urine would, as a rule, cut the hæmaturia short. With regard to ureteric stricture he was inclined to emphasise the close association of stricture with multiparity. Before coming to this conclusion he had collected all the pyelograms made in the Electric Diagnostic Theatre of the Royal Infirmary which showed a dilatation of the ureter which was due to stricture. It was found that in these cases the patients were multiparæ, the dilatation in all but two being confined to the right side. This corresponded accurately with the incidence as regards sides of the simple dilatation of pregnancy. None of the patients had suffered from acute pyelitis during pregnancy, but the symptoms could be shown to have developed shortly after a confinement. Mr. Middleton thought that the symptoms of a stricture of the ureter were divided into two syndromes: (1) idiopathic hæmaturia of pregnancy, and (2) pain in the renal region usually on the right side, occurring in a multiparous woman, and varying from a mild backache to pain so severe as to suggest renal colic. The pain often began as backache during a pregnancy and became intensified during successive pregnancies. In more than half the cases no abnormality would be found in the urine, and the decision to make a routine urological examination must be based on the symptoms and not on examination of the urine.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

A MEETING of this Section was held on May 26th, with Mr. R. A. STONEY, in the absence of the President, in the chair.

Cerebral Symptoms in a Boy.

Prof. H. F. MOORE and Mr. C. J. MCAULEY showed a boy, aged 15 years, who, five years before admission to the Mater Hospital, had sustained a head injury with a scalp wound in the left parietal region.

Two years later he began to suffer from twitchings of the right side of the face, right eye, and right arm. The twitchings were preceded by an aura of taste, but the boy never lost consciousness. He had one of these attacks while in hospital, and for some time after it he had considerable difficulty in speech.

On examination an irregular defect could be felt over the upper part of the left parietal bone. There was paresis of the right arm with distinct astereognosis. The boy walked with a hemiplegic gait and the abdominal reflex was absent on the right side. Babinski's sign, ankle- and rectus-clonus were present. Examination of the eyes revealed double optic neuritis with advancing atrophy, the latter being more advanced in the left eye. The Wassermann reaction was negative. Radiographic examination showed convolutional atrophy but no shadow of a bony depression. A diagnosis was made of a cerebral lesion involving the lower part of the left Rolandic area, possibly post-traumatic.

Operation was performed by Mr. McAuley. A large scalp flap was turned down over the left fronto-parietal region. There was an irregular linear defect in the upper part of the left parietal bone, through which a bluish membrane presented. The defect was enlarged, the extreme thinness of the skull being noteworthy. The membrane, when incised, proved to be the dura mater and some fluid escaped under moderate tension. The underlying brain was œdematous with flattened convolutions. Through the soft brain tissue a firm nodular mass in the interior of the frontal lobe could be palpated. The pial vessels were ligatured and the brain incised. The tumour was then gently enucleated. It weighed 98 g. and on section proved to be a tuberculoma.

The boy made a complete recovery, said Mr. McAuley, and had had no twitchings since the operation, power having remarkably increased in the right arm.

The CHAIRMAN said that the preliminary symptoms in this case were difficult to explain in view of the pathological findings. It was interesting to note the large size of the tumour and the consistency of it. Tuberculomas were usually small, and as they got bigger, they turned into definite abscesses.

Mr. WILLIAM PEARSON said he thought the prognosis in this case was very good, and asked if there had been any urinary trouble. During the late war he had seen a large number of frontal lesions, and the patients had almost invariably suffered from disturbances of micturition.

Mr. A. A. MCCONNELL said that in his experience tuberculomas were rare, and the prognosis usually bad, owing to the presence of multiple tumours and the onset of dissemination. He thought that in the present case the patient would probably remain well, as if dissemination had been going to occur it would have taken place by now.

Prof. MOORE, in reply, said that the weakness of the internal rectus had now quite passed away and the Babinski sign was absent.—Mr. MCAULEY, in reply, said he understood that the boy had at one time some nocturnal incontinence, but on admission to hospital this had disappeared.

Non-parasitic Cysts of the Liver.

Mr. F. J. MORRIN reported two cases of polycystic disease of the liver occurring during the third and fourth decades in sisters.

The family history revealed that the father died of pernicious anæmia, and a sister died at the age of 25 from some obscure abdominal complaint. One case was an abdominal emergency. At operation a ruptured parovarian cyst was found. The liver showed extensive polycystic disease, and in addition there were cysts in the transverse mesocolon and a cyst below the left kidney. The other patient complained of attacks of right-sided abdominal pain and vomiting. Operation disclosed polycystic disease of the liver and localised inflammatory reaction over some large cysts in the right lobe. In this case functional liver tests showed no deviation from the normal.

It was considered probable, said Mr. Morrin, that the condition was a developmental anomaly, the familial association of the reported cases lending support to this view. It was hard to diagnose owing to the absence of jaundice and freedom from digestive disturbance; whilst functional tests in one of his own cases showed that the pigmentary, glycogenic, and excretory function of the liver was unaffected.

The CHAIRMAN said the question of polycystic disease of the liver and kidneys was of interest from an embryological point of view, and he personally had always been of opinion that these diseases must be due to some congenital abnormality. The fact that the fluid contained in the cysts was of a more or less non-biliary character pointed, he thought, to the presence of cells not normally found in the liver.

Mr. MCAULEY said he thought that a large number of cases of polycystic disease of the kidney were associated with polycystic disease of the liver.

Dr. A. B. CLERY said that Dr. Lindo had suggested that the disease was due to the maldevelopment of mesoblastic tissue in the fourth month of life.

Mr. MORRIN, in replying, said that according to the literature no autopsies had been performed in cases of polycystic disease of the liver except in children, but the oldest patient operated on for the condition was 82. In the great majority of cases the condition did not lead to early death, though the more severe cases died in early life.

Radium Technique.

Mr. W. C. STEVENSON summarised the results of 15 years' work with radium, during which time he had treated 824 cases of cancer, 531 scars and injuries due to gunshot wounds during the late war, and 607 cases of non-malignant disease, making, with the cases treated this year, a total of 2143 cases.

While the technique was comparatively simple, the physical properties which govern radiation must be fully appreciated if disaster was to be avoided. He laid stress on the importance of obtaining uniform radiation and efficient treatment without over-dosage —for new growth was stimulated by too small doses— and the closest coöperation between the "radio-surgeon" and the specialist. He showed six patients; in three of these an apparent clinical cure of cancer of the tongue, involving the floor of the mouth, and one of cancer of the lip, had been obtained by inserting six iridio-platinum needles containing 54 mg. of radium element, combined with surface application. In another case of cancer of the tongue, a cauliflower growth had disappeared after ten days' treatment. A recent case of extensive cancer involving the whole upper lip amd mucous membrane of cheek was also shown, in which 12 needles containing 1 mg. of element each had been employed in three positions during 18 days. The growth in the lip had disappeared and most of the growth in the cheek.

The CHAIRMAN said that in cases of carcinoma of the tongue there was at present a great tendency to recommend radium rather than operation. Operation in these cases entailed considerable risk, and if it was possible to get something which was at least as certain of doing good and of preventing recurrence without operation, he thought it should be recommended. When, however, he came across a case of early cancer of the tongue which could be removed by a partial excision of the tongue, he did not feel justified in advising radium treatment, as in these cases it was possible to remove the growth at operation without producing any material deformity and cure could be promised. There was also a certain class of case in which great assistance was derived by either radium treatment or X ray treatment in rendering inoperable cases operable.

Dr. MAURICE HAYES also emphasised the danger of radiotherapy in inexperienced hands. The whole physics of radium should be thoroughly understood before the treatment of disease by this means was attempted. Radium burns, which were one of the chief dangers, could often be healed by the application of normal saline solution. Referring to the merits of radium-therapy versus operation, his view was that if a malignant condition was operable, surgery was preferable, except in the case of cancer of the tongue, where radium treatment left the tongue normal and speech unimpaired.

Mr. MCAULEY said that cases of epithelioma of the lip, whether early or late, benefited by surgery, but as cases of carcinoma of the tongue and floor of the mouth were practically never seen in the early stages they did better by radium treatment. It was a mistake to treat these cases by radium without excising the glands in the neck beforehand.

Mr. ARTHUR CHANCE said he was convinced that radium was the correct treatment for all cancers of the tongue except in very advanced cases where cure by any treatment was out of the question and the use of radium would discredit its value. Radium treatment was less dangerous than surgical removal and produced a better and less deforming immediate result. The ultimate results of surgery in cancer of the tongue could scarcely be worse, and time alone would show what they were with radium. A careful toilet of the mouth should precede radium applications; to extract a septic stump after radium application was to ask for septicæmia, as the vitality of the surrounding irradiated tissues favoured its development.

Mr. STEVENSON, in reply, thought there was a risk in doing operations after radium treatment. He had found saline useful for radium burns although some patients complained of pain following its application.

Reviews and Notices of Books.

SURGICAL PATHOLOGY.

By CECIL P. G. WAKELEY, F.R.C.S. Eng., F.R.S. Edin., Hunterian Professor, Royal College of Surgeons of England; Junior Surgeon, King's College Hospital; and ST. J. D. BUXTON, M.B., B.S. Lond., F.R.C.S. Eng., Junior Surgeon and Junior Orthopædic Surgeon, King's College, Hospital. Bristol: John Wright and Sons, Ltd. 1929. Pp. 904. 45*s*.

THE authors of this new text-book of surgical pathology have tried to put forward an account of the pathological side of surgery which will help readers with their clinical work. One of the many difficulties to be surmounted in the attempt to achieve this object is the regrettable fact that the pathogenesis of so many conditions is still unknown, though explanatory theories abound. The authors have succeeded well in their task and their impartial attitude towards controversial subjects is praiseworthy. They could not consider fully all the conflicting theories which confronted them without making the book so cumbersome as to be of little value to a student, and prominence has therefore been given, in each argument, to that theory which at the moment seems the most reasonable, other and less important theories being mentioned in passing. In this way the student who reads this book is prevented from such bewilderment in face of a large array of contradictory ideas that he forgets the central and essential fact that the cause of the condition he is studying is unknown. Another aim of the authors has been to connect the reading of pathology with the examination of museum specimens, and to this end the selection of illustrations has been most carefully designed. Many of them are new and have been made from specimens in the Museums of the Royal College of Surgeons and of King's College, while most of those which have previously appeared elsewhere have been taken from the *British Journal of Surgery*. The drawings, whether in colour or monochrome, and their reproductions, could hardly be improved. The diseases of bone are illustrated by many excellent X ray photographs.

The arrangement of the text follows orthodox lines and on the whole the space given to each subject is proportional to its importance. Perhaps some of the later chapters of the book have suffered compression as a result of the very large amount of space devoted to the pathology of bones (about one quarter of the whole book); but one would not willingly curtail this section, since it is uniformly excellent. The differentiation between rare and common conditions is well preserved. The classifications adopted are sound and they have been simplified as much as possible—a method which has its dangers, as the section on aneurysm shows. Here aneurysms of the aorta and of the peripheral arteries are considered together and the commonest cause of weakening of the vessel wall is said to be atheroma in a syphilitic man. This statement is at variance with the fact that we have no evidence that peripheral aneurysms are due to syphilis. Much of this particular section is rather confusing and it is below the high standard reached in the rest of the work.

The printing and binding of the book are excellent.

KER'S INFECTIOUS DISEASES.

A Practical Text-book. Third edition. Revised by CLAUDE RUNDLE, O.B.E., M.D. Lond., M.R.C.S. Eng., L.R.C.P. Lond., D.P.H., Medical Superintendent, City Hospitals and Sanatorium, Fazakerley, Liverpool. London: Humphrey Milford, Oxford Medical Publications. 1929. Pp. 614. 30*s*.

THE prolongation of the life of a text-book after the death of its author is indicated only in standard text-books of the highest class. The practical progress made during the past decade in the scientific handling of infectious diseases has not, however, involved any changes in definition, and the mass of important clinical detail collected by trained observers remains as the essential foundation of our knowledge of their epidemiology, course, and prognosis. The disappearance from current medical literature of Ker's classical work would therefore have been a calamity, and the publishers are fortunate in having been able to draw upon the ripe experience of Dr. Rundle in the work of revising a new edition. The format has undergone a change, the size having been reduced at the expense of the spacing of the type and of obsolete subject matter.

The result is a less bulky and cheaper work which, moreover, contains much new information, especially from the bacteriological and immunological standpoints, on scarlet fever, measles, diphtheria, small-pox, chicken-pox, vaccinia, erysipelas, and typhus. The number and size of the illustrations remain the same, the only new feature being that the coloured plates of the Schick test (after Zingher) in the second edition are now replaced by those which originally appeared in the Medical Research Council's monograph on diphtheria. Dr. Rundle has succeeded in retaining Dr. Ker's individual style, and while he has incorporated his own views on a few points, for example, on the infectivity of chicken-pox, due prominence is always given to the opinions of others. New facts are clearly set out with a due sense of relative importance. We could have wished for more information about the therapeutics of scarlet fever antitoxin, and even active immunisation in diphtheria, of which Ker was the pioneer in this country, could perhaps also have been treated with more detail. Post-measles encephalitis which, though admittedly rare has recently received much attention because of its resemblance to post-vaccinal encephalitis, is not mentioned among the complications of measles. Among laboratory methods now almost obsolete is the microscopic Widal test, for the sedimentation test is now exclusively used in most laboratories.

Dr. Rundle is to be congratulated for having prolonged the useful life of a text-book of which the fame is well deserved.

THE NEW HEALING.

By WILFRID A. STREETER. London: Methuen and Co., Ltd. 1929. Pp. 238. 7*s*. 6*d*.

THIS book is a polemical work in which the author condemns all other methods of healing except osteopathy, and makes claims for the recognition of the osteopath as a practitioner of healing acknowledged by the law. As it is a popular work and in the author's words "not a text-book of osteopathy," we find in it no statement of any pathological data upon which the claims of osteopathy to be considered a science can be based. The author attacks the General Medical Council and incidentally takes up the case of Dr. Axham, although the latter had, as far as we know, no connexion with any osteopath. But as the book contains a photograph of Sir Herbert Barker and the author walking side by side, we may assume that bonesetters are admitted as brethren who, not having received the necessary six years' training in an osteopathic college cannot, like the genuine practitioner of osteopathy, "achieve its greatest results in acute diseases such as pneumonia, influenza, and tonsillitis." For the osteopath shrinks from the practice of no special department. He professes to relieve deafness, and to be more successful in obstetric medicine and surgery than the regular practitioner.

It is no doubt desirable or almost necessary for the practitioners of all quack systems to try to establish a grievance. Hence the writer of this book complains of the General Medical Council and the state of the law in this country, but he apparently ignores the truth that there is no law or regulation which prevents the osteopath or the chiropractor practising his methods on any who choose to submit themselves to them. Mr. Streeter has not much respect for chiropractic or chiropraxy, which is an offshoot from osteopathy, but it seems to us that the newer cult has as much right to recognition as the older, and if chiropraxy were recognised and established, no doubt another offshoot would appear and clamour for recognition. The last chapter in the book is perhaps the most valuable, for in the form of "An Osteopathic Catechism," it enables us to estimate how trivial are the claims of osteopathy to recognition as therapy based on exact observation and scientific reasoning. The photographs in this book of imposing hospital, college, and sanatorium buildings in the United States are evidence of the extent to which osteopathy has gained hold over a section of the American public.

BLOOD-VESSEL TUMORS OF THE BRAIN.

By HARVEY CUSHING, Professor of Surgery, Harvard Medical School; and PERCIVAL BAILEY, Associate Professor of Surgery (Elect), University of Chicago. London: Baillière, Tindall and Cox. 1928. Pp. x.+210. 34*s*.

THE specialist would be the first to admit a collector's pleasure in the rare and bizarre manifestations which variegate the humdrum of his routine. In a sense blood-vessel tumours of the brain are "collectors' pieces," being not only rare, but almost sensational in their clinical aspects. The study of these remarkable growths arouses an interest which is all too seldom evoked by a surgical monograph.

The authors divide the blood-vessel tumours of the brain into two main groups: (1) the angiomas, and (2) the angioblastomas or true neoplasms. The former may be supposed to have arisen at a later stage of development than the latter, and always contain traces of compressed nerve tissue between the vascular loops comprising the lesion. The angiomas may be divided into those: (1) chiefly capillary (telangiectatic); (2) chiefly venous (angioma venosum); and (3) arteriovenous (angioma arteriale). All these tumours are commonly situated in the cortex of the cerebral hemispheres and their proximity to the motor cortex is responsible for the frequency of Jacksonian convulsions in their symptomatology. Capillary angiomas are of no great clinical significance, but both venous and arteriovenous angiomas present distinctive clinical features. The venous angiomas are not usually associated with increase of intracranial pressure, but sometimes a cutaneous angioma is present in the area of distribution of the trigeminal nerve on the same side; if calcification of the tumour occurs a characteristic radiographic appearance is presented. In the absence of these distinguishing features a venous angioma is unlikely to be diagnosed before operation, and will more probably be exposed unexpectedly in the course of craniectomy undertaken for Jacksonian epilepsy. The arterial angiomas, on the other hand, may often be recognised by an audible bruit and by the effects of the arteriovenous communication upon the intracranial and general circulation. These effects include papillœdema, unilateral exophthalmos, extracranial vascularity superficial to the tumour, increased carotid pulsation, and even cardiac enlargement. The large majority of angioblastomas are cerebellar and conform in their symptomatology with other cerebellar tumours. They may be solid or cystic; in the cystic form the cyst characteristically contains a mural nodule of solid growth. A certain proportion of cerebellar angioblastomas, as Lindau first showed, are associated with angioma of the retina, and other congenital malformations may be present, such as angiomas of the spinal cord, cystic kidneys, cysts of the pancreas, and hypernephromas.

Dr. Cushing and Dr. Bailey, whose book contains many excellent illustrations, discuss fully the pathology and treatment of these vascular growths. The angiomas, on account of their extreme vascularity, have so far proved too difficult a problem for surgery, but it remains to be seen whether electrosurgical methods may render their extirpation possible. Decompressive procedures, however, have a definite value in treatment and radiotherapy is worth a trial. Surgical methods are more easily applicable to the angioblastomas. Suboccipital decompression with cyst evacuation may give great relief, and it would seem possible to remove the tumour itself in some cases without undue loss of blood.

INFANT FEEDING.

Modern Methods of Feeding in Infancy and Childhood. Second edition. By DONALD PATERSON, M.D., M.R.C.P., and J. FOREST SMITH, M.R.C.P. London: Constable and Co. 1929. Pp. 149. 7*s*. 6*d*.

THE first edition of this volume of modern medical monographs appeared in 1926, and has well established itself as one of the most useful and practical of the shorter books on this subject. The second edition is larger by some 40 pages, and contains additions which considerably increase its utility and completeness. The original chapters on infant feeding have undergone slight alterations, involving a revised account of vitamins and more detailed attention to the use of condensed milks and acid milk. The principal addition to the book consists of an account of the diets of older children, both in health and in various forms of disease. These chapters are admirably clear and practical, giving definite indications of the quantities required, and stressing common dietetic errors such as excess of carbohydrate and of milk. They should be of special assistance to recently qualified practitioners, whose views on the subject are generally somewhat hazy.

STEPHEN HALES, D.D., F.R.S.

By A. E. CLARK-KENNEDY, M.D., M.R.C.P. Cambridge: The University Press. 1929. Pp. 256. 15*s*.

Stephen Hales, though not a medical man, occupies a place midway between Harvey and John Hunter as an experimental philosopher. The world has had to wait a long time for an authoritative biography of this eighteenth century parson, but Dr. Clark-Kennedy, Fellow of Hales's own college (Corpus Christi, Cambridge), has now supplied one. It is an admirable piece of work. The author was entrusted with the pious duty of delivering at Corpus an address on Hales on the 250th anniversary of his birth in 1927, an address which was subsequently published in THE LANCET. Many more facts accumulated than could be used in the time at the orator's disposal; he has now collected the results of his researches in book form. When Hales went to Cambridge as an undergraduate Newton was still at Trinity; shortly after, Whiston succeeded to the Lucasian professorship. In 1700 Richard Bentley was elected Master of Trinity, while Stukeley, the antiquarian, was a junior undergraduate and friend of Hales. The latter's ecclesiastical career began in 1709 when he was appointed perpetual curate of Teddington; this cure he served for more than 50 years; he was an industrious parish priest, who not only did his duty by his parishioners in his church work but was insistent in correcting parochial abuses. He was liberal in undertaking the greater part of the expenses incurred in enlarging the parish church. Like most other eighteenth century parsons, Hales was a pluralist; besides Teddington, he held the living of Porlock for four years and was then instituted to that of Farringdon. Dr. Clark-Kennedy gives an account of Hales's diversity of work on animal and plant physiology and on the ventilation of gaols and ships, as well as of his part in the development of Georgia. Hales was a most industrious and versatile worker. His well-known experiments on the *blood pressure* in horses were oddly enough the outcome of an attempt to discover the cause of muscular movement. Twenty-two years after his first experiment was performed his "Hæmostatical" papers were read before the Royal Society. In 1735 he was appointed one of the trustees to inquire into the efficacy of Joanna Stephens's medicines for the relief of the tone; together with the President and Censors of the Royal College of Physicians, and Cheselden, Cæsar Hawkins, and Samuel Sharp, and many notabilities among the laity, he must share the reproach of allowing Parliament to grant a large sum of money to a quack.

The book is well printed and contains numerous fine illustrations; it will be welcome in many quarters and reflects great credit on its author.

SYPHILIS: ITS INDIVIDUAL TREATMENT.

Die Individualisierung in der Luesbehandlung. By Dr. OSKAR D. GÜNSBERGER, Osijek. Leipzig and Wien: Franz Deuticke. 1928. Pp. 60.

THIS brochure is distinguished by a refreshing originality of outlook. The author draws a sharp distinction between the claims of the individual and those of the State. When these claims coincide, as fortunately happens quite often, no difficulty arises, but when they conflict, the author decides wholeheartedly in favour of the social standpoint. He treats syphilis as a "plague" and demands compulsory treatment, isolation, and internment to prevent harm to the present and coming generations; but he scarcely justifies his case by comparing syphilis with leprosy.

In his review of the value of various medicaments, Dr. Günsberger assesses their value in terms of satisfying both the individual and the social claim, and for this purpose he proposes a division into five periods: (1) of local prophylaxis; (2) of preventive therapy; (3) of abortive therapy; (4) of infectious manifestations; and (5) of non-infectivity (late latency). From the point of view of treatment, this division is much to be preferred to the old primary, secondary, and tertiary stages, which are no longer valid either clinically or pathologically.

Taking the author's periods in succession: (1) is known the world over and needs no extolling; prevention is better than cure, and cheaper; (2) is the treatment by "spirocid" or salvarsan of the disease during its first incubation period, to which the obvious objection is the absence of evidence of disease, and the natural reluctance to give treatment where in fact no disease may be present; (3) is when the patient consults his doctor, say, about the seventh week after contact with unmistakable signs of infection, when the arsenical remedies energetically and properly applied do produce complete cure; (4) Here treatment consists of a series of cures at suitable intervals, using as many and as various chemotherapeutical preparations as possible. Supervision alone may be required in the third and fourth year. In the fifth year a pyrexial cure winds up the treatment. The author deprecates with reason the long-sustained use of any one preparation for fear the spirochæte should adapt itself to that remedy. The diminished potency of mercury just before the introduction of salvarsan is ascribed to this cause—a thesis as difficult to prove as to disprove. He fails to understand why if a remedy cannot achieve sterilisation in, say, a month, it should be expected to do so in a year. (5) In the period of late latency supervision is better than treatment and pyrexial methods are the only hopeful measures except in some special cases, as severe infection in women who are suckling. In any case the treatment must be strictly individualised and directed to the manifestation of disease in the several organs.

Dr. Günsberger has much to say regarding the immunity factor in syphilis, which has, we must admit, suffered neglect of recent years, although we have not yet reached his sureness as to the methods by which shock therapy achieves its happy results. If his stimulating treatise brings back the reader's mind to first principles, and helps him to estimate the values and the potentialities of modern treatment, the author will have rendered a signal service to his generation. The book should be read with profit by every worker in the field of lues.

SPINAL ANÆSTHESIA.

By CHARLES H. EVANS, M.D., Clinical Assistant, N.Y. Post-Graduate Medical School and Hospital. New York: Paul B. Hoeber. 1929. Pp. 203.

SPINAL anæsthesia was acclaimed enthusiastically nearly 20 years ago, but the method fell into disrepute and has been banished altogether from many clinics. The discovery of less toxic drugs, improved technique and a better understanding of the principles of the method have led surgeons once more to explore its possibilities for general abdominal as well as lower extremity surgery. This monograph by Dr. Evans makes no real attempt to survey the different techniques which have been devised to analyse them and appraise their respective worth. Instead he deals very fully only with one technique of which he has had considerable personal experience, and this is probably wise. He has assisted at between 800 and 1000 operations under spinal anæsthesia, and only one of these has been followed by lung complications. Presumably not many of them were operations near under the diaphragm; if they were all concerned with the lower limbs the immunity from chest sequelæ would not be astonishing. In an extensive search of the literature Dr. Evans could only find two accounts of permanent nerve lesions attributable to spinal anæsthesia. We agree that reports of such lesions are reassuringly rare, especially when novocaine has been used. Dosage by weight is recommended; probably the dose could be graduated according to the size of the spinal canal, since the maximum dose ever given is far below the toxic dose of novocaine. The intramuscular injection of adrenalin is preferred to ephedrine for maintenance of the blood pressure, and is worth trial by other surgeons. A list of the operations performed would have been of interest. In 17 cases which are selected to illustrate the effect on blood pressure and pulse, the lowest pressure recorded was 44 mm.Hg and the next lowest 62 mm. Hg, but in only four of these was anæsthesia induced in the higher part of the spinal cord for upper abdominal operations. The information really needed is the average fall of blood pressure when high anæsthesia is induced. Dr. Evans is an enthusiast and appears rather to belittle the dangers and complications of this method, but since many other writers have perhaps erred in the other direction the reader who has followed the literature of the subject is not likely to be misled into taking a too optimistic view of this technique.

THROMBO-ANGIITIS OBLITERANS.

Clinical, Physiologic, and Pathologic Studies. By GEORGE E. BROWN and EDGAR V. ALLEN, Division of Medicine, Mayo Clinic. Collaborating in Pathology with HOWARD R. MAKOMER, Fellow in Surgery, The Mayo Foundation. London: W. B. Saunders Company. 1928. Pp. 219. 14s.

THE debt which medicine already owes to the Mayo Clinic is increased by the publication of this monograph, which is based on a study of over 300 cases of thrombo-angiitis obliterans. It contains an account of pathology, symptoms, and treatment which is a model of balance and lucidity. The increasing frequency of the disease is pointed out, and the authors show, what is already recognised in this country, that, while Hebrews are the predominant sufferers, no race is immune. The cases dealt with in this study are limited to the male sex, and the conditions causing this limitation are discussed. The authors support the view that thrombo-angiitis is an infective condition and offer tentative evidence of a specific micro-organism. A strong plea is made for early diagnosis, which is increasingly important since non-specific protein therapy and lumbar ganglionectomy have brought a more hopeful outlook. Clear descriptions of the types and stages of the disease are given, with their appropriate treatment, and the illustrations are apt. The book is a pleasure to read.

E LANCET.

SATURDAY, JUNE 15, 1929.

REATMENT OF SYPHILIS.

ıme past the feeling has been growing who are called on to treat syphilis nethods of treatment are not as satis- promised to be. With the introduction o arsenical remedies, from which such ts were anticipated, schemes of treat- id down, often with the blessing of epartments, which seemed to be de- llent lines but which in practice have dividual patients proportionate benefit. lthough widespread is not well docu- though more than a quarter of a million ilis have been dealt with in the various atres of England and Wales, no serious been made (with one notable exception) he results in relation to the treatment . Two main deterrents have coöperated this sparseness. Few clinics provide terial from which to draw trustworthy and the work of analysing the material rious. The diversity of practice which s seems to be largely due to a general wledge of the end-results of the various atment advocated by different workers; well have another contributing cause, lies deep in the structure of medical mely, the hardship to anyone engaged nent of individual cases of syphilis when not to modify his scheme by the results vidual experience. It is a temptation e resisted only by a few, to try out some r of the new preparations which flood arket, and already the value of Ehrlich become obscured by the preference majority of workers in this country for this, while admittedly less potent, venient not merely for the administrator its lesser potency is more than offset er ease of retaining the continued atten- tients submitted to it. It was for this the committee of experts appointed by Section of the League of Nations set llection of new data upon a standard basis for an evaluation of the results . But before this Committee began L. W. Harrison had already begun he records of St. Thomas's Hospital, y is now issued as a special report to Research Council.[1] Even this analysis cases has been complicated by irregu- dance and other factors.

standard unit of treatment a course n 5 grammes of an arsenobenzol com- ed with a minimum of 5 grains of grammes of bismuth over a period four months, Dr. Harrison's analysis en in primary cases which have never ve Wassermann reaction, good results pected from less than two full courses, se cases in which the W.R. had already even three full courses were not altogether satisfactory. Relapses it is found occurred mostly in the first year, and after the second the risk appeared comparatively small, but while examples occur of the eradication of syphilis with very small total dosages the fact remains that considerable amounts administered regularly over years failed to save the patient from late results. Given consecutively bismuth displayed no greater efficacy than mercury as an adjuvant to arsenobenzol; simultaneous administration, however, of arsenobenzol along with mercury or bismuth produced a series of cases which never showed clinical signs of neurosyphilis. The numbers on which both these deductions are based are admittedly small, but if an extended experience should confirm them their importance is fundamental. At present they do not refute the dictum of Nonne, who has always maintained that chemotherapy alone is powerless to prevent the late nervous manifestations of syphilis. A negative W.R. of blood and cerebro-spinal fluid is not regarded by him as evidence that syphilis has been cured, for the great vessels may continue to show damage in despite of these reactions. In a series of post-mortem examinations of paretics during the years 1908–14 Coenen found changes of the aortic wall in 22 per cent., whereas in a later series, 1919–23, the percentage went up to 43—and the later series, not the earlier, were probably treated with arsenobenzol. In a book, which we review in another column, Dr. Günsberger of Osijek seriously raises the question whether, in regard to the occurrence of metalues, such arsenical treatment is not really harmful to the individual in so far as it increases the likelihood of late nervous complications, although from the social point of view the treatment has been successful in destroying infectivity and thus preventing the development of disease in the next generation. There is, in Dr. Günsberger's view, a certain antithesis between the treatment of the individual and the safety of the community. This social success he believes already to be have been reached in Sweden, while in Austria there seems to be some sympathy for the view that when the claims of the individual and those of society conflict the community will decide wholeheartedly in favour of the social standpoint. The decision might not be so lightly taken in this country where the life and health of the individual is still the primary concern of the practitioner, but from this dilemma there may be a relief, for there is growing evidence that in an artificially produced pyrexia, called shortly pyrexial cure, we may find a means of modifying the habit of body which leads to late neurosyphilis.

At the McGuire Clinic in Richmond, Va., Dr. S. W. Budd and C. W. Williams have reported[2] the results of administering TAB vaccine to 65 patients in various stages of syphilis, and while admitting that fever therapy alone is markedly inferior in immediate results to salvarsan alone, they suggest that in combination it offers a more hopeful outlook than drug therapy alone. They found themselves able to reverse an apparently irreversible blood W.R. in nearly one-half of the cases treated, although they observe a wise reticence as to the permanence of these results. Dr. Harrison himself suggests that greater success might be obtained by attention to the patient's tissues—that is to say, by a strict individualisation directed to the disease of the organ involved, which is an essential point in Dr. Günsberger's thesis. Neglect of the immunity factor in syphilis may have conduced in large measure to the imperfect results obtained in practice.

THE

Telephones

PAYING A PATIENT'S BILLS.

THERE are judicial decisions which prove to be legally inevitable and yet to the uninstructed appear intolerable or ludicrous. The medical profession will form its own opinion upon the case of Maley *v.* Churcher in which the law has insisted that a doctor is personally liable for the hire of a motor-car ordered for the conveyance of a patient. Three successive tribunals—the county court, the Divisional Court, and the Court of Appeal—have come to the same conclusion, but the efforts of the Medical Defence Union will not have been wasted if practitioners are fully warned of the liability they may incur and if the statement of the law convinces the public of the necessity of amendment. It is worth while to set out the facts of the case, simple as they are, in some detail.

A young man named BOWER, 24 years of age, employed by a Mrs. CUSACK, of Eastbourne, was housed elsewhere in Eastbourne at a school called "Heatherdene" (8, Meads-street) during the school holidays. Mr. Bower had apparently tried to commit suicide by taking poison. Dr. D. G. CHURCHER, of Eastbourne, was called in and advised his return home for treatment to his father's house in Balham. The patient was in possession of his senses but hysterical, and Dr. Churcher thought it safer to send him by road rather than by rail. Dr. Churcher attempted without success to communicate with the patient's parents; he obtained the patient's authority for the hiring of the car, and he telephoned from the school to Maley Bros., motor-car proprietors in Eastbourne, in the following terms: "Dr. Churcher speaking; send me a car at once to 8, Meads-street to take a patient to Balham." The order was accepted, but some delay occurred, and presently he telephoned again, asking, "Is that car coming that Dr. Churcher ordered or not?" The car was by this time on its way. It took Mr. Bower and a nurse to Balham and brought the nurse back again to Eastbourne. At this point what was the position? Dr. Churcher knew himself to be acting as agent not as principal; he had properly obtained the patient's authority; the car proprietors knew that the order had been given by a medical practitioner, from an address which was not his own, and in connexion with the conveyance of a patient. Never having seen Mr. Bower before, Dr. Churcher was naturally unaware of his financial position; it was vitally important to send this hysterical patient back at once to the quiet of his family home, and this was scarcely a moment for prolonged inquiries It seems, moreover, that none of those concerned contemplated that Dr. Churcher had ordered the car otherwise than as agent. The car proprietors, who acted throughout in good faith and whose charge was the moderate sum of £5, evidently never thought that Dr. Churcher was to pay personally. They wrote a few days later to Mr. Bower's father at Balham a letter containing the sentence: "We are instructed that the amount for the hire of the car—£5—is payable by you." Subsequently they wrote again to him, expressing surprise that he had not paid the account, "particularly in view of our knowledge of the circumstances under which the car was ordered," and hinting at possible legal proceedings to enforce payment. Mr. Bower's father replied that the car was hired without his knowledge, authority, or consent. "My son was in Mrs. Cusack's employ, without salary, on the understanding that she was liable for his board, residence, expenses, and laundry; the hire of the car having been undertaken by herself or her agent, the expense is at her door; she paid my son's fare to Eastbourne and naturally she would have had to have paid his fare back." The father having repudiated liability, Maley Bros. wrote to Mrs. Cusack "With reference to the car ordered by you." Their letter indicates that they had already applied to Mrs. Cusack and had addressed Mr. Bower's father at her request. Mrs. Cusack replied that she ordered no car and must refuse responsibility; the money "is due from Mr. Bower himself, whose doctor ordered him to go to London by car as he was unfit to travel in any other way." Messrs. Maley in this dilemma wrote to Dr. Churcher—not to ask him to pay but to ask him to say "who you had in mind as the person responsible for ordering the car when you rang us up." Dr. Churcher replied that Mr. Bower was of age "and is responsible for the car just as he is for my fee."

The matter then found its way into lawyers' hands, and, nearly a month after the car was ordered, it was for the first time suggested that Dr. Churcher himself might be personally liable because he had not expressly disclaimed responsibility in his original telephone message. Clearly nobody would have dreamt of asking Dr. Churcher to pay if the patient had not been impecunious and if the father and the employer had not been at loggerheads. The county court judge, before whom Dr. Churcher was sued, said: "The defendant did not inform the plaintiffs that he was acting only as agent, and nothing was said as to the person responsible for the plaintiff's charges. . . . Although I am bound on the defendant's evidence to hold that he was in fact the agent of Bower, I am satisfied that this fact was not disclosed to the plaintiffs and that, unless the defendant's contention as to notorious usage is to prevail, he did not contract with the plaintiffs so as to exclude his liability as principal. The defendant gave the order without any limitation of liability and is prima facie responsible." The judge said the only defence to the claim was that a doctor acting for a patient has a character as agent so notorious that he cannot be made personally liable. Here the case of Wakefield *v.* Duckworth was considered. In that case solicitors, acting for a client charged with manslaughter, employed a photographer to make certain photographs for use at the trial; in giving the order they said: "Make your charges as low as you can, for the fellow is only a poor chap." It was then held that the photographer had no claim against the solicitors, a solicitor being notoriously agent for his client for many purposes and competent to bind him. In Dr. Churcher's case the judge refused to follow Wakefield *v.* Duckworth, or to take judicial notice of the fact that a medical practitioner acts as agent for a patient. The two higher courts before whom the case came on appeal were really bound by the county court judge's findings of fact. Unless Dr. Churcher could argue that there was no evidence whatever on which it could be held that he had made himself liable for the car, he could not overthrow those findings. Lord Justice SCRUTTON said he would himself have decided on the facts in the same way as the county court judge had done. It was a question of fact on which there was no appeal. "The defendant had used words on the telephone which prima facie rendered him personally liable, and he did not use any words indicating that he was contracting with the plaintiffs as agent and not as principal." Dr. Churcher's appeal was thus dismissed, though not without a hint that circumstances were conceivable in which a medical practitioner's agency might be established.

There is no need here to discuss the moral liability of Mr. Bower, his father, and his employer; the matter was decided on strictly legal grounds. Had the telephone message begun, "Dr. Churcher speaking *on behalf of a patient*," or—more clearly still—"You understand that I am not making myself personally liable," the claim against Dr. Churcher could not have succeeded. Everybody knew Dr. Churcher's position, but he suffers because he did not say what everybody knew. Whatever the law may oblige judges to decide, it is in fact notorious that a doctor in such a case does not intend to make himself liable as a principal. Medical practitioners will take warning from the case and will word their communications accordingly. Meanwhile we protest vigorously against the continued operation of legal rules under which the decision against Dr. Churcher is not only possible but apparently inevitable. This may be the common law, but it forfeits something of the general confidence if it ignores matters of common knowledge and if it runs counter to what many believe to be common sense.

THE ESTABLISHMENT OF NORMAL STANDARDS.

THE plea for the establishment of a department of clinical physiology set out in another column deserves attention, for though the argument ruthlessly exposes some of the defects in the medical curriculum, its tone is neither cynical nor destructive. It is generally admitted that our present knowledge of normal Man is, from the clinical point of view, sadly incomplete; Dr. LINDSEY BATTEN believes that well directed research would systematise this knowledge and make it readily available, so that anyone seeking information as to the occurrence of a supposed abnormality would know where to turn for it, and some check would be put upon that kind of "new discovery" in medicine whose brief inglorious career brings discredit to its supporters. The paths along which research should be directed would be chosen by following closely the work of clinicians and of laboratory physiologists and pathologists, trying out their conceptions and discoveries by control experiments on large groups of normal subjects. Its second and no less important function would be to spread such knowledge as already exists, and especially to teach the dominant facts to students, not necessarily only to students of medicine. Few would deny that in spite of all the time and energy spent in teaching and learning anatomy and physiology, the student goes to the wards almost completely ignorant of the material on which he is to work—the intact human organism. Of the habits of body of men, women, and children, of their essential physiological needs and their diverse types he has been taught very little. In particular he knows nothing of normal infants and children, of the phenomena of growth, or of the changes associated with age. He goes to the wards to find himself face to face with the problem of learning simultaneously the arts of investigation, direct and instrumental (which increase almost daily in complexity), and the clinical and pathological facts of morbid processes. The period officially allotted to the study of the normal is over and he has little incentive to prolong it; yet he will get no better chance, until he embarks on practice, to form a conception of its limits from which to differentiate the morbid. What wonder if he fails to do so, and goes into practice well versed in disease but ignorant of health, and likely to mistake unusual physical or physiological types, which have never been demonstrated to him, for the effects of those pathological conditions about which he has learnt so much?

This, in brief, is Dr. BATTEN's thesis. We agree with much that he says, but we must plead at least for one concession to human weakness. Let us not be too prompt to initiate control experiments on large groups of normal subjects whenever a new theory in physiology or pathology is tentatively suggested, even if its experimental support is slender. The flame of investigation is easily quenched; since the damping disappointments inseparable from a life spent in research must be counteracted, the flame must be kept alive by a favourable wind, even if this has to be produced by fans. A worker with the robust hardness of a ROBERT KOCH is rare indeed. Among lesser men small groups tend to foregather in mutual support, hailing with unmeasured expressions of joy a result which they know to be still uncontrolled; for this stimulation is the food on which research can thrive. At the next gathering, who would be so tactless as to ask whether the experiment has been successfully repeated, unless the information is volunteered? Besides, the listener of one meeting becomes the eager informer of the next. The time for critical examination will come soon enough, when conclusions are being drawn; but even then the fact that a so-called abnormality is found to occur in 20 per cent. of ordinary persons does not necessarily exclude the possibility that it may help to cause symptoms in some of them. If many idiosyncrasies are now labelled abnormalities, it is at least possible that in the future several characteristics now passed over as proper to a certain age or sex will be found to have a pathological significance. The research division of a department of clinical physiology would have to busy themselves for some considerable time before standards of normality for teaching purposes could be devised.

Meanwhile, in the medical schools, without the addition of a new department, a new teacher, or a single hour to the curriculum, a start might be made to clear the teaching of medicine from at least some of the reproaches to which Dr. BATTEN draws attention. Most, if not all, licensing bodies insist on a compulsory course, usually held by junior members of the staff, during which students fresh from the medical school are taught the methods of clinical examination and the use of instruments such as the stethoscope and ophthalmoscope. The zealous tutor, in his anxiety to interest his pupils, selects the finest heart murmurs and the loudest lung crackles he can find to show them, and if there is an example of ægophony in the wards his happiness is complete. All these signs are wasted on his audience, who have hardly heard of any of the diseases of which they are pathognomonic, and want only to learn to hear and recognise the normal. This class should be held, not in the wards, but first in a private room, the students examining each other, and then in the special departments of the hospital when these are not in use; in this way the results of percussing the heart can be controlled by the X rays and the fundus seen through the ophthalmoscope compared with the interior of the model eye. The limits of the normal already recognised are wide enough to exercise the perceptions and descriptive powers of the class, and during this preliminary course their attention should not be distracted by the curious cases which are exciting the attention of more experienced workers. Their teacher should be a clinician still interested in physiology, and such men are not, after all, rare. In this way students will start their career as clinical clerks with a different point of view, and a clearer conception of the wide range of deviations which are still within normal limits.

Annotations.

"Ne quid nimis."

DARWIN'S HOUSE.

Down House in which Charles Darwin lived during the greater part of his life, and where "The Origin of Species" was written, was opened to the public on Saturday last. The house was presented to the British Association by Mr. Buckston Browne, F.R.C.S., on condition that it and the surrounding grounds shall be maintained in the state given to them by Darwin and that the public shall have free acccess to the public rooms. Sir Arthur Keith, who declared the house open, spoke of the way in which Charles Darwin quite unwittingly had made these few acres of Kentish upland an international possession. It was just because he permitted the bare unbusked truth to speak for itself, going only so far as the light of reason would carry him. Only men who taught thus, said Sir Arthur, continued to teach for all time. What Darwin's achievement has meant to the study of natural history is set out nowhere better than in his own words, which we here reproduce from the concluding chapter of the "Origin":

> "When we no longer look at an organic being as a savage looks at a ship, as something wholly beyond his comprehension; when we regard every production of nature as one which has had a long history; when we contemplate every complex structure and instinct as the summing up of many contrivances, each useful to the possessor, in the same way as any great mechanical invention is the summing up of the labour, the experience, the reason, and even the blunders of numerous workmen; when we thus view each organic being, how far more interesting—I speak from experience—does the study of natural history become!"

Mr. Browne's gift will enable many to recapture the atmosphere in which Darwin thought and worked for 40 years—the phrasing is in the words of an inscription now erected outside the entrance gate. No student would ever know Darwin, said Sir Arthur Keith, until he knew Down, and to see Down was the best way to obtain an introduction to Darwin's works. Most of the furniture and other objects in the rooms are those used by Charles Darwin and his family, including the snuff jar which he kept not in his study but in the hall, in the vain hope of breaking himself of the habit. An American committee is coöperating with the British Association in an endeavour to recover Darwiniana now in America.

POST-OPERATIVE RUPTURE OF THE ABDOMINAL WALL.

RUPTURE of the abdominal wall after operation is a much neglected complication, and the reason for its neglect may be that surgeons think it a reproach to their technique. A similar obscurity—now fortunately dispelled—has until recently been the fate of Volkmann's ischæmic contracture. An attempt to elucidate some of the problems connected with repair of the abdominal wall has lately been made by Monod and Kiraly,[1] who base their conclusions on cases of their own and on series collected by Chavannaz in 1900 and Madelung in 1905. The subject has a very small modern literature and not much that is old. Post-operative rupture may occur soon after the operation, usually within the first fortnight, or it may follow years afterwards. Delayed rupture is, of course, extremely rare, and is not of the same practical importance as the post-operative form. Of general causes thought to predispose to the condition, cancer is usually placed first, but in none of the three series of cases reviewed did it account for more than one-fifth of the total. Syphilis is also said to be a predisposing cause, and Monod and Kiraly found that active syphilis was present in two out of the three cases in their series in which a Wassermann test had been done. Among local causes which may predispose to rupture, infection of the wound, abdominal distension, premature removal of the sutures, and a long incision are all common; but most important of all is incomplete suture of the peritoneum. The origin of some of these cases can be easily seen during the operation of re-suture when the rupture has not been complete, and it is often found that a piece of omentum has worked its way through a gap in the peritoneal suture, thus apparently starting the cleavage. The actual rupture is usually brought about by an effort on the part of the patient, coughing and vomiting being the commonest causes. It is interesting to note that there is rarely any pain at the time of rupture, and never any hæmorrhage. In fact the patient may only feel that there is something under the dressing, or, indeed, the accident may not be noticed until it is observed that the dressing is soiled by a pinkish serous effusion. When the condition is recognised early the prognosis is not so serious as might be supposed from the nature of the accident. Immediate suture of the abdominal wall is successful and, whether it is done in several layers or in one, the result should be a firm scar if the patient survives.

THE DOCTOR-CORONER.

RECENT correspondence in the *Times* has contained criticism of the procedure at coroner's inquests. Coroners are tending, it is suggested, towards the methods of the French examining magistrate; voluntary witnesses are cross-examined by the court itself in a hostile manner; suspects are at the disadvantage that they are not definitely charged with the commission of a crime nor are they warned (as they would be by a police inspector) that what they say may be used against them in another place. While one correspondent points out that all this is contrary to ideas of British justice and fair play, another ascribes the supposed malpractices of the court to the appointment of medical practitioners as coroners. Such appointments mean, it is said, that the coroner has no legal training; even if he has sought to supplement his qualifications by undertaking the examinations which a barrister has to pass, his knowledge of the law of evidence is theoretic and not practical.

These criticisms ignore the fact that Parliament has never said that a coroner must be a practising barrister or solicitor. The qualification is five years professional standing as a barrister, solicitor, or medical practitioner. Nor has Parliament declared that the procedure at an inquest must in every way resemble that which is used at other criminal courts. For obvious reasons the inquest cannot be assimilated to the assize court. The inquest is held to inquire into the cause of death. Until it has made some headway with its investigation, it is impossible that a definite accusation against a definite person can be formulated. There is therefore no charge, no defendant, no prosecuting or defending counsel; the tribunal itself must undertake the responsibility of eliciting the facts and must necessarily rove over a wide field. The coroner, using the discretion which the law permits him, is—as Mr. Justice Wills observed in the Crewe murder case—"fettered by no precise rules of evidence"; he is "bound to collect, so far as he can, all information and knowledge of disasters from neighbours and others who can throw any light upon the cause of death . . . he can oftentimes collect evidence, facts and statements which, whether or not they may ultimately be capable of being turned into evidence against the parties who are to be put on their trial, are often very valuable as supplying material for investigation by the police and as affording clues which may lead to successful inquiry." If, continued the learned judge, a coroner confined himself to the strict rules of evidence, he would throw away a great deal of the remaining usefulness of the inquest. These observations, uttered nearly 30 years ago, are of full force to-day.

---

[1] Presse Méd., 1929, xxvii., 253.

The coroner, perhaps, on his side, has a right to protest that his least considered remarks in court are sometimes torn from their context and reported with unnecessary elaboration. He tries to deal with all the aspects of the case but the reporter may be interested only in the case against a particular suspect. Doubtless there are coroners, as there are judges and stipendiary magistrates, whose running comments are no great help to the administration of justice, and whose individual views on certain favourite topics of their own (whether medical or legal) are apt to find a tediously constant expression. But the critics of the procedure at inquests make a profound mistake if they ignore the historical and popular associations of the coroner's office, or if they commit themselves to the theory that the only good coroners are lawyers and the only bad coroners are medical practitioners.

THE RED CELLS IN PERNICIOUS ANÆMIA.

THE work of Price-Jones has established that in pernicious anæmia there is an abnormally wide variation in the size of the red cells, and the presence or absence of this phenomenon may now be regarded as the absolute criterion for diagnosing the condition. The plotting of the Price-Jones curve, however, is so laborious as to be hardly feasible in a busy laboratory, whilst the "halo" method of Adrianus Pijper,[1] though affording means of demonstrating optically the same variation and the approximate average increase in size of the red cells, demands special apparatus and somewhat formidable calculations. Some time ago Haden[2] pointed out that a relatively small increase in the average diameter of the red cells causes a relatively great increase in the total red cell volume, and various workers have brought forward evidence to show that much of the valuable information to be gained from the Price-Jones curve can be got by calculations based on the total volume and total number of red cells. Wintrobe, whose work on blood standards has already been referred to in our columns, has recently dealt with the subject in a comprehensive way.[3] He points out (what has been recognised for some time) that the average corpuscular volume in cubic millimicrons may be obtained by dividing the total volume of red cells per litre, as determined by the hæmatocrit, by the total number of red cells per c.mm. The figure thus obtained he refers to as the corpuscular volume. This corpuscular volume he finds in healthy young adults to lie between the figures of 70 and 98 cubic millimicrons, with the average round about 83. In strong contradistinction to this, Haden found the corpuscular volume in pernicious anæmia to lie between 108 and *163 cubic millimicrons* with *an average of* 128. The difference between the normal red cells and those from cases of pernicious anæmia is conspicuous, and inasmuch as determination of the corpuscular volume only demands the use of a hæmatocytometer and a hæmatocrit, this particular determination bids fair to be of considerable use in establishing the diagnosis of pernicious anæmia. Wintrobe further draws attention to the interesting fact that, although the size of the red cell is increased in pernicious anæmia and though it carries a greater load of hæmoglobin than the normal red cell, the actual proportion of the volume of the red cell occupied by the hæmoglobin is no greater than in normal blood. Haden found the percentage of hæmoglobin in the red cell in pernicious anæmia to range between 16 and 35 per cent.; Wintrobe in normal blood finds very similar figures, the actual average being about 33 per cent. The proportion of hæmoglobin in the red cells is determined by dividing the hæmoglobin, expressed as grammes per cent., by the volume of red cells per 100 c.cm. of blood. Both for this calculation and for that of the corpuscular volume a hæmatocrit is required; the importance of centrifugation until the column of red cells has reached a final level is presumably apparent. Wintrobe, however, draws attention to a source of error which has possibly not been sufficiently considered. He *finds that the addition* of potassium oxalate to the extent of 20 mg. to 10 c.cm. of the blood under estimation caused a decrease in cell volume of 3·7 per cent., while addition to the extent of 40 mg. to 10 c.cm. of blood brought about a diminution of 6·7 per cent.

OBSERVATIONS ON UNILATERAL DIURESIS.

To the April number of *Guy's Hospital Reports*, Mr. H. I. Maister, Mr. W. H. Ogilvie, and Prof. M. S. Pembrey contribute a paper on a case of total cystectomy in which certain investigations were made of urinary secretion. The patient had a carcinoma of the bladder and at operation the ureters were brought to the surface. The urine excreted by the two kidneys was collected separately by an apparatus which kept the patient dry and allowed her to get about. Variations in the activity of the two kidneys were shown by estimating the volume and specific gravity of samples collected in consecutive periods of half an hour. The most interesting observation was that the application of warmth to the loin did not, as is usually supposed, produce diuresis but rather the reverse. When a hot poultice was placed over the right kidney the amount of urine excreted on that side was diminished and a diuresis was noted on the opposite side. On another occasion as a control the poultice was applied to the left side and a diuresis from the right kidney was obtained. It appears, therefore, that warmth over the loin produced a vaso-constriction of the underlying kidney and since the skin, apart from the poulticed area, was cold, a compensatory dilatation occurred with increased excretion on the opposite side. These observations are of a special interest in view of the common practice of applying warmth and cupping over the lumbar region for the purpose of stimulating urinary secretion—a method which seems likely to diminish rather than stimulate the activity of the kidneys. It may, indeed, be deduced that the application of warmth over a kidney might be of use in those cases of renal hæmaturia in which diminution of activity is thought desirable.

BOOTS AND SHOES.

ONE of the disadvantages of civilisation is to be found in the degradation of the human foot which is caused by the use of footgear. Many writers have pointed out the evils wrought by boots and shoes, *and by stockings, too, for that matter, and many an* essay has been written on the proper form and material of foot covering. The last contribution to the literature of this subject comes from Dr. J. D. Adams,[1] of Boston, who holds views on the footgear of the child which are sound as far as they go, but hardly seem to go far enough. A study of the history of boots and shoes and of the current practice in shoeing of many peoples all over the world, such as was in part attempted in our columns by Mr. Muirhead Little[2] in 1914, shows that, with the exception of sandals, all footgear tends to cause abduction of the great toe and gradual loss of the power of voluntary adduction of its phalanges. The Greek or Roman sandal with a thong between the great and second toes did not have this pernicious effect, and the same is true of certain sandals worn in India and elsewhere at the present time. The most primitive form of protection was probably a strip of the skin of an animal or some flexible leafs and the result of winding this or any other bandage round the foot and toes would be abduction of the great toe, involving in time loss of the support afforded by its phalanges. This tendency is evident in Red Indian mocassins, some of which are quite sharply pointed. The early Highland brogue, which was made out of a single thickness of deer's or other hide, had the same defect. The loss of the power of voluntary abduction of the hallux is incurred quickly because of the comparative feebleness of the so-called abductor hallucis and the mechanical disadvantage under which it acts, losing, as it does, all power of adduction after the first phalanx is abducted so that its long axis is a continuation of that of the metatarsal bone. But it is not only the great toe that has suffered from footgear. As soon as man added a stiff sole to the more or less sock-like mocassin or brogue, or made the sandal stiff, the muscles began to atrophy and the complicated musculature of the foot to lose its raison d'être. Every normal child appears to be born with active foot muscles and joints, but in every shoe-wearing adolescent the process of degradation and atrophy is gone through, until the foot becomes no more than a lever hinged at the ankle and jointed at the toes. Dr. Adams figures the radiogram of a "foot in a properly fitted shoe," but even in this a degree of hallux valgus is apparent. Such deformity is, we fear, unavoidable in all boots and shoes, and despite the provision of shoes of which the soles have straight or incurved inner edges, the hallux necessarily pressed upon at the metatarsophalangeal joint declines to avail itself of the space provided. We regretfully conclude that unless digitated stockings and sandals with toe-thongs become our only wear, we must have a more or less abducted great toe. Even the athlete's running shoe is badly shaped. Those that we have seen do not allow for adduction of the hallux and in so much sacrifice the support and propulsive leverage of the great toe.

[2] Boots and Shoes from Historical and Surgical Points of View, THE LANCET, 1914, i., 1738.

Men's boots and shoes may be bad, but if so, what epithet of depreciation is strong enough for the shoes of women? Now that all females are ladies, the workers among them have aped the fashions which were popular with the wealthy idlers of past generations who rode in carriages and did but little walking on their high heels and pointed toes. It is astounding that so few complain out of the millions who now for several years have been defying nature in this way.

SCLEROSIS OF THE RETINAL VESSELS.

SINCE the signs of retinal arterio-sclerosis were first pointed out by the late Marcus Gunn, this condition has been dealt with by many writers, notably by Foster Moore in 1917.[1] The subject has been reopened in a series of papers, reprinted from the *British Journal of Ophthalmology* for March, April, and May, 1929, by Dr. Noe Pines, a Russian ophthalmologist, now living in London. He distinguishes between general arterio-sclerosis in which the general blood pressure is not necessarily high and essential hyperpiesis in which it is. The two conditions, of course, are often present together, but it is the second and not the first, he argues, to which the retinal changes are due. As to what these changes are, he attaches little or no importance to the loss of transparency in the retinal vessels which is extremely common in elderly people. The alteration in the reflex which gives rise to the appearance known as "silver wire" arteries is more important but not always easy to determine. The most important signs of sclerosis he considers to be, first, white lines bordering the vessels—not on the disc or even in its near neighbourhood, as these may be purely physiological, but in the retina and especially at and near the points where artery and vein cross. These white lines he attributes to perivasculitis in the sheaths of the vessels. Secondly, signs of crushing of the veins at the arterial crossings evidenced by white lines, banking, and deflection of the veins. A number of reproductions of drawings from Hamblin's collection are given as illustrations, and this appears to be an excellent way of studying the subject. There is originality in the author's views as to the interpretation of some of the appearances. It is of interest, too, that he finds no connexion between this form of retinal disease and nephritis, and consequently does not consider the changes that he describes are premonitory of albuminuric retinitis. On the other hand, the connexion between sclerosis of the retinal vessels and those of the brain is notorious. Both depend on persistently high general blood pressure, and this again on some form of toxæmia. Once again we see that the ophthalmoscope is one of the most essential instruments of diagnosis on which the general physician has to rely.

TRANSPLANTATION OF AN EPIPHYSIS.

WE do not expect to hear of surgical novelties from the Sandwich Islands and therefore the report of a new procedure coming from Honolulu is the more welcome. Dr. G. F. Straub, of The Clinic, Honolulu, reports[1] the successful implantation of a section of diaphysis and epiphysis in 1912, as suggested by Murphy. The case was one of osteomyelitis of the tibia with consequent necrosis of the bone including the lower epiphysis, and the graft was obtained from the sound leg. As the operation was performed as long ago as 1912, a definite opinion can be formed on the value of the result. The leg, which at the age of 14 was 4·5 cm. shorter than its fellow, is now 5·0 cm. shorter, showing that growth has taken place pari passu with the sound limb. The deformity of the foot, due to unbalanced growth of the fibula before the operation, has much diminished, but there is still some calcaneo-cavus deformity. This paper is illustrated well by photographs and radiograms.

HOSPITAL MATERNITY WORK IN GLASGOW.

THE Glasgow Royal Maternity and Women's Hospital contains 114 beds, 25 of which are reserved for the antenatal department. The report of the hospital for the year 1927, which has reached us, covers the treatment of nearly 4000 in-patients and 3500 district cases, its general arrangement being based on that recommended by the Committee of the Royal Society of Medicine, in which cases which have attended the antenatal clinic and emergency cases are recorded separately. In Glasgow, however, a large number of patients apply for admission without having attended a clinic, or having been seen by a doctor or midwife, and for these it has been necessary to form a third section, numbering 700 in all. For the whole hospital a 2 per cent. decrease is recorded on the morbidity of the previous year. Comparison of the results obtained in the antenatal and emergency sections goes far to prove the value of antenatal work, particularly in centres where pelvic contraction is common. This is the case in Glasgow, for 288 cases of contracted pelvis were treated by trial labour, Cæsarean section, or forceps. Labour seems to have been induced only in six cases, in three of which no measurements are recorded, one of them resulting in the delivery of a 10 lb. baby at term in less than three hours. In two of the other three cases the pelvis is described as generally contracted although the diagonal conjugate measured 4½ inches. Cæsarean section was performed in 112 cases, mostly for contracted pelvis, eight of the operations being of the "lower segment" type. The mortality-rates were: maternal 11·6, fœtal 16·0 per cent. The report has been compiled for the second year in succession with great care by the registrar, Dr. J. N. Cruickshank, who remarks that the method of recording the cases has involved the omission of certain details. The reader would have liked more information, for instance, as to whether or not fœtal heart sounds were heard when the patient was admitted, especially in the series of "emergency breech extractions" where of 13 multiparæ admitted 8 children were stillborn and the remaining 5 died. The section of the report devoted to cardiac cases is of special interest and here the results obtained were excellent.

MINERAL WATER METABOLISM.

THE natural mineral waters of our own and Continental spas vary widely in their active constituents and recent investigation has perhaps tended to concentrate too much on the presence and possible effects of their radium, thorium, and actinium contents. Much work has been done in France and Germany on this basis and efforts have been made to show that the therapeutic action of these waters is similar to, if not identical with, that obtainable from pure solutions of these rare elements similarly used. The larger subject of the general pharmacology of these natural therapeutic agents, due in the main to their dissolved saline constituents, has thus been thrust somewhat into the background. The work of Dr. David Brown and Mr. A. Woodmansey, of which a digest appears in our present issue, is an attempt to remedy this omission. The fresh water from certain Continental and American springs has been shown to possess distinct and measurable catalytic properties which can be demonstrated in vitro. The Harrogate natural sulphur water has similar activities. R. McCarrison has shown the remarkable effect on rats of adding minute quantities of manganese to a diet deficient in certain essential accessory substances. Brown and Woodmansey have inquired whether this observation has a possible bearing on the mode of action of mineral waters. In their paper they attribute the general increase in tissue change, and the stimulation of special body ferments which they have observed, to the presence of manganese and its catalytic agency. Other measured effects are the retention in the body of large percentages of mineral constituents, notably sodium and barium, whose retention may be responsible in part for the metabolic changes observed. Knowledge must come slowly in a field in which the relation of cause and effect is so hard to assess; it is, however, work of this detailed and exact nature which is needed to increase our understanding of the mode or modes of action of these naturally occurring compound drugs and to give us a clue to their application in the treatment of disease.

INTRAVENOUS INJECTION OF ALCOHOL.

ALTHOUGH the method of anæsthesia devised by Dr. Miguel Garcia Marin, described on p. 1247, is not the novelty which it has been hailed as in various quarters, there are, nevertheless, details in it which are new and which may prove of value. Intravenous anæsthesia has, of course, been extensively practised with ether, with hedonal, and also, though less extensively, with ethyl alcohol. There are certain obvious advantages in this method, which are pointed out in the paper by Dr. J. D. Constantin, and there are counterbalancing disadvantages. These have hitherto outweighed the advantages to such an extent that intravenous anæsthesia has never established itself as a method of choice for routine work. It remains to be seen whether the improvements introduced by Dr. Marin will alter this state of affairs. The most important innovation is the use of isotonic glucose solution as the conveying medium for the anæsthetic. This may free the use of alcohol from one of the objections which largely led to its discontinuance—viz., the fear of damaging the red cells of the blood which are cremated by strong alcoholic solution. We notice the mention of hæmoglobinuria in Dr. Constantin's paper, which suggests that this danger is still not to be disregarded. A representative of THE LANCET was given the opportunity of seeing Dr. Marin's method employed and certainly as far as the two patients concerned are a test, the result was eminently satisfactory. But the operations were not a severe trial of anæsthesia. The induction of unconsciousness was quiet, but took longer than with most modern inhalation methods. The condition of respiration and circulation was excellent throughout and recovery was unattended by vomiting. One disadvantage of intravenous anæsthesia has always been the large amount of fluid added to the circulation which resulted sometimes in pulmonary œdema. We wonder whether a similar objection or others will arise to the instillation of large amounts of glucose solution. So far as the comparatively slender direct evidence now available goes, Dr. Marin's method appears to deserve further trial, which doubtless it will get from anæsthetists in this country.

THE ENEMIES OF RESEARCH.

MOST of us are inclined to treat the activities of the antivivisectionist with a certain detachment, for they do not interfere with the work of the ordinary practitioner. The research worker who has suffered directly from these attacks has no such philosophic attitude, and Prof. A. V. Hill seized the opportunity of his Stephen Paget Lecture to the Research Defence Society on June 10th to return a Roland for their Oliver, and to attack the whole spirit which informs opposition to man's painful progress. Too few, he said, realise fully the facts of man's gradual evolution; most people still think that Adam arrived full grown a few thousand years ago, with a complete university education and a degree in zoology. He drew a vivid picture of Nature's age-long experiment in living things by expressing them in the scale of a single lifetime. In that notation it had needed 49 years for man to learn to settle down in villages. Halfway through his fiftieth year he had learned to write; Christianity had been his religion since the middle of April of that year; printing had been invented a fortnight ago, steam less than a week, cars about a day, and wireless for a few hours. We are yet far from Utopia, said Prof. Hill, but the gradual progress of knowledge has improved men's lot and character and outlook in the last half-million years and may reasonably be expected to continue to improve them in the next 50 million. To the scientist, as to most reasonable men, that heritage of painfully acquired knowledge is a sacred thing. In Prof. Hill's words, "The capacity for knowledge, for understanding himself and his environment, is man's essential characteristic and his alone; to deny him the exercise of this fundamental gift would be an unpardonable, an almost unthinkable offence." To Prof. Hill antivivisection is "only a passing phase in the varying follies of mankind, while the fanatical desire to obstruct the advance of knowledge for one or other cause is a permanent factor in man's mental constitution, a mild form of mental disorder which has expressed itself from time to time in various hideous forms, in cruelty and persecution, in hatred and malice, in the perpetual treachery of hindering mankind in his slow and pathetic efforts to climb the ladder of civilisation. He instanced an "Anti-Rail-Road Journal" published in 1835, supported by the most worthy institutions and claiming to "fight only on the side of truth for the exposure of the railway system." Prof. Hill illustrated his lecture with a selection from a hundred letters he had received from antivivisectionists; most of them were incredible and many unprintable. "I know a gentleman living in Compton-street that has had two of his pussies stolen by your bloodhounds," ran one, and another: "From personal observation I have noticed that a vivisector becomes a seducer, an abortionist, and a potential murderer"; while a gentleman in E.12 wrote: "In my particular circle of friends we are doing all in our power to prevent any further subscription being sent to any hospital." On May 24th last the Parish Paper of St. Jude's-on-the-Hill, Hampstead Garden Suburb, contained an appeal from the Rev. B. G. Bourchier to intelligent people to take the opportunity of the general election to put an end to the waste of public money involved in medical research. "When," declared the lecturer, "by telling lies and spreading calumnies, by petty persecution in private or malicious persecution in the police-courts, by attempting to forward legislation forbidding the use of snails, lobsters, and frogs for research the antivivisectionist provides a wanton hindrance to the advance of knowledge, the matter ceases to be a joke, and if she tries to hinder the work of hospitals my blood begins to boil." He traced the desire to injure or kill those whose opinions differed from one's own through the Old Testament and the Middle Ages, instancing Galileo and other persecuted scientists. The Inquisition, at any rate, he observed, did not commit murder by proxy, but the antivaccinationists had declared that the death of Stephen Paget was a direct answer to their prayers. Prof. Hill put forward a vigorous defence of the work of hospitals and research departments and a plea for scientific tolerance combined with continuous scepticism of theory. His concluding words will be echoed by all who believe in evolution. "There are enemies of knowledge in all classes and categories and parties. We should be a great brotherhood unbroken by frontiers and national hatreds. If there is one thing in the world that should be international it is the pursuit of knowledge. . . . Individual freedom from molestation is the hard-won basis of modern civilisation; so it is with the advance of knowledge. . . . Modesty, friendliness, humanity, and a reasonable sense of humour are the basis of human welfare."

NEW POSTS IN THE LONDON PUBLIC HEALTH SERVICE.

OUR advertisement columns this week contain an announcement of no little importance. Under the new Local Government Act, the functions of the poor-law guardians of London and of the Metropolitan Asylums Board are to be transferred next April to the London County Council and over 80 hospitals and infirmaries, with a staff of some 16,000, will thus come under the Council's direct control. Obviously this will immensely increase the work of the public health department, and as a preliminary step the Council has decided to appoint three principal medical officers who will be responsible for coördinating the "transferred and existing health functions." The department will be reorganised into three divisions, and the new officials who are to preside over them will take precedence over the present senior medical officers and will receive a salary of £2000 a year, rising to £2500. These appointments will take effect from Oct. 1st, the question of medical staff of lower rank being deferred for later consideration. The transferred hospitals themselves employ 400 full-time medical officers, besides technical experts in various branches to the number of 150. The nursing staff is reckoned at not less than 7500 and the Counci proposes to appoint, also from Oct. 1st, a matron-in-chief on whom will fall, inter alia, the task of "reorganising the varied conditions which now obtain in the nursing services to be transferred."

INQUIRY INTO EPIDEMICS IN RESIDENTIAL SCHOOLS.

THE Medical Research Council, after consultation with the Ministry of Health and the Board of Education, have appointed a committee to inquire into the prevalence and mode of spread of minor epidemics in residential schools, especially those believed to to be spread by so-called droplet infection, and to report upon the means by which they may be prevented or restricted. The names of the committee are as follow: Sir George Newman (Chairman), Dame Janet Campbell, Dr. R. H. Crowley, Surgeon-Commander S. F. Dudley, Dr. J. A. Glover, Prof. M. Greenwood, F.R.S., Dr. L. R. Lempriere, Miss E. M. Newbold, M.A., Prof. W. W. C. Topley, and Mrs. Joyce Wilson, M.R.C.S. (Secretary).

THE CARBOHYDRATE CONTENT OF FOODS.

AS medical men we usually think of the carbohydrates as readily assimilated sugars or complexes of sugars each containing six carbon atoms. We are apt to forget that this group of foodstuffs also includes a large number of substances such as cellulose and complexes of the pentoses, or sugars with five carbon atoms, which, although broken down in the intestine with comparative difficulty, are of very considerable economic importance to the agriculturist on account of their nutritive value for herbivorous animals. In arranging diets both during health and in disease it is obviously more important to know how much carbohydrate is likely to be assimilated from a given quantity of food than to know the amount of carbohydrate actually measurable by chemical analysis. This is particularly desirable in the treatment of diabetes, and the physician is sometimes puzzled by the enormous differences in the figures given by different authorities for the amounts of carbohydrate in certain vegetables. Such discrepancies may arise from a lack of agreement as to the degree of utilisation by man of the less soluble carbohydrates. The Medical Research Council has just issued a report[1] bearing upon this subject which includes careful analyses of the carbohydrate contained in common British fruits and vegetables. The percentage of carbohydrate available for man is estimated from the hexose sugar, including that derived from starch, on the one hand, and the amount of the less valuable pentose derivatives on the other. The tables given in the first part of the report furnish a very valuable practical means of computing the available carbohydrate content of the diet of the diabetic patient. The broader question of the food values of vegetable carbohydrates forms the subject of the second part of the report. The authors confine themselves deliberately to a discussion of the fate after ingestion of those carbohydrates which are not included in the ordinary starches and sugars which form the main source of energy for the metabolism of man—namely, cellulose, pentosans, and the condensation products of lævulose, of which the inulin of artichokes is the best-known member. The mammalian organism does not possess specific enzymes for breaking down these products, so that even herbivorous animals, which may derive a considerable portion of their energy from such substances, have to rely on bacterial decomposition in the intestine to make them available for absorption. It has been found that man can utilise small amounts of cellulose or of the pentose complexes as efficiently as herbivorous animals, although his alimentary canal is not adapted for dealing with large quantities, so that in practice even a vegetarian does not derive any appreciable quantity of energy from this source. During the late war the scarcity of food led to serious attempts in Germany to determine whether such cellulose-containing substances as straw and wood could not be made available for human nutrition. The difficulties lay partly in the unpleasant bitter taste which the addition of these substances to flour produced and partly in the diarrhœa which they so frequently provoked, which naturally led to a greater loss of available food than the amount gained by the additions. The laxative effect of cellulose and similar substances is frequently made use of in clinical medicine. McCance and Lawrence point out that this effect is not due directly to the bulk of their indigestible residues, but rather to the stimulation and irritation of the intestinal glands which they produce and which lead to an increase in cell detritus and in the products of glandular activity which results in a considerable increase in the bulk of the fæces. The food value of vegetable carbohydrates has an obvious bearing on the question of the relative merits of white and wholemeal bread. As a source of energy they say there is no doubt that weight for weight white bread is better than wholemeal bread. It has been found that on a mixed diet including white bread 8 per cent. of the energy value of the food was lost in the fæces, while with wholemeal bread the amount lost was 14 per cent. The vitamin B contained in wholemeal can be supplied in other ways and any laxative effect produced by the indigestible carbohydrate residue can be secured equally well by the consumption of other vegetable products, so that the authors of this report see no reason at present for any universal advocacy of wholemeal bread.

---

[1] The Carbohydrate Value of Foods. By R. A. McCance and R. D. Lawrence. Med. Res. Counc., Spec. Report Ser. No. 135. H.M. Stationery Office. Pp. 73. 2s.

WE are happy to be able to announce that the King's convalescence is making progress. The collection of pus which formed under the site of the old scar has now drained and the abscess is nearly healed. X rays show the existence of one or two minute sequestra, but there is good prospect of the condition clearing up without further interference.

Sir William Thompson, whose death occurred last Sunday at Dublin in his sixty-ninth year, had not long retired from the position of Registrar-General for Ireland.

IN the annotation on the Birthday Honours in our last issue it should have been stated that Dr. H. K. Graham Hodgson, honorary radiologist to King's College Hospital, receives a C.V.O. in recognition of his services during the King's illness.

Mr. T. Franklin Sibly, D.Sc., has accepted the post of Vice-Chancellor of the University of Reading. The severance of his connexion with the University of London, where his short term of office as Principal has entailed heavy responsibilities during a period of reorganisation, will be widely regretted. The good wishes of the many friends he has made in London will follow him to his new work.

Mr. Arthur Greenwood, the Minister of Health in the new Government, was a student of Victoria University who became head of the Economics Department of Huddersfield Technical College and lectured on Economics in the University of Leeds. He was Assistant Secretary of the Ministry of Reconstruction in 1917–19 and Parliamentary Secretary to the Ministry of Health during the last Labour Parliament. He has been a close student of the health and physique of school-children to which he has made some personal contribution. Miss Susan Lawrence, M.P., has been appointed Parliamentary Secretary to the Ministry of Health.

Dr. Christopher Addison has been appointed Parliamentary Secretary to the Ministry of Agriculture and Dr. Drummond Shiels Parliamentary Under Secretary to the India Office.

Mr. F. G. H. Holt has been appointed Secretary and Manager of THE LANCET in succession to the late Mr. R. E. Sare.

DONATIONS AND BEQUESTS.—Mr. Richard Berriman Chellew, of Tremorvah, Truro, Cornwall, shipowner, left £1000 each to the Royal Cornwall Infirmary, and St. Dunstan's Hostel for Blinded Sailors and Soldiers.—Mr. Lawrence Matthew, of Elmsholme, Grange-road, Ealing, left £500 each to King Edward's Memorial Hospital, Ealing, and to the Hostel of St. Luke's, Fitzroy-square, W.—Miss Maria Margaretta Horrocks, of Ribblesdale, Preston, left £500 to the Preston and the County of Lancashire Queen Victoria Royal Infirmary, and £300 each to the Preston Industrial Institution for Blind Children, the Harris Orphanage, Fulwood, and the Royal Cross School for Deaf and Dumb Children.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCIV.—TREATMENT OF EMPYEMA.

THE principles which should guide the treatment of empyema will be discussed under two headings: (1) Tuberculous, and (2) Non-tuberculous cases.

Tuberculous Empyema.

This condition may arise as a late result of pleural effusion but is more frequently found as a complication of artificial or spontaneous pneumothorax, and strictly should be called pyopneumothorax.

When a clear effusion develops in the course of artificial pneumothorax treatment the prognosis does not become more serious, but if that effusion is purulent the outlook at once becomes very grave. Except in a few cases of ruptured lung the condition is due to the tubercle bacillus alone and not to a mixed infection, for not only is the pus characteristic in appearance, but no other organism except the tubercle bacillus is found. As soon as tuberculous pus has developed in the pleural cavity the following principles of treatment should be adopted:—

1. Remove the pus by aspiration and not by open drainage.
2. Encourage the lung to expand in order to obliterate the pneumothorax or empyema cavity.
3. Should the lung fail to re-expand, some thoracoplastic operation should be performed to obliterate the cavity.
4. Attend to the general condition of the patient.

In order to cleanse the cavity and assist the lung to re-expand it is best to wash it out with a 1 in 5000 solution of methylene-blue or with Dakin's solution. I use two needles for this purpose; through the upper one oxygen is introduced in a steady stream while the pus flows evenly out of the lower needle. By this means the intrapleural pressure is kept even throughout the procedure. When as much pus as possible has been removed, methylene-blue or Dakin's solution is introduced through the upper needle and the pleural cavity gently washed out. The lower needle is then removed and the intrapleural pressure is taken by a manometer connected with the upper needle. The pressure is left at about −6 cm. water. By these means the lung will re-expand in a certain number of cases, although the aspiration may have to be repeated. If there is a perforation in the visceral pleura it may be difficult to wash out the cavity, and Dakin's solution should not be used. In such cases, after removing the pus, oil of gomenol has been introduced, but in my experience this has not proved helpful, although good results in a few cases have been described by other writers.

If the lung fails to re-expand, the pleural space should be closed by thoracoplasty, since the mortality in those cases which are left alone is very high. It is important to see that the patient's condition is as good as possible before operation, and therefore he should be given a period of treatment in the fresh air with a generous diet, including plenty of glucose. A preliminary operation for phrenic evulsion is advisable and the subsequent thoracoplasty is usually performed in two stages, although some surgeons prefer to complete it at one operation.

Non-tuberculous Empyema.

In these cases treatment depends largely on whether the pus is free in the pleural cavity, or whether it is in a local pocket cut off from the general pleural cavity by adherent pleura. If it is free in the pleural cavity, the condition is really one of pyothorax, and any operation for open drainage will convert it into an open pyopneumothorax, and in this condition the mortality is very high indeed.

When an open wound is made into the pleural cavity on one side the pressure is affected practically to the same degree on the other side, provided there are no adhesions and the mediastinum is free. Consequently, during inspiration much of the air that should enter the lungs through the trachea enters the pleural cavity through the open wound. In addition to this many of these cases have a pneumonic condition, so that the lungs are already getting insufficient air and an open pneumothorax results in a fatal dyspnœa.

The great principle of treatment should therefore be to avoid an open pneumothorax. This may be done by inserting a drainage-tube with a valve so that no air can enter the pleural cavity, but pus can leave—in other words, a negative drainage system is established. The tube may slip out, however, and treatment by repeated aspiration in this stage is perhaps better.

In some cases the condition may be cured by aspiration alone, but usually the liquid, which is at first cloudy, becomes more and more purulent and drainage later becomes necessary. As a result of the aspiration, however, the lung partially re-expands and adhesions form to the chest wall. Moreover, time is given for the acute pneumonic process to subside, so that the patient is in a better condition to stand an operation.

In practice it is found that in a case of pneumococcal lobar pneumonia the empyema forms after the patient has recovered from the pneumonia, and there are so many adhesions that the empyema is shut off from the main pleural cavity, and consequently open drainage often gives excellent results. The pus is usually very thick and drainage is necessary.

In cases of streptococcal pneumonia, however, especially in those very acute forms which follow influenza, a cloudy serous effusion forms early in the disease whilst the patient is still thoroughly toxic and before adhesions have had time to form. It is in these cases that early operation and open drainage give such disastrous results.

W. J. Stone[1] has published the results of three series of cases:—

(*a*) Eighty-five cases treated by early operation and drainage had a mortality of 61·2 per cent.

(*b*) Ninety-six cases treated by early aspiration and late operation had a mortality of 15·6 per cent.

(*c*) Ninety-four cases treated by early aspiration and late operation with a mortality of 9·5 per cent.

The importance of avoiding an open pneumothorax is clear, and for practical purposes it may be assumed that when the effusion has developed into frank pus adhesions will have formed, and operation is safe.

Re-expansion.

Another important principle in treating empyema is to encourage the lung to re-expand in order to obliterate the empyema cavity. If this is not done subsequent thoracoplastic operations may be necessary in order to deal with a chronic empyema. The re-expansion of the lung is prevented largely by the fibrinous exudate which forms and organises over the visceral pleura, and by the air which enters through the operation wound. To remove the fibrinous membrane from the lung—in other words, to decorticate the lung—the empyema cavity should frequently be irrigated with Dakin's solution. Not only will this remove the membrane, but it will also tend to sterilise the empyema cavity and so prevent the pus from re-forming. The practice of washing out the cavity after operation is a very important one, and if carried out carefully will prevent many of the late complications of empyema.

It is also important to attend to the general condition of the patient. As a rule, the appetite returns when the acute toxic effects of the pneumonia have passed off, so that it is possible to give a nourishing diet before operating; this increased appetite is probably another factor in lowering the mortality when preliminary aspiration, rather than early operation, is adopted.

It is, of course, possible to operate too late as well as too early. On general principles it may be considered safe to operate when the effusion has developed into frank thick pus and when the patient has got over the initial toxæmia of the pneumonia. The bad results of early operation are due to the absence of adhesions with a freely movable mediastinum and to the toxic condition of the patient.

Conclusion.

To sum up, the following principles should be observed in the treatment of empyema:—

1. Remove the pus, but always avoid an open pneumothorax.
2. Encourage the lung to re-expand and obliterate the empyema cavity. In order to do this the cavity should be irrigated with Dakin's solution, and any drainage of a large cavity should be arranged as far as possible so that air cannot enter from outside.
3. Sterilise the cavity by frequent irrigations with Dakin's solution.
4. Attend to the general condition and nourishment of the patient.

L. S. T. BURRELL, M.D., F.R.C.P.,
Physician, Royal Free Hospital and Hospital for Diseases of the Chest, Brompton.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1928 statistics of three boroughs:

Name of borough and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Hove .. .. (50,497)	9·5	15·2*	0·83	2·57	1·7	2·8	73/31†	21	8·3
Margate .. .. (29,260)	12·6	10·9	0·78	1·98	0·75	2·3	38/—	—	0·0
Stafford .. .. (28,740)	15·1	10·2*	1·03	1·31	1·5	1·9	60/34	23	4·6

* The standardised rate was: for Hove 11·2 and for Stafford 10·1.
† Infant deaths in the first week of life only.

Hove.

Dr. Augustine Griffith says the chief event of the year was the extension of the borough, increasing its area from 1594 to 4010 acres. The county council has delegated its powers under the Nursing Homes Act and 30 homes have been registered, 3 for maternity cases, 8 for maternity and other, 3 for invalids, and 16 for medical and surgical cases. No applications were refused. An epidemic of measles, with many severe cases and 10 deaths, raised the question of the inadequacy of the hospital to provide for this disease. There were 97 admissions for scarlet fever, which caused no deaths in the borough, to 10 for measles. The council completed 86 houses during the year, bringing the total of municipal houses up to 521. There are 46 more in course of erection and tenders accepted for another 50. There are still some families "living under bad conditions." The council contribute towards the cost of the Portslade child welfare centre which is used by the mothers of their housing estate.

An agreement has been made with the guardians for the admission of puerperal pyrexia cases to the Steyning Union Infirmary. Licences were granted to six vendors for "Certified" and to eight for "Grade A" milk. One of the sanitary inspectors was sent for a week's course of instruction at Wye Agricultural College. Two prosecutions for milk, deficient in fat 15 per cent. and 13·3 per cent. respectively, failed because the bench decided the milk was "as it came from the cows." A small outbreak of milk-borne scarlet fever was attributed to a dairy employee, who had tonsillitis for 24 hours before giving up work and consulting his doctor.

Margate.

Dr. Rowan McCombe points out that the population during the height of the season exceeds 100,000 and that this has an important bearing on the demand for water. Thus while the daily average pumped (from the chalk) during 1928 was just over 2 million gallons, the maximum quantity pumped in one day was 3,375,000 gallons. Broadstairs takes supplementary water (the maximum in one day in 1928 was 500,000 gallons) from Margate and 28 outside parishes also depend upon this supply. A scheme has been sanctioned for a new "mass concrete" reservoir with a capacity of 2,000,000 gallons at a cost of £20,000 and a large expenditure in land purchase to protect the purity of the water will shortly be necessary. A further expenditure of £100,000 on new mains is expected to make provision for the demands of the next 30 years. During 1928 £17,200 was spent in laying an iron pipe to convey the sewage of the colliery village of Aylesham, a distance of four miles to new disposal works situated about one and a half miles north of the water-pumping station. The sewage of Margate is effectually screened before being discharged into the sea, and as it is only discharged 600 yards from the cliffs at high water "when the tide is racing out to the North Sea," it is claimed that "it is physically impossible for any sewage to find its way to the foreshore" and that the Margate sewer outfall works, designed by the borough surveyor, Mr. E. A. Borg, are as near perfection as possible.

Hitherto Margate has only had a cottage hospital with 40 beds, chiefly for accidents and surgical cases. It is expected that the new hospital with accommodation for 60 patients will be completed next year. The Kent County Council have delegated their powers under the Nursing Homes Act, which came into force on July 1st, to Margate. Twelve applications for registration received were all granted. Two of the four practising midwives are municipal and the fees which they earn are paid into the borough fund. They spend their spare time in antenatal visiting and Dr. McCombe considers the benefit to the poor people from their services, at a very small cost to the ratepayers, "almost incalculable."

Since 1920 the corporation have, by erecting 356 houses, alleviated the housing problem to a certain extent, but there are still applicants for houses, living in sub-let rooms. No subsidy houses were erected during 1928. A similar deficiency in milk fat (viz., 14 per cent.) to those which led to unsuccessful proceedings in Hove resulted in a fine of £5 for a Margate vendor. Some of the 14 private slaughter-houses are of obsolete construction and too close to dwellings. The only alternative is considered to be a public abattoir and the question of its provision has been deferred for a year. Six vendors have licences for "Certified" milk, four for "Grade A (T.T.)" and two for "pasteurised." One outside farmer was removed from the register owing to the unsatisfactory way in which the milk was handled on his premises. The hours of bright sunshine registered were 1983·7 and the rainfall was 24·25 inches.

Stafford.

Dr. J. T. Macnab describes a small outbreak of mild small-pox at the end of the year. The original case occurred in an institution and was mistaken for chicken-pox. The last of the seven cases was diagnosed on Dec. 31st. The outbreak drew attention to the need for a shelter for the occupants of houses needing thorough disinfection. During the last nine years the corporation have built 604 and private enterprise 337 houses. There are still 136 houses to be completed on Stone Road Estate and when they are finished it is proposed to pause to see what private enterprise will do. Dr. Macnab doubts if houses at suitable rents will be forthcoming from this source. Forty houses on the corporation estate have been earmarked for necessitous applicants and when complete will bring relief to the poorer families. They have three bedrooms and are to be let at 9*s.* per week inclusive of rates.

Dr. Macnab is anxious to have the Octavia Hill system tried. Under such a system the new tenants would be selected and grouped according to their existing home conditions; they would be encouraged to respond to the better environment by the woman manager maintaining close touch with the housewife; they would be given a better house when they had made good; and, furthermore, coöperative schemes for the purchase of lawn-mowers and garden implements and other schemes to foster the interest of the tenants in the estate would be organised.

The Coöperative Society are providing two large modern abattoirs. The provision of a third similar one would supply the needs of the town, enable 13 unsatisfactory slaughter-houses to be closed, and make thorough meat inspection practicable. Another need is the installation of filtration plant at the swimming baths, so that every day may be clean water day instead of only two in the week. The new reinforced concrete service reservoir, capacity one million gallons, came into constant use in June.

The Isolation Hospital, with 22 beds, has to serve a population of 38,000 in the borough and the rural district, and its admissions were practically limited to scarlet fever and diphtheria during 1928. There were 82 notifications of diphtheria in the borough and two deaths, "both of which could have been avoided if medical aid had been called in sooner." Dr. Macnab also draws attention to the danger of delaying the use of antitoxin till the bacteriological report comes in and to the entirely inadequate doses sometimes employed. During the summer many of the cases were associated with a particular engineering works. The manager gave every facility in the tracing of carriers and in stopping the use of common towels, drinking cups, &c. The spread of cases ceased with the discovery of the chief carrier.

Antenatal consultations are held once a week and the need for them is shown, says Dr. Macnab, by the occurrence of 15 neonatal deaths and 21 stillbirths (equivalent to 4·8 per cent. of the total live births). Fourteen of the stillbirths were investigated. The only mother who attended the antenatal centre was sent to her own doctor for hydramnios, which proved to be associated with an anencephalic fœtus. During the last three years the deaths from 1 to 5 years have averaged only 13, while for the years 1914 to 1916 the annual average number was 24, suggesting that infant welfare work also reduces the mortality in subsequent years. Of 406 children who completed the age of 9 months during 1928—

86 per cent. were breast fed at the first visit:
67 „ at the end of three months; and
55 „ were breast fed for over six months; while
14 „ were artificially fed at the first visit.

Efforts of the health visitors to encourage breast-feeding are still handicapped by unwise advice given to the mother "that her milk does not suit the baby." Stafford has no municipal maternity home and a maternity annexe to the infirmary would fill a great want.

MENTAL HOSPITAL REPORTS.

THERE were 655 patients on the books of the *City of London Mental Hospital* at Stone, Dartford, at the end of last year, and applications for admission continued to be numerous. In fact, more private patients wanted to come in than could be accommodated. Seventy-five of the 176 patients admitted were uncertified. The recovery-rate was 62 per cent. of direct certified admissions and 41 per cent. of voluntary cases. The death-rate was 3·2 per cent., and there was no serious illness or epidemic disease. The operating theatre, dental surgery, X ray room, ultra-violet light installation, and laboratory have all played their part in helping to bring about this satisfactory result. A new fire alarm system has been installed and the heating system has been remodelled. The male hospital ward has been supplied with a clinical room and the female infirmary section with a verandah. The visiting Commissioner remarks on the general comfort and amenities of the institution, observing that "it would indeed be difficult to find any modern refinement of technical practice or procedure of proved value which is not represented here." Four nurses obtained their M.P.A. certificate during the year.

The *Plymouth Mental Hospital* report for the year ending March 31st, 1929, has an air view of the institution as frontispiece. At the end of 1928 there were 525 patients on the register; the annual admission figure was much lower than that of the year before. The death-rate was 5·13 per cent., in spite of nine deaths from general paralysis and three from tuberculosis. The medical superintendent points out, however, that this low rate cannot be maintained, as 10 per cent. of the hospital population is over 70 years of age and the next influenza epidemic is bound to take a heavy toll of these feeble senile patients. The recovery-rate was 38·2 per cent. The building is overcrowded and treatment is hampered thereby. An extension scheme is to be initiated by building a nurses' home, which will free some sleeping space on the female side but will not help the problem of day space. The whole building has been re-wired and a new tennis-court has been laid down. The dental surgeon visited regularly during the year, and the ophthalmic and surgical consultants rendered services when required. One male and two female wards are "open-door" and 30 patients of each sex have had parole beyond the estate. Another 65 are free within the grounds. Excursions to the seaside and moors are conducted. A clinic for early mental and nervous cases is to be started at the South Devon and East Cornwall Hospital. One attendant and two nurses passed the final examination of the R.M.P.A.

The report of the *Cheshire County Mental Hospital* at Parkside for the year ending March 31st, 1929, is illustrated with two photographs of the ultra-violet light installation and includes an extract from Dr. Dove Cormac's paper on this form of treatment (see THE LANCET, 1929, i, 142). More than 50 patients were treated with benefit during the year. On the last day of 1928 there were 1301 patients on the books of the institution; this is 22 more men and 11 less women than the normal accommodation provides for. A joint meeting of the Upton and Parkside committees decided that this was not an opportune moment for building, but that the urgent need for further accommodation should be met by trying to obtain beds for chronic and senile cases in the workhouses. The admission-rate during 1929 was quite 20 per cent. below the average. Of the 190 cases admitted 97 offered little hope of cure. The recovery-rate was 33·6 per cent. and the death-rate 5·46 per cent. Heart disease was the cause of death in 25 cases, lobar pneumonia in 10, and general paralysis and cancer in 5 each. Five cases of general paralysis were treated by induced malaria, with satisfactory results. There were ten cases of typhoid fever, recurring from the epidemic two years ago, and an epidemic of influenza in the spring. Five men and two women are suffering from tuberculosis. Sixty-two women were occupied in various forms of handicraft, and 22 men in brush and toy making, upholstery and cocoanut-fibre matting work, and the products of the occupation therapy department found ready sale. The occupation officer also controls a recreation department where the patients are taught games and country dancing. Two male and four female wards are administered on the open-door principle, and parole was granted to 100 patients outside and nearly as many more inside the estate. A number of verandahs have been added to the wards. A total of 1825 pathological investigations were carried out in the laboratory, the majority being routine examinations of urine. Thyroid was tried on 11 patients suffering from dementia præcox, but the benefits observed were only temporary. The superiority of hot cocoa over hypnotics has been confirmed. As in the past, monthly meetings for the local medical profession were held at the hospital and were well attended. Fourteen female and four male probationers obtained the final certificate of the R.M.P.A.

PRIVATE MENTAL HOSPITALS.

The Cassel Hospital.

The report of the Cassel Hospital for Functional Nervous Disorders for 1928 provides as usual much valuable information drawn from first-hand experience in the treatment of minor mental ailments. This report contains the tables which have been omitted from the last two, giving the results of the treatment of each patient in full detail. Besides the individual case-histories, which make very instructive reading, Dr. T. A. Ross writes at some length on his experience of focal sepsis and schizophrenia. The number of patients who have been relieved by operations for sepsis, after other methods have failed, is small. Dr. Ross points out an important fallacy which in most cases falsifies the conclusion that benefit has been derived from operation. The majority of the patients were relieved of their symptoms by methods which were certainly psychological. All patients received physical treatment such as rest, exercise, fresh air, and good food, but many who had been receiving these things for a long time before they went to Swaylands responded favourably to the fresh ideas which they encountered. Moreover, an operation has in itself a strong psychological element, which varies considerably with the enthusiasm of the person who recommends it. Before any cure is directly attributed to an operation for focal sepsis, it must be ascertained beyond doubt that the infection had a direct causal connexion with the disorder, and that it was not merely an excuse for the neurosis. Many patients undergo operations for focal infection, undertaken after careful investigation, and derive no benefit. The operations, moreover, carry a certain amount of risk to life. Dr. Ross mentions one indication for operation which he has not found in the literature—that is, when a patient has an organic disease to which he falsely attributes his symptoms. An operation performed under this indication must, of course, not be a serious one, but may be useful in driving the patient out of this entrenched position into the open, where he may become amenable to analytical treatment. For instance, a patient came to Swaylands in the full belief that he had tabes. He would not discuss his psychology, as he held that it was irrelevant. After some weeks he began to accept the continued daily proof that, whatever he had, it was not tabes. He then complained of lumbago, until it was proved that he had not got it; then he fell back on a chronic nasal discharge, which he said was poisoning him. He was most unwilling to go to the rhinologist and equally unwilling to have a deviated septum straightened, but as he was committed to the position that his mental symptoms could only be due to a physical disease, and as this was the only one he had left, he could not back out. Since his original symptoms persisted after this last stronghold had been reduced, he decided to give the psychological view a hearing, and has begun to improve. This patient illustrates, according to Dr. Ross, the interesting point that patients who put forward a theory of disease do not wish it to be taken too seriously. Dr. Ross quotes an observation made by a medical student of considerable intelligence, who was a patient last year. "The neurotic is apt to choose diseases, aches and pains, which he is fairly convinced have no serious significance; but let a doctor tell him he is suffering from a disease, and he will be seriously disturbed."

Dr. Ross's experience has shown him that schizophrenic states, even though they may recur after disappearance, do not necessarily lead to dementia. Some patients, with clearly marked schizophrenic symptoms, have become well without any special method of treatment. They are treated with particular care and given a special nurse, on whom it is constantly impressed that they are very sick people. The difficulty is that it is practically impossible to keep them without a special nurse, and many have to be sent away. They must not be left alone for very long, and association with them is bad for the psycho-neurotic patients. The general atmosphere of Swaylands is, Dr. Ross thinks, well suited to them, and he has proposed to his committee the experiment of providing a few special nurses, and keeping a few cases for a couple of years. Unfortunately, their recovery is usually slow. Dr. Ross gives his usual interesting figures, obtained by following up discharged patients, and discusses some illustrative cases of psychological maladaptation.

The Lawn, Lincoln.

A hundred years ago one *Paul Parnell*, a surgeon of Lincoln, left a legacy of £100 towards the provision of a private refuge for the mentally afflicted. From this benefaction arose the hospital for mental and nervous disease, known as The Lawn, Lincoln, of which the centenary will be celebrated in November of this year. The first physician to the hospital was *Dr. E. P. Charlesworth*, to whose disinterested and persevering benevolence a statue in the grounds bears witness. Under his rule and that of his successor, Dr. Gardner Hill, The Lawn gradually became a home of compassionate and enlightened care. It is a registered hospital, where educated persons of limited means can be treated either as voluntary boarders or as certified patients. Many changes in personnel are recorded this year, including the medical superintendent, the matron, some senior members of the nursing staff, and the secretary. It is interesting to note that Dr. Mary Barkas, who has been made medical superintendent, is the third woman to hold this post, the first, Dr. Lillian Cunard-Cummins, having been appointed in 1898. The new matron and sisters appointed are qualified in mental as well as in general nursing, and the hospital has been recognised as a training school for female nurses. Certain structural alterations have been made, including the adaptation of an admission ward for mild and borderline cases and for convalescent patients; a verandah roofed with glass permeable to ultra-violet light has been added. Dr. Barkas reports that the total number of patients and voluntary boarders under treatment during the year was 107, the average number resident being 69; 16 patients and 19 voluntary boarders were admitted during the year. The recovery-rate, calculated as a percentage of the year's admissions, was 66·6. The recovery-rate of voluntary boarders was low in comparison with that of the certified cases, partly because they are apt to leave before mental health is properly re-established and partly because the type of case which recovers quickly and completely is incapable of exercising volition. The general health was good throughout the year. A number of patients go into the town and country regularly on parole, with friends or with nurses in mufti. Rug-making has been taken up with ardour and the medical superintendent hopes to extend occupational therapy. The appointment of a specialist in domestic economy to supervise household matters has proved a great success. Dr. Barkas, giving her "first impressions," points out that in a small hospital with limited financial resources there cannot be any great outlay on laboratories, pathological research, and elaborate treatment apparatus; it must concentrate on mental illness and treatment. She holds that treatment of maladjustments by psychotherapy in its widest sense constitutes the primary task of the psychiatrist.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 1ST, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 242 (last week 298), scarlet fever, 1704; diphtheria, 926; enteric fever, 41; pneumonia, 1267; puerperal fever, 48; puerperal pyrexia, 109; cerebrospinal fever, 17; *acute poliomyelitis*, 3; *acute polio-encephalitis*, 2, encephalitis lethargica, 25; dysentery, 9; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The largest incidence of small-pox at the moment is in London (Bethnal Green, 12; Poplar, 7; Stepney, 11); Chesterfield R.D., 10; South Shields, 11; West Ham, 29; Leigh (Lancs.), 6; Northampton, 8; Peterborough, 16; Stoke-on-Trent, 15; Spenborough (Yorks.), 8; Pontefract R.D., 13; and Merthyr Tydfil, 5.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on June 4th–5th was as follows:—Small-pox, 286 under treatment, 16 under observation (last week 307 and 10 respectively); scarlet fever, 1352; diphtheria, 1547; enteric fever, 14; measles, 136; *whooping-cough*, 651; puerperal fever, 27 (plus 8 babies); encephalitis lethargica, 116; poliomyelitis, 1; "other diseases," 63. At St. Margaret's Hospital there were 17 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 55 (0) from measles, 5 (2) from scarlet fever, 51 (15) from whooping-cough, 17 (2) from diphtheria, 43 (7) from diarrhœa and enteritis under two years, and 47 (7) from influenza. The figures in parentheses are those for London itself.

For the first time over a period of ten weeks no death from small-pox is reported from the great towns. Liverpool reported 18 deaths from measles, Leeds 7, Salford and Sunderland 6 each. Liverpool also stood highest with 4 deaths from whooping-cough. Diarrhœa accounted for 6 deaths in Birmingham. Manchester reported 4 deaths from influenza.

The number of stillbirths reported during the week was 205 (corresponding to a rate of 39 per 1000 births), including 46 in London.

DEATHS FROM SMALL-POX.

FOUR cases of small-pox occurring recently in Gravesend have ended fatally. We are indebted to Dr. C. D. Outred, medical officer of health, for the following details.

CASE 1.—Female, aged 16, a daily domestic. Onset April 5th, rash appeared on the 7th, notified and removed to Gravesend Isolation Hospital on the 10th, died on the 18th. Disease severe, Eastern type. Unvaccinated.

CASE 3.—Female, aged 24, house duties. Onset April 19th, rash appeared on the 20th, died on the 21st at home before being seen by a medical practitioner. Disease severe, Eastern type. Unvaccinated. Source of infection unknown.

CASE 6.—Female, aged 25, house duties, sister of the previous case and living at the same address. Onset April 19th, rash appeared on the 20th, notified and removed to hospital on the 22nd, died on the 25th. Disease severe, Eastern type. Unvaccinated.

CASE 7.—Male, aged 64, labourer unemployed, living in the same street as Cases 3 and 5. Onset May 4th, rash appeared the same day, notified and removed to hospital on the 5th, died on the 8th. Disease severe. Unvaccinated.

The total number of cases notified was seven, of which four were of a severe type and died; all four were unvaccinated. Of the three mild cases, one was vaccinated at about the time of infection and was only slightly affected.

by the disease. Of the other two, one (No. 4, aged 46) had been vaccinated in infancy. Four houses were affected, but no connexion with the different families was established except in the case of No. 7, who was a direct contact. Two cases were removed from one house (No. 1 sister, and No. 6 brother). Three cases were notified from 10, Bentley-street, and one case from each of two other houses.

The fatal case at Caerphilly (the only death among 76 notified cases) was that of a woman, aged 56, who was notified on April 3rd. When seen by Dr. T. W. Thomas, medical officer of health, on the following day, she had a temperature of 104° F. and was comatose, with incontinence of urine and fæces. Later she had hæmorrhage from the bowels. The rash was very scanty. This woman had been vaccinated in infancy and showed two small marks. She declined to be revaccinated when her son aged 16, living at the same address, was certified to be suffering from small-pox, and removed to hospital on March 18th. On April 4th she was too ill to be removed and she died on the 8th. The death certificate was filled in: Encephalitis; small-pox. No P.M.

MILK CONSUMPTION AND THE GROWTH OF SCHOOL-CHILDREN.

A TEST IN A RURAL DISTRICT.

By M. L. CLARK, L.L.A.,
ROWETT RESEARCH INSTITUTE.

THE extensive tests on the value of milk for school-children carried out over a period of two years in Scotland and Northern Ireland[1] by the Rowett Research Institute, Aberdeen, and the Scottish Board of Health showed that the addition of milk to the diet of children in the larger towns was followed by an increased rate of growth and general physical improvement.

In these tests no observations were made on children attending rural schools. It was suggested that a small test on similar lines might be arranged in a purely agricultural district and an offer of a donation to cover part of the cost was received. A test was therefore done in two small rural schools in an English agricultural county. The numbers of the children at the schools—10 in the control and 19 in the milk school attending during the seven-month period—are, of course, far too small to allow of any conclusions being drawn or to warrant any statistical analysis The details which are given below are of value only inasmuch as they show that in two rural schools chosen at random much the same results were obtained as in the large-scale tests in the towns. The only definite conclusion that might be drawn is that we are not warranted in assuming that even in agricultural districts children receive the optimum amount of milk. It would be of great interest to ascertain whether this small sample is typical of the whole agricultural area.

It would be valueless to give all the data in detail. The main results are as follows.

1. *Amount of Milk Consumed at Home.*

Rural (1929)	3½	pints per person per week.
Scotland (1927)	2½	

Even the amount shown in the rural inquiry is only one-third of that which is considered to be the optimum for the growing child (Sherman).

2. *Effect on Growth of Addition of Three-quarters to One Pint of Milk, According to Age.*

33·6
Heart

were treat
results. Th
recurring from
epidemic of in

	Average increase in Height.	Average increase in Weight.
l (1929)	1·402 in.	4·304 lb.
ol (1929)	1·125 in.	4·000 lb.
	+0·277 in.	+0·304 lb.

The height increases correspond closely with those of the large-scale tests which were as follows:—

	Average increase in Height.	Average increase in Weight.
Milk groups (1927)	1·470 in.	3·617 lb.
Non-milk groups (1927)	1·212 in.	2·974 lb.
	+0·258 in.	+0·643 lb.
Milk groups (1928)	1·459 in.	3·578 lb.
Non-milk groups (1928)	1·181 in.	2·461 lb.
	+0·278 in.	+1·117 lb.

3. *Effect of Addition of Milk on General Condition.*—A distinct increase in liveliness and general alertness as well as a physical improvement was noted by the teacher of the children receiving milk. The attendance during the feeding period (October, 1928, to May, 1929) averaged 97·1 per cent. in the milk school, while the control school only reached 84·1 per cent. The average attendance during the six months October, 1928, to April, 1929, for the district containing the two schools was 85·8 per cent. and for the whole county 86·8 per cent., which shows that the control school had not suffered disproportionately from illness. Comparing the amount of time lost by the children, the average in the milk group was 3½ days per child in the seven months, in the control group 19½ days.

We know that during the last decade a great improvement has taken place in the health of the school child in towns. This glimpse of a small rural community would suggest the probability that the children in such districts may also require further aid to assist them to attain to better physical condition and growth.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Irish Medical Men in England.

CERTAIN statements attributed to Dr. Alfred Cox, Medical Secretary of the British Medical Association, in a London paper last week have given rise to discussion in medical circles in Dublin. In Dr. Cox's view, there is an over-production of doctors in Ireland, which tends to unbalance the medical labour market in England. It is suggested that only some 10 per cent. of medical men educated in the Irish Free State are absorbed by practice in that country. This is a startling under-statement of the fact. An examination of the Medical Register shows that approximately 40 per cent. of those who obtain their medical qualifications in the Irish Free State remain there. For the whole of Ireland the figure would be about 50. Dr. Denis Coffey, President of University College, Dublin, in an interview given to the press, points out that England has always relied on Scotland and Ireland to keep up a supply of medical practitioners, only about 50 per cent. of the medical men practising in England having received their qualifications there. The proportions at present are said to be approximately: English qualifications, 48–50 per cent.; Scottish, 32 per cent.; Ireland, 14 per cent.; colonial and foreign, 5½ per cent. If there is any unbalancing of the English labour market it seems to come from Scotland rather than from Ireland. Moreover, the number of those qualifying in Ireland has not increased appreciably in recent years, and is, of course, much less than it was six or seven years ago. The undoubted success of both Scottish and Irish medical men in practice in England serves to show that their services are both required and appreciated there.

Honorary Fellowship for Dr. Denis Coffey.

At the last meeting of the Royal College of Physicians of Ireland, Dr. D. J. Coffey was unanimously elected an Honorary Fellow of the College. Dr. Coffey is President of University College, Dublin, and also President of the Irish Free State Medical Registration Council, and his election may be regarded as a compliment not only to him personally but in both these representative capacities, as the head of a College which possesses a virile and progressive medical school, and as the head of the educational and registration authority of the medical profession of the Irish Free State. Before his appointment as President of University College, Dr. Coffey was for some years Professor of Physiology in the Cecilia Street School of Medicine. He was both an original worker of much ability and an attractive teacher. Many feel that his transference to administrative duties deprived physiology of an investigator of great promise. In 1912 Dr. Coffey was given the Honorary Degree of LL.D. by the University of Dublin.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Local Government Act.

Now that the general election has ended in a Labour victory, several parishes, burghs, and education authorities in Scotland have passed resolutions asking for a suspension of the Local Government Act until certain matters are reconsidered. The Glasgow education authority is among the first to make this demand. The problem of the parishes, however, is not the same as the problem of the burghs, or of the education authorities. The demand for suspension is not a simple matter. The protesters will soon realise what an intricate and closely knit measure the new Act is. It involves immense financial reconstruction, which is the product of about 40 years' investigation and criticism. In Scotland, ever since the Balfour of Burleigh Royal Commission (over 30 years ago), the problem of rates, site values, and kindred questions has never died down. Committee after committee has attempted solutions, but until now nothing serious has emerged. In the new Act, at one stroke, the local authorities are re-formed and grants rearranged in such a way that no authority suffers. These measures cannot well be reversed and even "suspense" might end in great confusion. Apart from this, however, the mere merits of some of the new provisions—e.g., the hospital clauses—will commend those provisions to every reformer anxious to see sickness taken out of the poor-law. This is one of the great achievements of this century and no Government will readily go back to the old muddle. There are many other points to argue upon, but the importance of the present protest lies in the fact that they arise almost before the Act comes into operation.

One very important point emerged when the Bill was in committee and Section 36 is a partial answer to it. In Scotland, the city councillors do not all go out of office at one time. In Edinburgh, for example, a third of the town councillors (over 70 in number) retire each year. It has been suggested that, at the first election under the new Act, the whole town council should retire and a new council be elected. This is what happens with the county councils and the education authorities, and it gives better scope for the men and women of the old authority to become candidates for the new concentrated authorities. If only one-third of the town council retires, the new candidates, who must face problems of education and poor-law as well as public health and other town council work, will be limited to those who contest one-third of the seats. It would certainly be better, on the whole, if the town councils, like the county councils, went out of office to the full extent of their membership. Otherwise, the two-thirds remaining in office, who were appointed without reference to the new duties, will dominate the situation. This point is one that may well be reconsidered.

Artificial Cream.

The Department of Health for Scotland has issued a circular explaining the new Act concerning artificial cream. This is a much more important circular than its length indicates. Artificial cream has been experimented with for several years, but it did not seriously affect the market until the use of all preservatives in cream was forbidden. It was soon discovered that, while the ordinary market for immediate or rapid consumption domestically could be, on the whole, supplied without much difficulty, the baker and confectioner market could not. The cream used for cream cakes, and various confections, could not, without preservative, maintain its freshness for the long period required and, almost immediately on the appearance of the anti-preservative regulations, bakers and confectioners began to use "reconstituted" cream, and the trade journals were soon full of pictures of emulsifying machines. The reconstituted cream was "genuine" in the sense that it was made up of butter-fat, dried milk, and a proportion of water, and, as it could be made sterile from the start, it served the purpose better than cream that in less than 24 hours went sour. The usual protests were made; the cream trade alleged prospective ruin and unfair competition. Unfair in one sense the competition certainly was, for reconstituted cream is not fresh cream—that is, "that portion of natural milk rich in milk fat which has been separated by skimming or otherwise." But artificial cream is a wholesome food product and the real unfairness only begins when it is passed into the market as "cream." The trade protest has been successful and artificial cream must now be so defined. In other words, measures are obligatory to let the consumer know what he is buying. The curious point is that, although cakes and confectionery were a material factor in the protest, "the Department are advised . . . however, that the Act does not apply to fancy cakes or confectionery containing cream so prepared, or to ice-cream." The new powers are stringent; but they do not interfere with the manufacture of this excellent food so long as it is frankly labelled by its proper name. It is difficult to avoid the reflection that if the creameries and dairy farmers had spent more time and energy in producing "clean" milk and cream, they need not have suffered such loss of trade as the growing popularity of artificial cream is sure to involve.

Mental Defect.

Addressing the annual meeting of the Scottish Association for Mental Welfare held recently in Edinburgh, Prof. G. M. Robertson spoke of the serious consequences to society if the lives of sub-normal persons were not supervised. It was now possible to form some idea of the extent of mental defect, and though previous estimates had been high they had evidently not been high enough. It appeared that about eight out of every thousand persons living were mentally defective, and that the number of defectives in England and Wales amounted to about 300,000 of the population. Accepting those calculations as the proportion that also existed in Scotland, the number of defectives in this country was about 40,000. Those who gave rise to most anxiety and trouble were the young adult defectives of the higher grades. Endeavours must rest on the basis of a tripod of three distinct operations: early detection and appropriate training when young; a suitable occupation, protected from unequal competition, when adult; and friendly supervision of life at home. When after-care work had been well organised on those lines, the records of old pupils of special schools had been encouraging.

Effect of Influenza on the Death-rate.

The returns made for the first quarter of the year by the Registrar-General for Scotland show deaths numbering 26,386. This number is 10,527 more than that of the previous quarter, and 5503 more than the mean of those of the first quarters of the preceding ten years. Since national registration was started in 1855 the only quarters in which greater numbers of deaths were registered were the last quarter of 1918 and the first quarter of 1919, when the numbers were 28,619 and 28,959 respectively, the high mortality then as now being largely attributable to influenza. In the first quarter of this year deaths from influenza numbered 3035, of which 409 were attributed to influenza as a sole cause, and 2626 to influenza with some contributory cause. Deaths from bronchitis, pneumonia, and influenza during the quarter numbered 9581, the corresponding figures in the previous quarter and in the first quarter of 1928 being 2664 and 3768 respectively.

National Health Insurance.

At the annual conference of the Scottish National Association of Health Visitors, Women Sanitary Inspectors, and School Nurses, held at Dundee on June 1st, Dr. A. S. M. Macgregor, medical officer of health for Glasgow, in the course of an address on the Coöperation of Public Health Services said the Insurance Act began by saying that it was an Act for the prevention and treatment of disease. The prevention of disease really meant that proper attention could be secured at the earliest possible moment. This was not yet possible in the case of children, and it would meet these very grave defects if the medical benefits were extended to the children of insured persons. It would allow clinics to perform special functions and the diseases of children would be properly looked after. He was satisfied that this would come sooner or later, but he was sorry that the Commission on the Insurance Act had not made this their first consideration.

Lady Cowdray recently presented the title deeds of the Viscountess Cowdray College of Nursing to the Aberdeen branch of the College of Nursing Club—a gift estimated in value as over £20,000. It is understood that this gift is associated with the thanksgiving movement for the King's recovery.

The new department of zoology, which was formally opened on May 15th by Prince George, fulfils a long felt want at the University of Edinburgh. It is the second of the "King's Buildings"—the first of which, the new chemistry department, was opened in 1924—and occupies an open site on the southern outskirts of the city. The scheme for its erection was originally made possible by a gift of £20,000 in 1923 from the late Mr. Pullar. This was augmented in 1926 by £18,000 from the trustees of the Carnegie Trust for the Universities of Scotland and subsequently £74,000 was received from the International Education Board of which Mr. J. D. Rockefeller, jun., is the founder. At the opening of the new buildings, Sir Alfred Ewing, the Vice-Chancellor, pointed out that the University owed these gifts mainly to the scientific reputation, personality, and unsparing efforts of the present occupant of the chair of zoology, Prof. Ashworth.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

An Order of Physicians.

A GREAT fuss has been made for some time past about setting up an "Ordre des Médecins," a sort of disciplinary body within the profession, similar to that established by the barristers in the French law courts. Many leading medical men think it might be useful and that it would stop the activities of the very small number of physicians who lack elementary morality and employ their skill, which is often considerable, in ways which are not legitimate. Prof. Balthazard has asked his colleagues of the Academy of Medicine to vote an address to the Government supporting the scheme, and a young doctor has lately chosen the subject for his inaugural thesis. There are those, on the other hand, who think it useless to introduce a court which would probably have no other authority than that of the ordinary judges. Parliament will have to take the matter up, for a deputy, who is not a doctor, has put forward a proposal for a Bill to create an Order of the kind envisaged. This does not, of course, mean that it will soon come up for discussion, for the Parliaments of all countries have the same disregard for professions which represent so small a number among the voters. Many a practitioner likes to recall that even in his youth he had already heard a great deal of talk about the proposal and that nothing has been done about it with the passing of the years.

Practice and Pharmacy.

In France the physician is not allowed to sell drugs to his patients; he must write his prescription and have it dispensed by a pharmaceutical chemist. The law makes one exception, however. When there is no chemist within 7 kilometres (4¼ miles) the medical man may prepare and sell drugs of his own prescription. He is then called a "propharmacien," a word that does not seem to have any equivalent in English. These "propharmaciens" number 2700 on French territory and have held recently a meeting in Paris. The principal object of the meeting was to consider their attitude towards the new measure of social insurance. As a matter of fact they had been simply forgotten when the Bill was drawn up, and as the pharmaceutical profession is, in France, protected by very strong laws, they expected, unless some alteration was made, to be deprived of their ancient right to sell drugs to the insured patient. Naturally this is of no little importance to them since half, or at least a third, of their income is derived from such sales, it was also of importance to the people they served who would have been obliged to go to the next chemist to fetch their drugs, sometimes at a distance of 10 and 12 miles. The funny part of the business was that when their representatives went to explain these facts to the man in charge of the technical direction of the social insurances they were surprised to find that the eminent director had not the slightest conception of their status and thought they were duly qualified pharmacists who had also taken medical diplomas—an entirely different thing in the eyes of the law. As soon as the misunderstanding was cleared up an agreement was reached and now the propharmaciens are out of danger.

New Antistreptococcal Serum.

Prof. Vincent claimed at the last meeting of the Academy of Sciences that he has prepared a new antistreptococcal serum of real curative power. Hitherto, he said, the streptococcus has been regarded as producing a very low degree of immunity in animals so that the serum prepared against it has not been very reliable By selecting suitable strains of streptococcus giving strong reactions in horses he has obtained a serum with a high power of immunisation. Three cases were described in which it has given excellent results.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Mental Hygiene.

THE mental hygiene movement continues to progress with rapid strides. This spring the new Neurological Institute, costing two million dollars, has been opened as an integral part of the Medical Centre at 169th Street, New York City. At the dedicatory ceremony both Mr. Robert Thorne, the president of the institute, and Dr. Frederick Parson, the New York Commissioner of Mental Hygiene, emphasised the importance which would be attached to research work and to preventive medicine.

Although New York State authorised the expenditure of 50 million dollars for its mental institutions in 1923, there is now urgent need for further expansion. The new Governor, Mr. Franklin D. Roosevelt, has been appealing to the public over the radio to support his demand for another bond issue of equal size to that authorised six years ago. He says that the number of patients in these institutions is increasing at the rate of 2000 per annum, and that by 1936 New York will have 20,000 more mental patients than there are beds for. Even at the present time the Manhattan State Hospital is compelled to house 7000 patients, though its proper capacity is for only 4800. In Illinois the State Mental Hygiene Association is pressing for a 40,000,000 dollar ten years' building programme to relieve congestion in the mental hospitals of that State.

In some parts of the country enthusiasm for the eugenic attack upon mental disease is getting well beyond the bounds of prudence. In the Missouri State legislature, for example, a Bill has been introduced which would make it obligatory upon the court to order the sterilisation not only of the insane, feeble-minded, and epileptic, but also of all persons convicted of "murder (not in the heat of passion), rape, highway robbery, chicken stealing, bombing, or theft of automobiles." Concerning this Bill and others like it, the *Mental Hygiene Bulletin*, the official publication of the National Committee for Mental Hygiene, has the following comment:—

"Almost without exception these Bills are scientifically unsound, when they are not technically absurd, and frequently they are drafted without the assistance of even the meagre scientific knowledge that we now possess with regard to the laws of heredity, the causes of the complex phenomenon of crime, and the basic principles of a sound sociology. Worst of all, they place, potentially at least, an appalling power to wreak private vengeance in the hands of politicians, motley boards of officialdom, and politically-influenced or professionally-mediocre doctors of medicine who do not begin to comprehend the possibilities for evil of such hastily concocted "remedies" for the ills of society...What we need is a great deal more scientific research in the field of human biology, especially with regard to the mechanisms of human heredity, and the inheritance of native and acquired characteristics. We ought to have research of a genuinely impartial nature into the results obtained in those States which have actively functioning sterilisation laws before writing any more grotesque, unsound, and thoughtless legislation into our statute books."

Standards for mental hygiene work have been formulated after careful study and investigation in a "suggested survey schedule" for the study of "Mental and Functional Nervous Diseases" by the American Public Health Association. Copies can be obtained from their offices at 370, Seventh Avenue, New York City.

A Tuberculosis "Cure."

Mail fraud indictments have been issued against five men in connexion with an alleged swindle claiming to provide a cure for tuberculosis. Post office inspectors estimate that 10,000 people have been victimised and that the "healers" have collected approximately a million dollars in fees and sales of "guaranteed cures." Government chemists and medical experts are said to have filed reports stating that the preparations sold by the alleged combine could produce no beneficial effect in pulmonary disease. The San Romay Company, as the organisation was called, appears to have operated from Los Angeles with a branch office in Denver.

MEDICINE AND THE LAW.

Doctor's Trial for Manslaughter.

THE jury disagreed at the Central Criminal Court on June 4th on the trial of Dr. Hugh Windsor Bell, an anæsthetist, of Oakley-street, Chelsea, for the manslaughter of Miss Kathleen Kelly. At the original proceedings in May, at the Marylebone Police-court, the wife of Dr. Bell was also charged, it being alleged that Dr. Bell performed an illegal operation upon Miss Kelly by himself at the house of a Mrs. Capper at Kensal Rise, but that Mrs. Bell knew it was to be done, took some part in arranging it and afterwards sought to take the blame, saying that she had performed the operation with her husband's instruments. The magistrate discharged Mrs. Bell owing to the lack of evidence against her, and committed Dr. Bell for trial. Dr. William L. Harrison, of Granville-gardens, Shepherd's Bush, who attended Miss Kelly's family professionally, stated that he had been consulted by her in February and March. In April she was brought to Dr. Bell by Mrs. Capper. Dr. Bell stated that he found Miss Kelly to be pregnant and formed the opinion that a miscarriage had started. He advised her to enter a nursing-home, but she refused (being anxious that her mother should not know of her condition) and she arranged to go to Mrs. Capper's house instead. She offered him £75 to attend her so long as necessary and paid him in notes. He came to the conclusion that it was necessary to perform an operation, which was perfectly legal. He stated that, in performing it, he thought he accidentally made a punctured wound of which he was not aware at the time. In cross-examination he agreed that, upon his evidence, Miss Kelly must have performed an illegal operation upon herself, but that he had not disclosed this fact to the coroner. Dr. A. W. Bourne, of Harley-street, stated that in complicated cases the operation described by Dr. Bell was a common practice.

The charge against Dr. Bell now stands postponed till next Sessions for trial before a fresh jury. In the circumstances further comment would be improper. Something may, however, be said of the general question, raised in the course of the case, as to whether the charge should have been one of murder or merely of manslaughter. At the police-court the magistrate thought at first that the accused ought to be committed for murder. Defending counsel contended that a man should not be put to the pain of being committed on a charge on which he was very unlikely to be convicted or even tried, and the magistrate allowed the charge of manslaughter to stand. At the Central Criminal Court the prosecuting counsel seems to have imparted a little prejudice by observing that Dr. Bell might consider himself fortunate not to be charged with murder. Upon this, Mr. Justice McCardie remarked that the essence of murder was intent to kill, and he was glad that there had been no attempt to present a charge based on the harsh, mediæval, and, in his view, repulsive doctrine of constructive murder.

Constructive Murder.

The doctrine of constructive murder has to deal with cases of unintentional killing by a person doing or attempting to do an act other than murder. Here there are three grades of homicide of ascending gravity. First, if the act was lawful, the unintentional killing is merely homicide by misadventure. Secondly, if the act is unlawful but not felonious, the killing is manslaughter. For example, to kill a trespasser while kicking him out with unnecessary violence, or to kill a man in the course of an unlawful assembly, would be manslaughter. Thirdly, if the act intended or attempted is felonious, then the killing is murder. Thus, to take the example familiar in the text-books, to kill a man unintentionally while firing a gun at somebody's hens in order to steal them, is regarded as murder, because the stealing would be a felony; on the other hand, to kill him while firing at the poultry without any such intent of stealing would be manslaughter. Such is the legal theory, dependent—it will be noticed—upon the anachronistic distinction between crimes (not always the most serious) classified as felony and crimes (not always the least serious) classified as misdemeanour. The full doctrine of constructive murder has not escaped judicial criticism. Stephen thought that the case ought not to be murder unless the act is one known to be dangerous to human life—such as unintentionally causing the death of a human being by burning down a house with intent to defraud. In the application of the doctrine to cases of alleged criminal abortion a certain difference of opinion manifests itself on the bench. Lord Mersey, when presiding over an assize court, once told the jury that, if they thought the deceased woman died as the result of an unlawful operation performed by the accused, he was guilty of murder; but he added that, if they thought the accused could not as a reasonable man have expected death to result, they might find a verdict of manslaughter. This reasonable view has commended itself to other judges, though it is unfortunate that the legal position should here be a matter of personal practice rather than of universal and established principle. The tendency to seek verdicts of manslaughter rather than of murder where deaths result from criminal abortion should not be regarded as a weakening of the administration of justice. As is possibly indicated by the working of the Infanticide Act of 1922, juries may prove more ready to convict if their verdict does not involve a sentence of capital punishment.

Obituary.

SIR WILLIAM FAIRBANK,

HON. SURGEON TO HIS MAJESTY'S HOUSEHOLD AT WINDSOR CASTLE.

WE regret to announce the death of Sir William Fairbank, so well known for his long and intimate association with the Royal Household at Windsor, which occurred at his residence, Moulsey House, Windsor, on Sunday last, June 9th.

William Fairbank was born in 1850, the son of Mr. Thomas Fairbank, a Yorkshireman. He was educated at Forest School and proceeded to St. Bartholomew's Hospital, where he joined the medical school, obtained prizes in anatomy, and qualified in 1872 as L.S.A. Lond., and in the following year as M.R.C.S. Eng. His skill as an anatomist was recognised by his appointment to a prosectorship of anatomy at the College. Shortly after qualification he was appointed resident medical officer at the Royal Albert Edward Infirmary, Wigan, a post which he held for three years, and at the close of which he took the L.R.C.P.I. after doing obstetric work at the Rotunda Hospital, Dublin. His long association with professional, civic, and court life in Windsor commenced when, in 1880, his elder brother, Dr. Thomas Fairbank, died suddenly, as still a young man, and holding the position of Surgeon-apothecary to the Queen's Household at Windsor. Dr. Thomas Fairbank had been very popular in his official position, and succession to it was offered to the younger brother William, as well as the post of Surgeon-in-Ordinary to Prince and Princess Christian. These responsibilities William Fairbank discharged while also conducting a general practice. He was visiting surgeon to the Royal Infirmary, Windsor, surgeon to the police at Windsor Castle, and later was appointed Honorary Surgeon to Queen Victoria's Household. This post he held for 21 years, and in sequence became Surgeon to King Edward's Household for 10 years, and to King George's Household for the next 13 years, when he retired. As honours in direct connexion with these appointments he received the M.V.O. in 1911, was promoted C.V.O. ten years later, and K.C.V.O. in 1924, while in 1919 he was made O.B.E.; he received the Jubilee medal in 1887, with bar in 1897, and the Coronation medals of King Edward and King George.

Apart from his Court appointments and private practice, Sir William Fairbank found time to discharge important civic duties. For many years a member of the Corporation of the Royal borough, he was Mayor of Windsor in 1919-20, and deputy Mayor in the following year, out of which appointment arose the interesting connexion between Hardecourt-aux-Bois and Windsor, for Fairbank was one of the mayoral delegates to France deputed to visit the ravaged districts, and, after the adoption of Hardecourt-aux-Bois as a special charge upon Windsor, he raised funds by his individual endeavour for the re-erection of the village. From that date forward he visited Hardecourt-aux-Bois every year to the material benefit of the inhabitants whose orchards and gardens he restocked, and whose inhabitants showed their gratitude by gracefully naming after him their main carrefour.

Sir William Fairbank was a member of the Berkshire County Council, and a County and Borough magistrate, while he was also chairman of the Commissioners of Inland Revenue for Windsor and Maidenhead and of the Windsor and Maidenhead Insurance Commission. In two further directions he notably assisted the medical welfare of the community, for he was a pioneer in education and in emergency medical aid. He was a Governor of Holloway College, the leading spirit of the St. John Ambulance Brigade of the district, and a Knight of Grace of the Order of St. John of Jerusalem. For nearly 40 years he gave first-aid lectures in Windsor and Slough, and it was at his initiate that first-aid facilities became available at many railway stations in the country, the lack of such facilities on the Great Western Railway having attracted his attention. At the time of his death he was honorary consulting surgeon to King Edward VII. Hospital, Windsor.

A life so full of public interest was closed by some years of ill-health. A severe operation did not preclude recurrences, and for some time before his death he was in a very serious condition, though he continued to see a certain number of old patients. He was a widower, his wife, the daughter of Mr. John Woodcock, J.P., having died five years ago; but he leaves three daughters and two sons, one of whom is Mr. H. A. T. Fairbank, orthopædic surgeon to King's College Hospital.

SIR CHARLES O'BRIEN HARDING,

M.R.C.S. ENG., L.R.C.P. LOND.

WE regret to announce the death of Sir Charles O'Brien Harding, so prominently known in connexion with medical and civic work in the borough of Eastbourne, which occurred on June 7th, in the seventy-first year of his age, and after some months of ill-health.

Charles O'Brien Harding was the son of a medical man, Mr. John Fosse Harding, and was one of the numerous successful doctors who have received their education at Epsom College. In 1879, after some preliminary work at the Sussex County Hospital, he became a student at St. Bartholomew's Hospital and obtained the M.R.C.S. Eng. and later the L.R.C.P. Lond. He filled the office of house surgeon at the hospital, and also became distinguished as a player of Rugby football, for he was captain of the St. Bartholomew's team which wrested the inter-hospital cup from St. George's Hospital, where it had remained for several years, played for the United Hospitals, which was in those days a team with a fine match list, and also appeared for Middlesex.

On leaving the hospital he went certain voyages as surgeon to the Orient Steam Navigation Company, and then began private practice in Highbury, holding also the appointment of surgeon to the Holloway and North Islington Dispensary; but shortly afterwards he commenced practice in Eastbourne, where he became at once a popular and successful practitioner and associated himself prominently with the development of the great watering-place.

The interest which he showed in the public life of Eastbourne and the confidence and esteem which he enjoyed among his fellow-citizens are displayed by the fact that for 35 years he served continuously on the Town Council, was Mayor of the borough no less than six times, and was largely instrumental in the erection of the town into a county borough 18 years ago. For 25 years he was a magistrate, and as a regular attendant on the bench he proved himself alike generous and impartial, and when, at the end of the war, in recognition of a strenuous mayoralty during 1915-19, he received the honour of knighthood, all who knew him, and they were many, could see in his public and in his professional career the undoubted merits which had won him the distinction. He was presented publicly with his portrait by a large group of friends, and this hangs in the public offices of Eastbourne.

Sir Charles Harding married in 1889 Amy Roberts, who died in 1902, and he leaves five children, three sons and two daughters.

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, 1929.

COMMITTEE AND OTHER BUSINESS.

Dr. W. C. Rappleye, Director of Studies of the Commission on Medical Education organised by the Association of the American Medical Colleges, and Dr. A. S. Erulkar, Physician to the King Edward Memorial Hospital, Bombay, were present throughout this session at the invitation of the Council.

The following members were re-elected to the Penal Cases Committee: Sir Robert Bolam, Mr. H. L. Eason, Sir Norman Walker, and Dr. D. J. Coffey.

The Pre-medical Examination.

In moving the report of the Education Committee, Sir Humphry Rolleston commented on various matters which had been remitted to it. The first of these was a correspondence with the Conjoint Board of England. In December, 1928, the Council had addressed a letter to the Board, pointing out that its regulations allowed a student to commence his course of study for the first professional examination before the pre-medical examination in chemistry and physics, and that he might complete his professional curriculum at a medical school in less than five academical years, the minimum time laid down in the resolutions of the Council for the course of study for a medical qualification. The Board had thereupon pointed out that at least one university in the United Kingdom allowed 12 months of study of chemistry and physics after matriculation to be counted as part of the regular medical curriculum; a student could therefore obtain his degrees after four and a half years at a medical school. The Board itself recognised, as part of the regular curriculum, a period of not more than six months, science study at a recognised school, after the preliminary examination. No candidate could therefore obtain his diplomas without completing four and a quarter years at a medical school; three academic years must be devoted to clinical subjects after the examination in anatomy and physiology. The two terms of anatomy and physiology *that might be taken before* the pre-medical examination did not count as part of the regular medical curriculum of five academic years. This point had not been made clear in the Regulations, and the Board's committee of management was recommending to the Royal Colleges that all the five terms of anatomy and physiology should be taken after the pre-medical examination. The Board also proposed to recommend the institution of an examination in elementary biology as Part 2 of the pre-medical examination. In this event, two terms of anatomy and physiology would be taken before Part 2 of the pre-medical examination. The Education Committee, after considering the matter, had formed the opinion that provided the medical course lasted for five years after the pre-medical examination, and that not less than three years remained available after the examinations in anatomy and physiology, teaching and examining bodies were free to arrange the curriculum as they thought fit.

Antedating of Medical Study.

Correspondence has also taken place with the University of St. Andrews in regard to the antedating of medical students. There were three cases in which students, having passed the pre-registration examination in December, applied to be antedated to October, which was the date when they began their work in the University. This was refused on the ground that the Resolutions of the Council, which came into force on Jan. 1st, 1923, provided that—

> "before registration as a student or commencement of of the regular medical curriculum every person shall be required to pass, in addition to an approved examination in general education, an examination or examinations, conducted or approved by one of the Licensing Bodies, in the subjects of physics (theoretical and practical) and chemistry (theoretical and practical)."

In the reply the University admitted that the time spent in the study of pre-registration subjects had been part of the time recognised by antedating, but said that during the same period the students had been studying botany and zoology as subjects *for the first professional examination, and that*, under their regulations for the pre-registration examination, the same attendance which prepares the candidate for this in chemistry counts afterwards as the first stage of the instruction for the first professional examination in that subject. The correspondence continued, and eventually the Secretary of the University had written:—

> "So far as I can see, the situation is this—either registration is of some moment to the student, in which case several of our students have been disadvantaged; or the registration is of no service whatever to the student, and in the circumstances the university need not go out of its way to advise the student to register with the General Medical Council, more particularly if the Council refuse to antedate, although they have power to do so."

By the President's direction the Secretary was therefore asked to state whether or not his university had fully considered the question and had deliberately *decided that in future they would not follow the* Resolutions of the Council, and that they would permit students to begin the regular medical curriculum before they had passed an approved examination or examinations in physics (theoretical and practical) and chemistry (theoretical and practical).

The Committee, said Sir Humphry, were somewhat surprised that after this length of time there should be any misunderstanding as to the views of the Council, which are quite clearly set forth in the Resolutions in regard to professional education. It was highly desirable for statistical reasons that all students should be registered. Hitherto the Scottish Bodies had been particularly loyal in adhering to this view, and the Committee considered that it would be a matter for great regret if the University of St. Andrews discontinued the practice. At the same time the Committee desired to indicate that the point at issue is not whether or not students should be registered, but *whether or not the University* is prepared to conform to the Resolutions of the Council. The Committee would await with interest the decision of the University.

Age of Matriculation.

The Committee had received the following resolution passed last December by the Headmasters' Conference:—

> "That this Conference regrets the tendency of the regulations of the General Medical Council now in force to encourage too early a matriculation age; and urges that the Medical Council and the licensing bodies should be approached on the matter."

The Secretary had added that the point of the resolution was that headmasters deprecate matriculation at the age of 16, which some universities are now prepared to tolerate in order that intending medical students may take their pre-registration *science course at the university. Headmasters* were emphatically of the opinion that school is the right place for this work and the right place for students of that age.

The Committee reported that it was somewhat at a loss to understand why this resolution was passed. Considerable correspondence had taken place between the Registrar and the mover of the resolution, to whom it had been made clear that the Council, when they changed the minimum age for the registration of students from 16 to 17, had considered whether it was advisable to make the age 18, but they had come to the conclusion that the time had hardly arrived for this. The idea they had in mind was that the average boy would pass his examination in general education at about the age of 16½ to 17, and would remain at school for a further year in order to study the further subjects of elementary chemistry and elementary physics, after which he would proceed to the university or medical school where his curriculum proper would begin at about the age of 17½ to 18.

The Education Committee were of the opinion that it is advantageous that a boy should study the pre-registration subjects at school and remain there as long as possible. It is not, they consider, in his interest that he should go to a university or medical school too young. If means were devised whereby a boy could obtain a school certificate with credits in elementary chemistry and elementary physics and with a theoretical and practical examination in each, which of course would have to be passed in addition to the examination in general education, this would meet the views of the Education Committee as a minimum, and might help to solve some of the difficulties set forth at the Headmasters' Conference.

The report of the Examination Committee contained detailed tables of exemptions from courses of study and examinations granted during the year. Other tables showed results of examinations held by all the Licensing Bodies. These tables are expected to be of great value in assisting the various bodies to coördinate their policy. All the Licensing Bodies have agreed to the publication of the Visitors' Reports on the examinations in pathology and materia medica. This record should be of use in enabling the bodies to study one another's procedure.

On the joint advice of the Education and Examination Committees, the Council decided to resume the inspection and visitation of qualifying examinations early in 1930.

Finances.

The income of the Council and all its branches showed decreases due to the falling off of registration fees. The prolongation of the last Summer Session over the Whit holidays resulted in an increase of £690 in the fees paid to members, and of £106 for extra programmes and minutes. The deficit of £1285 was the first one recorded since 1911, and represented three years' arrears of income tax, together with the cost of the appeal. But for these exceptional items, there would have been a surplus of £396. Sir Holburt Waring prepared the Council for a possible slight deficit at the end of the current year, but remarked that the financial position of the Council was thoroughly sound and that, if there were a deficit, it could well be set against the substantial amounts saved in the last 17 years.

The Pharmacopœia Commission.

The number of copies of the British Pharmacopœia, 1914, sold was 2222—an increase on the preceding year.

The Pharmacopœia Commission is meeting weekly, and has now held 13 meetings. Mr. Charles Herbert Hampshire, M.B., B.S., Ph.C., has been appointed Secretary from June 1st, and has already been attending meetings of the Commission, which has made substantial strides in the formidable task before it. It has drawn up lists of suggested omissions and additions to the Pharmacopœia. These will be circulated to various bodies in the United Kingdom, Dominions, and Colonies for criticism. It has already received, from the Canadian Committee on Pharmaceutical Standards, lists of proposed omissions and additions, together with other important suggestions. It has set up panels of reference in various subjects; valuable advice has already been received from those dealing with pharmacology anæsthetics, skin, nose and throat diseases, and tropical medicine. t is in communication with the Advisory Committee ppointed under the Therapeutic Substances Act, nd has considered various substances dealt with n that Act. At one of its meetings Dr. Hartley (of the Medical Research Council's Department of Biological Standards) was present and offered valuable assistance. It hopes to get into touch with the Pharmaceutical Society on the subject of the Codex, a new edition of which is being considered. It hopes to bring about an understanding whereby the Codex would be truly supplementary to the Pharmacopœia, and contain an authoritative description of drugs and preparations which either have never been, or have ceased to be, in the Pharmacopœia.

The subject which at the moment is giving the Commission the greatest concern is that dealing with pharmaceutical work which will require to be done. Statements made in the monographs of drugs to be retained in the Pharmacopœia will require careful revision; in writing monographs of new drugs many statements about them will require verification before they can be accepted. The Commission have not yet before them information as to laboratories, outside those connected with trade, where such work could be done; to be of any value the work must be performed carefully, within a definite space of time, and with due regard to economy. The Commission will, as soon as possible, put forward the plan which in the circumstances seems to it best to fulfil these requirements.

Col. Norman C. King was reappointed General Registrar.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. T. A. Smyth is placed on Retd. List with rank of Surg.-Capt.

The following appointments are notified: Surg.-Comdr. W. I. Gerrard to *President*, for Medical Dept.; Surg. Lt.-Comdr. M. B. Devane to *Stuart*, to be accommodated in *Valentine*; Surg.-Lt. A. L. Moorby to *Sandhurst*.

ROYAL ARMY MEDICAL CORPS.

Col. A. O. B. Wroughton, late R.A.M.C., retires on retd. pay.

Lt.-Col. J. T. Johnson, from R.A.M.C., to be Col.

Maj. A. E. S. Irvine to be Lt.-Col.

The undermentioned Capts. to be Majs.: G. D. Yates, J. W. Malcolm, C. C. G. Gibson, B. H. C. Lea-Wilson, H. G. Hobson, G. J. McGorty, and J. S. B. Forbes.

ARMY DENTAL CORPS.

Capt. S. A. Rodda to be Maj.

TERRITORIAL ARMY.

Col. J. S. Warrack retires on completion of tenure as A.D.M.S. 44th (Home Counties) Div., and retains his rank with permission to wear the prescribed uniform.

Capt. H. Mather to be Maj.

Capt. J. H. Mellotte resigns his commn.

Lts. G. W. Elkington and T. F. Greenhill to be Capts.

Lt. C. C. P. Anning resigns his commn. on account of ill-health.

G. P. Smith and A. V. Mackenzie (late K.S.L.I.) to be Lts.

ROYAL AIR FORCE.

Flight Lt. C. T. O'Neill is promoted to the rank of Squadron Leader.

The undermentioned Flying Officers are promoted to the rank of Flight Lt.: G. W. McAleer and E. P. Carroll.

INDIAN MEDICAL SERVICE.

Lt.-Col. F. A. F. Barnardo retires.

COLONIAL MEDICAL SERVICES.

The following new appointments have been made by the Secretary of State for the Colonies during May: Dr. C. D. Williams, Lady M.O., Gold Coast; Dr. J. C. D. Carothers and Dr. G. C. Young, M.O.'s, Kenya; and Dr. R. B. S. Smith, M.O., Northern Rhodesia. Dr. W. Crawford and Flying Officer J. T. Sorley have been appointed to the West African Medical Staff.

CHELTENHAM GENERAL HOSPITAL.—Extensive enlargements, which have cost £32,000, have now been completed. The additions include a new wing with two wards of eight beds each, six wards for private patients, and a well-equipped electro-therapeutic department. The nurses' home has also been extensively enlarged.

Correspondence.

"Audi alteram partem."

THE EXAMINATION OF TUBERCULOSIS CONTACTS.

To the Editor of THE LANCET.

SIR,—Appreciating as I do the *obiter dicta* of THE LANCET, it seems only fair to express an earnest *caveat* regarding the opening statement in your leading article of June 8th on Early Mortality from Tubercle. The sentence runs as follows: "One of the least profitable duties of the tuberculosis officer is that which concerns the examination of 'contacts.'" The statement cannot be accepted without serious qualification and I am happy to notice that in a subsequent reference to "the examination of contacts" the words are added, "as usually conducted." This makes all the difference possible.

As largely responsible, long ago, for the introduction of the systematic examination of contacts, I find myself to-day more than ever convinced as to the supreme significance of the measure with a view to the eradication of tuberculosis. It is none the less certain that, if the purpose of the procedure be misunderstood, or lost sight of, and if misdirected methods be followed, the so-called examination is likely to be futile. The picture you draw of the examination "as usually conducted" certainly makes one uneasy. The indication that, in such examination, the tuberculosis officer's outlook is towards the detection of *pulmonary* disease does not suggest the pathological knowledge of the live problems of tuberculosis which one would hope for in the specialised service. The majority of tuberculosis officers are surely not thus limited in vision. I am glad to be in frequent contact with men whose outlook is entirely different.

There is imminent need for greater breadth of instruction regarding tuberculosis in the case of medical men preparing for the health services, as well as undergraduates. The objective of current teaching in many places remains as it was a generation ago, that is, the diagnosis and treatment of pulmonary tuberculosis with a side glance at other manifestations of tuberculosis. This seems to me entirely wrong. A satisfactory outlook on the far-reaching problems of tuberculosis should have regard to facts observable in the experimental animal, facts of comparative pathology and the successive stages in the natural history of tuberculosis in the human subject. The "reconstruction" of the natural history has been rendered possible during the present generation through continuous observation of the evolution of tuberculosis in the same individual from infancy throughout thirty or more years. The serious worker in tuberculosis ought nowadays to be so familiar with the natural history of tuberculosis that a thorough clinical examination, *appropriate to the age of the individual* in question, may be rapidly overtaken and supplemented by bacteriological tests when the first line of evidence requires corroboration. In this connexion I am unable to subscribe to your statement that the so-called "tuberculous seedling" is not the precursor of the consumptive adolescent.

In illustration of the value of comparative pathology let me cite an example of much significance. Recently, in our tubercle-free herd (some 50 cows) in connexion with Gracemount Farm under the Tuberculosis Trust, the long continued series of negative reactions to the tuberculin test was broken by a young cow which, six months before, had passed the test successfully. In the interval between the two tests—exactly six weeks before the latter test—the cow in question had been allowed into a park not attached to our farm. In the park were several cattle belonging to another herd with which our cow came naturally into contact, and one of those cattle was admittedly sick. In accordance with our plan for the maintenance of the tubercle-free herd, the reacting cow was immediately sent to the slaughterhouse. At the careful autopsy which followed, a single retropharyngeal gland was found much enlarged and definitely tuberculous. No trace of tubercle was found elsewhere.

Such observations in comparative pathology have illuminating and inspiring value in the search for evidence of tuberculosis in the human subject.

I am, Sir, yours faithfully,

R. W. PHILIP.

University of Edinburgh, June 8th, 1929.

To the Editor of THE LANCET.

SIR,—The opening paragraph of your leading article conveys at some length the surprising opinion that "one of the least profitable duties of a tuberculosis officer is that which concerns the examination of 'contacts.'" Having mentioned that the average mother will readily bring to the dispensary all the children of school age which she possesses, the article goes on, "The result is highly gratifying to all concerned, for unless the tuberculosis officer's imagination has been captivated by the possibilities of paravertebral percussion, he is able to report that the 'contacts' are not suffering from tuberculosis." This sentence seems to imply a singularly unflattering conception of the whole system of examination of "contacts." Indeed, it negatives the existence of any system of any kind.

All "contacts" of school age are in the first instance under the supervision of the school medical officer. They may be divided into two classes; (*a*) without symptoms, (*b*) with symptoms. With regard to (*a*), the importance of routine examination of children particularly exposed to tuberculous infection cannot, I think, be gainsaid. Class (*b*) comprises the vast majority of "contacts" of school age the tuberculosis officer meets with. A "contact" is brought for examination whose mother states that he has no appetite for his food, hsa been getting thin, has lost all his colour, has a nasty little cough in the mornings, and so forth. We will assume that the tuberculosis officer's imagination has not been "captivated by the possibilities of paravertebral percussion," we will assume further that he finds no definite physical signs of disease; his next procedure, according to the opinion expressed in your article, would be to assure the mother that the child is not tuberculous, shake hands all round, perhaps, and that's that! I doubt exceedingly whether a single tuberculosis officer exists in this country who would make a diagnosis, positive or negative, in such a case after one examination.

For instance, in the tuberculosis school clinic which I conduct in Hull, the routine followed in all such cases includes careful records of weekly weight, daily records of temperature and pulse when at all possible, skiagrams of the chest, examination at regular intervals with a thorough assessment of all symptoms and signs, and so on. All this is very necessary in each case. But the following extraordinary extract from your article would seem to indicate that such measures represent so much wasted time: "As a social investigation, as an opportunity for giving a little elementary instruction in the laws of hygiene the expedition may have been justified. From any other point of view the examination of contacts as usually conducted is futile, for, speaking generally, children of school age do not suffer from pulmonary tuberculosis." This sentence puzzles me. We know, of course, that pulmonary tuberculosis usually manifests itself in children in the form of hilum tuberculosis. (Some object to this term, but that is irrelevant in the present context.(Even apical phthisis of adult type is by no means unknown in school-children. (I have at present out of 44 children under 14 years, eight such cases, three of them T.B.+) Does the writer of your article deny the existence of hilum tuberculosis as a definite entity?

Finally, assuming that many "contacts" of class (*b*) type may not be demonstrably tuberculous, no one will deny that they are potentially so. And is not such a case from all points of view among the most important and, after treatment, the most gratifying of those with which the tuberculosis officer has to deal?

I am, Sir, yours faithfully,
P. RONAN FANNING,
Medical Officer, Hull Municipal Tuberculosis Sanatorium.

Cottingham, E. Yorks, June 10th, 1929.

CHORIONEPITHELIOMA IN A MALE.

To the Editor of THE LANCET.

SIR,—The annotation on this subject in your issue of June 1st (p. 1159) has many points of interest. In the case of the young man of 25 described by Drs. Tansey and Utz, the site of the primary tumour was in the left lung, and the authors suggest that chorionic cells had lodged in the lung since fœtal life, having got there from the maternal circulation. In commenting on this assumption, you prefer to make the admission that no adequate explanation of such a condition can at present be given, if it is certain that the malignant tissue is derived from chorionic cells. Now, it is a fact that primitive tissues are frequently "included" in normal differentiated tissues for long periods (e.g., moles, nævi, dermoid cysts) and that these primitive tissues sometimes become malignant. Adult tissues cannot, of themselves (i.e., in the absence of pregnancy), produce or grow into chorionic cells or tissues. Therefore, it is necessary to presume that when found in such an adult they have lodged there, and as they could not have got there since fœtal life, it appears quite certain that that is what actually occurs in these rare cases. Moreover, the occurrence may not be so very rare, as it is not usual to search for chorionic relics in post-mortem examinations other than those in which malignancy has been present. In support of the foregoing, I would mention the classical legal example of circumstantial evidence, that if a gold-fish is found in a bucket of water it is quite evident that someone has put it there. I cannot see any virtue in a course of action or a line of thought being "simpler" if it leads us to merely negative results," and I cannot agree that ". . . no adequate explanation of such a condition can at present be given." I submit that what occurs in such a case of "chorionic rests" going on to malignancy, is that these primitive cells are held in check by the body tissues, like any other foreign body would be, and there is a position of "stalemate" between the chorionic cells and the body tissues. If, however, general tissue poisoning takes place due to disease, &c., then (as I believe I have logically proved in my book, "The Cancer Mystery solved," 1927)—

> "these primitive tissues can only be precariously under trophic nerve influence, as they are not in their natural site in the body. There must be our first condition present, however, namely, general tissue poisoning. . . ." "As in all other cases of tumour growth, local irritation, producing local tissue reaction, is then required to produce local anaphylaxis and so damage trophic nerve control. The amount of local tissue reaction which is required to produce this loss of trophic control, in these cases, is very much less than in normal tissues, as these tissues are primitive and are under only weak trophic control."

It would appear then, that this patient's tissues become molecularly changed through poisons circulating in his system from bowels, teeth, food, or drugs, &c., &c., and that local irritation was supplied by the presence of the "chorionic rests," reinforced probably by tobacco smoking or an acute bronchitis. Local anaphylaxis occurred around the "chorionic rests" and so injury of the neurilemma of the trophic fibres in the vicinity. This, in turn, removed the restraining influence of the surrounding tissues upon the "rests" and they now grow in exactly the same way as very malignant *secondary* tumours might do, although in Drs. Tansey and Utz's article they are described quite correctly as "the primary tumour."

I am, Sir, yours faithfully,
ANDREW S. MCNEIL, L.R.C.P. & S. Edin.

Orpington, Kent, June 3rd, 1929.

THE ICTERUS INDEX OF THE BLOOD SERUM.

To the Editor of THE LANCET.

SIR,—Dr. G. W. Milroy, in your last issue (p. 1189), mentions hæmolysis as one of the sources of error in the technique of the icterus index. I have found hæmolysis a great source of trouble when serum is used and, in fact, a large number of specimens of serum, although clear to the naked eye, showed the bands of oxyhæmoglobin when examined by the spectroscope. Such specimens are useless for the icterus index.

Hæmolysis can best be avoided by withdrawing blood by a needle or syringe and needle previously washed out with normal saline and collecting it in a tube on whose inner surface a thin film of potassium oxalate has been deposited from a strong solution by evaporation. The oxalated specimen should be centrifugalised as soon as possible and the plasma withdrawn by a dry teat pipette. I have found plasma much easier to work with than serum and there is the additional advantage that one has not to wait until clotting occurs before completing the test.

If spectroscopic examination shows some hæmoglobin to be present the bilirubin cannot be estimated by the icterus index method and a quantitative van den Bergh reaction should be performed, since a small amount of hæmoglobin does not interfere with this test. I am, Sir, yours faithfully,

C. ALLAN BIRCH, M.D., M.M.S.A., D.P.H.

Royal Infirmary, Liverpool, June 8th, 1929.

LOCAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—In his note on Spinal Anæsthesia in your last issue (p. 1194), Mr. C. A. Pannett states that it is usual in any operation done under local anæsthesia with novocain to find sensation returning in an hour. This, he adds, is not peculiar to the spinal method: a drug which will produce prolonged anæsthesia is much wanted. For several years I have carried out all my plastic operations under local anæsthesia, and the majority of them occupy from two to three hours to perform. I use a 2 per cent. novocain solution in 0·9 per cent. sodium chloride, with 1 in 10,000 adrenalin.—I am, Sir, yours faithfully,

C. ABBOTT-BROWN.

South Molton-street, June 7th, 1929.

MEDICAL CANDIDATES FOR PARLIAMENT.

SUCCESSFUL AND UNSUCCESSFUL.

THE result of the Scottish Universities poll, to decide between four candidates for three seats, was announced on Monday last, and the name of Sir George Berry, who stood second in the final result, has now to be added to the list of medical men and women entitled to sit in the new House of Commons. The election was carried out on the proportional representation system, and the actual figures were as follows:—

Buchan, J. (C.)	9959
Berry, Sir George (C.)	9262
Cowan, D. M. (L.)	6698
Kerr, Dr. James (Lab.)	2867

At the declaration of the poll in Edinburgh, Dr. Kerr protested against the practice of issuing figures of the election from day to day, and the Returning Officer joined with him in deprecating a practice which seems to be quite unofficial in Scotland although accepted in a London University election.

Medical News.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful :—

THIRD EXAMINATION FOR M.B., B.S.

With Honours.—C. F. Cosin (*a*) Guy's Hosp. ; E. A. Hunter (*a, c, University Medal*) London Hosp. ; A. L. Light (*a*), Univ. of Leeds ; E. G. M. Palser (*c*) Univ. Coll. Hosp. ; S. F. Russell (*d*) and H. A. H. Selbourne (*a*), St. Bart.'s Hosp. ; and C. E. W. Wheaton (*c*) St. Thomas's Hosp.

(*a*) Distinguished in Medicine.
(*c*) Distinguished in Forensic Medicine.
(*d*) Distinguished in Surgery.
(*e*) Distinguished in Midwifery.

Pass.—Lucy E. Arthur, and Mabel A. Baker, L.S.M.W. ; C. G. Bowen, Guy's Hosp. ; Annie G. Busher, L.S.M.W. ; E. C. B. Butler, London Hosp. ; Alison M. Clark, St. Mary's Hosp. ; Rosa O. J. Clark, L.S.M.W. ; S. L. A. Clarke, Guy's Hosp. ; Joan C. Clatworthy, Univ. Coll. Hosp. ; F. S. Cooksey, King's Coll. Hosp. ; Hilda C. Dean, Charing Cross Hosp. ; C. G. de Couilliard, Middlesex Hosp. ; V. P. de Zoysa, Univ. Coll. Hosp. and Ceylon Med. Coll. ; C. J. Donelan, St. Bart.'s Hosp. ; D. E. Dunnill, Guy's Hosp. ; Dorothy V. Dunolly, Univ. of Durham ; A. M. Easton, St. Thomas's Hosp. ; A. C. Elkin, Univ. Coll. Hosp. ; C. N. Evans, St. Bart.'s Hosp. ; G. S. Ferraby, King's Coll. Hosp. ; Kathleen E. Gambrell, L.S.M.W. ; Isaac Gordon, St. Bart.'s Hosp. ; D. P. Gray, Middlesex Hosp. ; Bridget S. P. Gurney, L.S.M.W. ; C. E. Hagenbach, St. George's Hosp. ; Emily M. Hall, St. Mary's Hosp. ; H. N. W. Harley and R. L. Harward, Guy's Hosp. ; F. F. Hellier, Univ. of Leeds ; C. F. Howes, St. Thomas's Hosp. ; E. C. H. Huddy and W. F. Hudson, Guy's Hosp. ; H. E. James, Univ. Coll. Hosp. ; Philip Kaplin, St. Mary's Hosp. ; D. W. S. Kaye, King's Coll. Hosp. ; H. J. Krichefski, Univ. Coll. Hosp. ; S. C. H. Lane, Guy's Hosp. ; A. J. C. Latchmore, Univ. of Leeds ; I. B. Limbery, St. Thomas's Hosp. ; G. H. Livingstone, King's Coll. Hosp. ; W. S. McConnell, Guy's Hosp. ; J. V. Macgregor, Univ. Coll. Hosp. ; M. L. Mistri, Guy's Hosp. ; Anna P. Montgomery, Charing Cross Hosp. ; Jocelyn A. M. Moore, L.S.M.W. ; Joyce Morgan, Westminster Hosp. ; D. T. R. Morris, Univ. Coll. Hosp. ; C. B. Nicholson, Middlesex Hosp. ; C. G. MacM. Nicol, Charing Cross Hosp. ; C. G. Paine, St. Mary's Hosp. ; Keren I. Parkes, King's Coll. Hosp. ; G. C. Pether, Middlesex Hosp. ; A. P. Petigura, Univ. Coll. Hosp. ; C. B. Picken, Guy's Hosp. ; Betty J. W. Pilsworth, L.S.M.W. ; G. L. S. Plumbly, Univ. Coll. Hosp., H. W. A. Post, Guy's Hosp. ; Israel Preiskel, St. Bart.'s Hosp. ; K. H. Pridie, Univ. of Bristol ; E. I. Puddy, St. Mary's Hosp. ; W. G. Richards, St. Thomas's Hosp. ; Marjorie E. Roberts, L.S.M.W. ; I. M. Robertson and R. D. Robinson, St. Bart.'s Hosp. ; Janet M. Rocke, L.S.M.W. ; A. P. Ross, King's Coll. Hosp. ; A. S. D. Russell, St. Thomas's Hosp. ; Beatrice A. Savill, King's Coll. Hosp. ; J. E. Schneider, St. Thomas's Hosp. ; E. M. Sharples, D. Shaw, and C. G. Sinclair, St. Bart.'s Hosp. ; Namasivayam Sinnadurai, Middlesex Hosp. and Ceylon Med. Coll. ; E. J. J. Smith, St. Bart's. Hosp. ; P. A. M. Soutter, Westminster Hosp. ; J. B. Sugden, Univ. of Leeds ; A. R. Thompson, London Hosp. ; F. S. Thornton, St. Thomas's Hosp. ; Decima M. Tracey and Frances J. Vinter, L.S.M.W. ; Nora W. Wamsley, Charing Cross Hosp. ; A. J. Watson, Middlesex Hosp. ; S. A. Wickramasinghe, Ceylon Med. Coll. and St. Bart.'s Hosp. ; Philip Wiles, Middlesex Hosp. ; W. A. Wilson, Univ. Coll. Hosp. ; Arthur Wiseman, Guy's Hosp. ; E. A. Wood, Univ. Coll. Hosp. ; Joyce R. Woods and Mary Worthington, L.S.M.W. ; T. C. Yip, St. Bart.'s Hosp ; and B. A. Young, Univ. Coll. Hosp.

The following candidates passed in the undermentioned parts of the examination :—

Group I.—Ellen M. Barnes, Univ. Coll. Hosp. ; J. N. Bhada, Univ. Coll. Hosp. and Grant Med. Coll., Bombay ; C. V. Bloom, London Hosp. ; W. E. R. Branch, Univ. Coll. Hosp. ; Eileen A. Chennell, St Mary's Hosp. ; Mabel J. Cooke, L.S.M.W. ; W. V. Cruden, St Bart.'s Hosp. ; Catherine Day, L.S.M.W. ; R. F. Fidler, Middlesex Hosp. ; Alice E. N. Gilby, L.S.M.W. ; D. R. Griffith, St Thomas's Hosp. ; Ernest Grundy, Univ. of Leeds ; F. R. Gusterson and G. F. Harrison, St Thomas's Hosp. ; E. F. Hewlitt, Guy's Hosp. ; J. F. L. King, St. Bart.'s Hosp. ; George Lee, St. Thomas's Hosp. ; Dorothy M. Lufkin, Univ. Coll. Hosp. ; Dorothy F. McIntosh, Charing Cross Hosp. ; T. H. Negus, St. Thomas's Hosp. ; A. T. Pagan, St. Bart.'s Hosp. ; L. M. J. A. Pilot, St. George's Hosp. ; J. C. Saldanha, Univ. Coll. Hosp. ; C. P. Scott, St. Thomas's Hosp. ; Mary Scouloudi and Mary E. Sharp, Univ. Coll. Hosp. ; Rupert Shelley, St. Thomas's Hosp. ; A. G. Signy, Guy's Hosp. ; Marjorie V. N. Sudds, L.S.M.W. ; K. G. Sugden and C. B. V. Tait, St. Bart.'s Hosp. ; and L. E. Vine, Univ. of Bristol.

Group II.—A. M. Boyd, St. Bart.'s Hosp. ; Bertha A. Briant and Lilian P. Edwards, L.S.M.W. ; H. K. Evans, Middlesex Hosp. ; Rees Evans, Univ. Coll. Hosp. ; B. M. Fonseka, Middlesex Hosp. ; Ruth C. Galletly, L.S.M.W. ; V. F. Hall, King's Coll. Hosp. ; Margaret L. Hamburger, L.S.M.W. ; G. B. M. Heggs and R. A. King, St. Mary's Hosp. ; K. E. Lane, Guy's Hosp. ; L. P. E. Laurent, Univ. Coll. Hosp. ; Arthur Levy, St. Thomas's Hosp. ; F. J. G. Lishman, E. W. Martindell, and Ralph Oliver, Univ. Coll. Hosp. ; Raymond Purvis, St. Thomas's Hosp. ; Sylvia M. Ransford, L.S.M.W. ; J. A. Robson, St. Bart.'s Hosp. ; R. C. N. Shires, Univ. of Leeds ; W. D. Steel, Univ. of Birmingham ; S. A. Underwood, St. Mary's Hosp. ; E. M. Wijerama, Ceylon Med. Coll. and Univ. Coll. Hosp. ; and N R. W. Wynn-Williams, Middlesex Hosp.

L.S.M.W. = London School of Medicine for Women.

UNIVERSITY OF CAMBRIDGE.—At a congregation on June 8th the degree of Bachelor of Medicine was conferred on *Robert Gallimore*.

UNIVERSITY OF DURHAM.—On the occasion of the installation of the Duke of Northumberland as Chancellor of the University, the honorary degree of D.C.L. was conferred on, amongst others, Sir John Rose Bradford, P.R.C.P., and Lord Moynihan, P.R.C.S.

ST. MARY'S HOSPITAL DINNER.—The annual dinner of past and present students of St. Mary's Hospital, London, will be held at the Trocadero Restaurant, Piccadilly-circus, on Friday, Oct. 4th, with Sir John Broadbent in the chair.

ST. BARTHOLOMEW'S HOSPITAL.—Mr. Grey Turner, professor of surgery in the University of Durham, is taking charge of the teaching in the surgical unit of St. Bartholomew's Hospital, in place of Prof. Gask, for a fortnight from June 10th to 22nd. On former occasions Prof. Harvey Cushing, of Boston, Prof. Hugh Cabot, of Ann Arbor, and Lord Moynihan have acted in a similar way.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held at Newcastle-upon-Tyne on Friday, June 21st, at 2.30 P.M. Among the speakers will be Dr. Glen Davison, Dr. Farquhar Murray, Dr. Harvey Evers, and Dr. Leonard Hill, F.R.S.

STRANGEWAYS RESEARCH LABORATORY, CAMBRIDGE. A course of instruction in the Technique of Tissue Culture will be given from July 9th to August 10th. Only a limited number of applicants can be received, and those wishing to take the course should send their names not later than June 30th, to Dr. H. B. Fell, at the Laboratory.

SOCIETY FOR THE STUDY OF INEBRIETY.—At a meeting of this Society at 11, Chandos-street, London, W., on Tuesday, July 9th, at 4 P.M., Mr. W. McAdam Eccles will deliver a presidential address on Some Gaps in the Study of Inebriety, and Sir William Willcox will open a discussion on the Toxic Effects of Methylated Spirits and Impure Forms of Alcohol.

POST GRADUATE COURSE AT CARLSBAD.—The eleventh international medical post-graduate course, with special reference to balneology and balneotherapy, will be held at Carlsbad from Sept. 15th to 21st. Medical men from many European countries are to give addresses, and reduced fares will be granted on the State railways of Czecho-Slovakia. Further information may be had from Dr. Edgar Ganz at Carlsbad.

NATIONAL ASSOCIATION FOR PREVENTION OF TUBERCULOSIS.—The fifteenth annual conference of this association will be held at Newcastle-upon-Tyne from Oct. 10th to 12th. On the first day an address entitled "Tuberculosis on Tyneside, a Sociological Survey," will be given by Mr. Henry Mess, Ph.D., and will be followed by a discussion. Later in the proceedings, Dr. Edouard Rist, of Paris, will open a discussion on the Factors that Produce Pulmonary Tuberculosis ; Dr. William Brand will outline a Scheme of National Propaganda regarding Tuberculosis ; and Dr. A. H. Macpherson will speak on the Combined Treatment and Technical Education of Tuberculous Youths. Numerous other addresses will be given, full particulars of the meeting being obtainable from the Secretary at 1, Gordon-square, London, W.C.1.

ROCKEFELLER MEDICAL FELLOWSHIPS.—The Medical Research Council announce that on behalf of the Rockefeller Foundation they have awarded seven travelling Fellowships for the academic year 1929–30. These Fellowships are awarded to graduates who have had some training in research work either in the primary sciences of medicine or in clinical medicine and surgery, and who are likely to profit by a period of work at a chosen centre in America or, in special cases, in Europe before taking up positions for higher teaching or research in the British Isles. The *new Fellows are:* Olive Burton Buckley, M.R.C.P., of King's College Hospital, London ; George Aleck Crocker Gough, Ph.D., of the National Institute for Medical Research ; William Robert Henderson, M.B., of the Royal Infirmary, Edinburgh ; Donald Hunter, F.R.C.P., Assistant Physician to the London Hospital ; George Eric Lewis, M.R.C.S., of the London Hospital ; Moses Myer Suzman, M.R.C.P., of the College of Medicine, Newcastle-upon-Tyne ; and Janet Maria Vaughan, B.M., of University College Hospital, London. Dr. Gough's Fellowship is tenable at the University of Munich ; the others at centres in the United States. Dr. Lewis has been appointed on modified conditions while receiving emoluments from another source.

METROPOLITAN HOSPITAL SUNDAY FUND.—The total collected by this Fund up to date is about £45,000.

Mr. Arthur Greenwood, the Minister of Health, has appointed Mr. A. Nevil Rucker to be his private secretary, and Mr. P. N. R. Butcher to be his assistant private secretary.

WILLIAM MACKENZIE MEDAL.—This medal for original contributions to ophthalmology of outstanding merit has been awarded for 1928, by the custodians of the Glasgow Eye Infirmary, to Mr. W. S. Duke-Elder.

TERRITORIAL ARMY AMBULANCE CHALLENGE SHIELD.—Nine medical units competed for this on June 8th. It was won, for the second year in succession, by the 167th (City of London) Field Ambulance, who gained 333 marks out of a possible 400. The Runners-up Cup, presented by Lieut.-General Sir Matthew Fell, Director-General of the Army Medical Services, was won by the 170th Cavalry Field Ambulance with a total of 314 marks.

LIVINGSTONE COLLEGE.—Commemoration Day was held on June 5th at Livingstone College, Leyton, when the Bishop of Chelmsford presided over a large gathering. The thing for which the College stood, he said, was the need for instructing missionaries in the elements of medical law, first in order that they might take care of themselves, and, secondly, that in case of need they might be a real help to the people to whom they were going. The Rev. P. D. Robert and Mr. J. E. Ruddle spoke of the great value of the training they had received; Mr. W. McAdam Eccles spoke of the financial position of the College, which requires £270 before Sept. 30th in order to avert an overdraft; and a short statement was made by the Principal, who said that 24 students had entered this year, of whom eight were for the full session. Entrants in the last July course numbered 32, and 24 came for the "care of health" courses. A vote of thanks was proposed by the Mayor of Leyton, and seconded by Dr. L. E. Wigram.

CONFERENCE ON MATERNITY AND CHILD WELFARE. The fifth English-speaking conference on maternity and child welfare will be held at Friends House, Euston-road, London, N.W., from July 2nd–4th, with visits to institutions on the following day and a special post-graduate course for medical practitioners. The subjects of debate will include the care of the child between 1 and 5 years of age; the factors affecting the psychological welfare of children under 5; maternal morbidity; the holding of special V.D. clinics for women and children in connexion with maternity and child welfare departments; and methods of preventing undue delay in the out-patient departments of hospitals. A lecture on rickets will be given by Dr. Eric Pritchard on July 2nd, and a presidential address on the problem of abortion will be delivered on July 4th to the Maternity and Child Welfare Section of the Society of Medical Officers of Health by Dame Louise McIlroy. There will be numerous social functions, and the Child Welfare Travelling Exhibition of the National Council for Maternity and Child Welfare will be open daily at the house of the British Medical Association. Further particulars may be had from Miss J. Halford, hon. secretary of the National Association for the Prevention of Infant Mortality, at 117, Piccadilly, London, W. 1.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, June 18th.—5.30 P.M. General Meeting of Fellows. Ballot for election to the Fellowship.

THURSDAY.—5 P.M., DERMATOLOGY. Cases will be shown at 4 P.M.

FRIDAY, June 21st.—8 P.M., OBSTETRICS. Specimen: A Gigantic Fœtus. Shown by Dr. Lawton Moss. Cases Two Cases of Adenomatous Tumour of the Vulva. Shown by Mr. A. J. Wrigley. Short Communication: Mr. G. F. Gibberd: The Use of Animal Bladders for the Iuduction of Premature Labour. Further notes on Difficult Labour in Australian Aboriginal with Postmortem Measurements of the Pelvis, by Prof. Cleland and Drs. Dawson Wallace and Hackett. (Adelaide). Paper. Mr. C. D. Read and Mr. Frederick Roques: Some Results of the Surgical Treatment of Pelvic Endometriomata. OTOLOGY: Summer Meeting at Cambridge (Friday, June 21st, and Sat. 22nd). Papers: (2 to 4 P.M.) Mr. Lowndes Yates: The Evolution of the Sense of Hearing. Mr. J. S. Tucker: Localisation of Sound. Mr. Seccombe Hett, Dr. A. G. Wells and Dr. Murray Levick: Ionisation as a Treatment for Middle-ear Suppuration. (4.30 to 6 P.M.). Dr. Albert A. Gray: The Application of the Principles of Maximum Stimulation to Clinical Otology. Mr. G. Wilkinson: Demonstration of a Model Resonator Designed to Illustrate the Mechanism of the Cochlea.

SATURDAY.—OTOLOGY (*cont.*). Papers (9.30 to 11 A.M.): Mr. M. Vlasto: The Chorda Tympani Nerve. Mr. C. S. Hallpike: Some Observations on Bone Conduction. Mr. Alex. R. Tweedie: Demonstration of Apparatus for Control of Conversation Test. Mr. Norman H. Barnett and others will take part in the discussion. DISEASE IN CHILDREN: The Provincial Meeting will be held at Nottingham on Sat., June 22nd.

BIOCHEMICAL SOCIETY.

SATURDAY, June 15th.—11.45 A.M. (at the John Innes Horticultural Institution, Merton, Surrey). Communications: H. W. Kinnersley and R. A. Peters: Observations on Carbohydrate Metabolism in Avitaminous Birds. E. Boyland; The Lag Between Phosphate Esterification and Carbon Dioxide Evolution in Alcoholic Fermentation. H. B. Stent, V. Subramanian and T. K. Walker; The Degradation of Succinic Acid by Aspergillus Niger. R. Scott-Moncrieff (introduced by J. B. S. Haldane): The Isolation and Identification of Some New Anthocyanins. E. Phillis: The Sugars of Tulip Bulbs. H. J. Channon and G. A. Collinson: Absorption of Liquid Paraffin From the Alimentary Tract of the Rat and Pig. T. Moore: The Association of Vitamin A Activity with Carotene in the Carrot Root. D. L. Collison, E. M. Hume, I. Smedley-MacLean and H. H. Smith. The Nature of the Vitamin A Constituent of Green Leaves. H. W. Dudley: The Isolation of Acetyl Choline from Natural Sources.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS.

THURSDAY, June 20th.—8 P.M. (Essex Hall, Essex-street, Strand, W.C.): Mrs. C. B. Hodson: Birth Control Clinics in the United States. To be followed by a discussion.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

FRIDAY, June 21st.—8.15 P.M. (preceded at 7.45 P.M. by a Demonstration): Dr. J. F. C. Haslam: Some Health Problems of British Guiana. The Manson Medal will be presented to Sir Ronald Ross and the Chalmers Medal to Major A. C. Sinton, I.M.S.

LONDON CLINICAL SOCIETY.

THURSDAY, June 20th.—8.45 P.M. (at The London Temperance Hospital). Sir Humphry Rolleston: Medical Friendships, Clubs, Societies. (Third Annual MacAlister Lecture).

LECTURES, ADDRESSES, DEMONSTRATIONS. &c.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, June 17th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Ward Visit. 2 P.M., Mr. Donald Armour: Operations.

TUESDAY.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, June 17th.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

MONDAY, June 17th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Collier: Polyneuritis.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Post-traumatic Neuroses. (1).

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Purdon Martin: Chorea.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, June 19th.—4.30 P.M., Mr. R. H. Jocelyn Swan: The Examination of a Urological Patient.

UNIVERSITY OF SHEFFIELD POST-GRAUDATE CLINICS.

TUESDAY, June 18th.—3.30 P.M. (at the Jessop Hospital): Mr. Chisholm: Gynæcological Cases.

FRIDAY.—3.30 P.M., Dr. Yates: Late Complications of Head Injuries.

Appointments.

WOOD, GRACE H., M.B., Ch.B. Liverp., D.P.H., has been appointed Asst. M.O.H. for Bournemouth.

Mansfield and District Hospital: DAVIES, J. LLEWELLYN, M.B., B.Chir. Camb., F.R.C.S. Eng., Consulting Urological Surgeon; MALKIN, H. JORDAN, M.D. Lond., F.R.C.S. Edin., Consulting Gynæcological Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

Bath, Royal United Hospital.—Asst. H.S. At rate of £100.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—Asst. P. 50 gns.

Bolton Infirmary and Dispensary.—H.S. At rate of £150.

Bradford City.—Locum Tenens for Bacteriological and Pathological Work. 12 gns. per week.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £120.

LASH.—On May 28th, at Mundesley, Captain Henry Andrew Lash, M.R.C.S., L.R.C.P., (Hon.) Lieutenant-Colonel B.E.F.

MARSH.—On June 6th, 1929, John Hedley Marsh, J.P., surgeon, of Cumberland House, Macclesfield, in his sixtieth year. Interment, Saturday, at the Macclesfield Cemetery, at 2.30.

McHARDY.—On June 5th, at Broomfields, Nayland, Colchester, Dr. Caroline McHardy.

SHAROOD.—On June 3rd, at Rowlands-road, Worthing, Edward Julian Sharood, Deputy-Inspector-General, M.D., R.N., in his 91st year.

STEPHENSON.—On May 15th, 1929, at the Manor House, Grimsby, George Skelton Stephenson, M.D., J.P., aged 80.

THOMPSON.—On June 9th, in Dublin, Sir William John Thompson, M.D., F.R.C.P.I., aged 68.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NATIONAL COUNCIL FOR MENTAL HYGIENE.—The Council has addressed a letter to local authorities and other public bodies, drawing attention to the urgent need for improved facilities for the treatment of poor persons suffering from nervous or mental breakdown of a type which does not constitute insanity. The rich are able to go into nursing homes under specialist treatment, but little or no accommodation at present exists for patients whose means are small. In England and Wales two special hospitals, the Lady Chichester Hospital at Hove and the Maudsley Hospital in London, provide beds for such patients; but only one or two out of the large number of general hospitals make any special provision, and then only to a meagre extent. Poor patients have, therefore, usually to be sent to the observation wards of poor-law infirmaries; these are unsuitable for cases of nervous breakdown since all kinds of mental illness are nursed in the same ward. The Council urge that when submitting schemes to the Ministry of Health in regard to the administration of the new Local Government Act local authorities will provide for accommodation and treatment in the ordinary public or municipal hospitals of patients suffering from nervous breakdown and the early symptoms of mental illness in addition to any provision which may be made for more established cases in special hospitals.

Notes, Comments, and Abstracts.

SWISS SPAS.

By J. F. Halls Dally, M.D. Camb., M.R.C.P. Lond.,

PHYSICIAN TO THE MOUNT VERNON HOSPITAL,

From remote times the health-restoring properties of the mineral and thermal springs of Switzerland have been widely appreciated. The Romans made considerable use of them, and later their benefits were exploited by various religious communities, who bequeathed many pretty legends anent the discovery of certain sources. Very quaint are some descriptions of early methods of bathing, such as being lowered by ropes through crevices in the overhanging rocks into dark and abysmal waters (Ragaz-Pfäfers), or of mixed bathing in ample and voluminous gowns whilst seated at floating trays on which meals were served (Loëche-les-Bains), or again of the "family bath" in which whole families would bathe together (Baden). The older equipment suggests a hardier—or more tolerant—race of invalids than that which visits the modern and luxuriously furnished baths, most of which are installed in the hotels, and in many cases in a private bath-room adjoining the bedroom.

Switzerland offers such a variety of scenery, climate, and opportunity for sport or excursion; its springs are so numerous, and its spas situate at such different altitudes in valleys, on plains or high plateaux, that the physician has little difficulty in selecting a spa which, whilst suited to the patient's complaint, at the same time will provide him with complete change and continuous interests. Although in brief compass it is impossible to give a detailed account of each, yet the following data may be helpful in indicating salient features of the various sources and the chief maladies for which they are found useful.

1. *Natural Strong Brine.*

Such waters are found at *Rheinfelden* (altitude 940 ft.), also at *Bex* (1410 ft.), and consist in a nearly saturated brine, applied generally and locally, with or without the mother-lye, as baths, compresses, external, rectal, and vaginal douches, gargles and inhalations, either (*a*) diluted, (*b*) undiluted, (*c*) as effervescent baths, by introduction of CO_2 under pressure, or (*d*) given internally with milk. In each place cold spring water is taken internally as a diuretic and to counteract slight constipation often induced by the brine.

Indications.—(1) Subacute and chronic rheumatism; septic arthritis; gout; traumatic atrophies and paralyses. (2) Diseases of children—recurrent and chronic catarrh, adenoids and enlarged tonsils, gland and bone tuberculosis; rickets. (3) Gynæcological disorders of puberty and the climacteric; pelvic inflammations; sterility and habit of abortion. (4) Cardio-vascular affections—post-infective myocardial disease; high and low arterial pressure.

2. *Sulphur Waters.*

(*a*) Strong. *Schinznach* (1050 ft.) has a daily output of 400,000 gallons of hot water, smelling strongly of sulphur, at a temperature of 91·7° F., from a cylindrical well some 9 ft. in diameter, the sulphur appearing as an iridescent film on the surface of the water, which is used as baths, irrigations, inhalations, and local applications. *Gurnigel* (3800 ft.) has strong H_2S water at a temperature of 50° F., also another spring containing little H_2S but more calcium sulphate. (*b*) Weak. *Baden* (1240 ft.) has a daily output of sulphur water in a volume of 200,000 gallons daily at a temperature of 116° F.

Indications.—Skin diseases, including eczema and psoriasis, but excluding syphilis; chronic rheumatism; slowly healing wounds and sinuses; respiratory catarrhs; gynæcological maladies.

3. *Thermal Waters.*

(*a*) Simple. *Ragaz* (1400 ft.) is a subalpine station with invigorating climate, beautiful scenery, a good golf course, and a large swimming-bath. Much benefit is ascribed to radio-activity maintained by constant flow of thermal water at 93° F. through all the baths.

Indications.—Arthritis; arterio-sclerosis; nephrosis; nervous exhaustion; multiple sclerosis (relief of spasticity); endocrine imbalance; hydræmia. Dilatation of heart and aorta, also high and low arterial pressures, are improved by specially designed continuous baths for the forearms and [illegible] at increasing temperatures.

[illegible] E[illegible]thy. *Loëche-les-Bains* (4630 ft.) combines a [illegible] high alpine climate with gypseous thermal Dr. A. [illegible]ons at 125° F. daily, permitting lengthy Treatmen[illegible] [illegible]800 ft.) in a sheltered valley of pines, Dr. Albert [illegible] of Maximum [illegible]mposition but less in temperature (78° F.) and quantity. A non-protein dietary is the special feature of this spa.

Indications.—Respiratory affections; metabolic excess; chronic renal and vesical inflammations.

4. *Chalybeate Waters.*

(*a*) *Disentis* (3450 ft.) nestles on an elevated plateau amid beautiful meadows and forests. Abundant fruit and vegetables are daily supplied at the hotel. Disentis is noteworthy in that it possesses the most powerfully radioactive spring in Switzerland (48 Maché units).

Indications.—Gout and rheumatism; cardio-arterio-renal affections; digestive disturbances; anæmia; weakness after illness and strain; neuralgias, particularly migraine.

(*b*) *Schuls* (4029 ft.), lying in a sheltered basin in the centre of the Engadine Alps, possesses waters with similar therapeutic properties, and in combination with the following adjacent spas has an abundance of mineral sources.

5. *Muriated Alkaline Sulphated Waters.*

Vulpera-Tarasp (3947 ft.), in the gorge of the river Inn, is the finest sulphate of sodium spa west of Austria. The waters of the Lucius and Emerita springs are strongly mineralised, with a high percentage of carbonic acid, lithium, and boric acid. The Bonifacius spring belongs to group IV., in that it is an alkaline chalybeate water.

Indications.—Diseases of metabolism; chronic infections and intoxications; circulatory, respiratory, and urinary affections.

The season at the above spas begins in the early summer and lasts until September, during which time the climate is equable and mild.

CRUISING IN LUXURY.

When Britain first (at Heaven's command) arose out of the azure main, it was, we may recall, on the distinct understanding that her inhabitants should be seafarers. And despite many subsequent changes of government the relics of a maritime tradition still linger in this country, so that every nice girl loves a sailor, and your true-blue Englishman thinks yearningly of the sea whenever he is given a holiday.

In these days, unfortunately, he thinks of a good many other things as well, such as sunshine, good company, foreign cities and people, athletic sports, comfortable chairs, bridge, drinks, and dancing; and it sometimes seems a little difficult to satisfy so many claims of intellect, imagination, and the senses—not to mention health. But modern industry is like the Slave of the Lamp. No sooner is a wish expressed than it is satisfied; and the pleasure-cruising steamer solves the problem of the ideal holiday for countless of our fellow-countrymen.

A ship of this kind, to quote from the literature of the subject, is like the sundial, which marks but the sunny hours; it carries no freight, it avoids the busy commercial ports, and it is primarily designed for the comfort of its passengers. The sightseer spends his days ashore without the bother of finding hotels or moving luggage; he is spared the irritation of travel, and when the day is over he can come back confidently to a clean and comfortable cabin, good service, good baths, clean clothes, and the hundred and one advantages of an established resting-place.

The Arandora Star.

In an attempt to produce the most perfect of cruising steamers the Blue Star Line have withdrawn their modern oil-burning vessel, the *Arandora Star*, from the South American service and have spent £200,000 in fitting her up for holiday purposes. Since she was already designed to take only first-class passengers it has been possible to reach a high standard both of elegance and luxury, and the representative of The Lancet who inspected her during a preliminary voyage from Greenock to London concluded that passengers who like this kind of life will find little to criticise in their accommodation or entertainment. The special suites are of course exceptionally comfortable, but the ordinary cabins are large and convenient, each having hot and cold running water, a radiator, an electric fan and forced draught ventilation for warm weather, and excellent mirrors and cupboards.

The adaptation of a ship of 27,000 tons displacement (15,000 tons gross) to the needs of only 350 passengers has made it possible to consider their comfort to an unusual degree. The large and beautiful dining-room has ample space for enough small tables to take the whole party at one sitting. The smoke-room, lounges, and ballroom are on the same scale; part of the deck has been enclosed for use in cold weather; there is plenty of room for games and walking; a gymnasium is provided on the boat-deck; and a swimming tank [illegible] to [illegible] [illegible]acious or perspiring.

[illegible] *the Crew.*

[illegible] [illegible]lls the dual civilisation [illegible] Machine." On the

f[illegible]

surface in the sunshine are the passengers in bright clothes, with no object but enjoyment, whilst in the bowels of the vessel lives a race which does the work and gets very little fun out of it.

The conditions offered by the merchant service, and the laws which govern them, still need drastic amendment, but the men's accommodation on board a modern liner such as the *Arandora Star* shows many signs of the improvement which is slowly taking place. A cruising steamer requires a very large staff of stewards, but here their needs have been met by converting space formerly used for cargo. A number of the senior ratings are fortunate enough to have two-berth cabins; in no case is provision made for more than 16 men in a single room; and at the time of inspection there was space to spare because the number of men in the larger cabins was considerably less than the number for which they were intended. All the men's quarters are fitted with forced ventilation and are lighted by electricity. Messrooms are provided for the sailors and engine-room staff, but the stewards get their food standing in the kitchens at the conclusion of the passengers' meals. These men work very long hours and do not get enough sleep or fresh air. The life of a steward, like that of many hotel servants, is generally recognised as unsatisfactory, and for remuneration they depend largely on gratuities from passengers. In common with everyone else employed on a cruising steamer they get little leave away from the ship, for the intervals between voyages are reduced to a day or two and the vessel is almost continuously at sea for some six months at a time.

A small number of bathrooms and showers, together with plenty of wash-rooms, and water-closets in single compartments, are available for the crew, and men coming off duty in the engine-room can reach their sleeping-quarters without going on deck. The ship contains a hospital with two 4-bunk wards, a bathroom, and a cabin for the sick-berth attendant. Passengers interview the surgeon in a consulting-room and dispensary which was under reconstruction when the visit was paid. An operating table is kept in reserve.

Holidays and Health.

The *Arandora Star* leaves London to-day, Saturday, on her first cruise, bound for the Norwegian fjords and Spitzbergen. Later in the year she will visit the Mediterranean countries. Holidays of the kind she offers are increasingly popular, but from the medical point of view they are conspicuously more suitable for some types of patient than for others. Medical men who hold no definite views on sea voyages will find much to interest them in a symposium on the subject in the *Practitioner* for March, to which a paper is contributed by Dr. W. Hamilton Allen, the surgeon of the *Arandora Star*. We take this opportunity of conveying our thanks to Dr. Allen for the kindly consideration shown to our representative, and also to the chief officer and second engineer for courteously placing their time at his disposal.

THE VEGETABLE KINGDOM AND THE PUBLIC HEALTH.

On May 31st Mr. H. V. Taylor gave a Chadwick Public Lecture on this subject to a large audience in the Chelsea Physic Garden, with Sir William Collins in the chair. Since people had taken to living in such great numbers in cities, he said, horticulture had become of much greater importance, its extension in the last 20 years having been phenomenal. Among garden products the tomato, like the potato, had originally come from South America. It required water and steady warmth. Cheap glass and a method for the precise regulation of temperature had made it possible to grow tomatoes under glass all the year round. This country was largely supplied from the Channel Islands, and also from the Canaries, where farming land otherwise worth £10 an acre might let for £150 per acre if it was suitable for growing tomatoes. The annual consumption of this vegetable in Great Britain was 3¼ million cwt.

Potatoes first came from a tableland in the Chilian Andes, and it seemed that whoever brought them to Europe, it was not Sir Walter Raleigh; in fact there was a statue in Germany to Sir Francis Drake as the introducer. Considerable prejudice against this crop had been aroused when it was first brought to Europe, and in France their dissemination was only secured by guile. Parmentier got a guard of soldiers from the King for his experimental field by day, and as he expected, the neighbours raided his field by night when the soldiers had gone away, and found his treasured plants valuable to them, so that the prejudice ceased. The new crop was so satisfactory that people came to rely too much upon it, and in 1845, when the potato blight appeared in Ireland and wrecked the year's crop, ten million pounds' worth of other foodstuffs were not enough to replace it. People did not agree, said Mr. Taylor, about the potato's most desirable qualities. In Ireland and Scotland a potato was wanted which in cooking turned into a dry flour; the favourite in England was the King Edward, which in Ireland they regarded as only fit for pigs. In Belgium and France they liked a yellow waxy variety that contained protein as well as starch. The annual consumption in this country was 2 cwt. per head.

Turning to apples the lecturer recalled how a grower from Ribston Priory found in France an apple he liked, pocketed the seeds, tried them in Yorkshire on his return, and grew the Ribston pippin, from which Cox later developed the best of all apples, Cox's orange pippin. Oddly enough, this apple was not appreciated in France. The apples of commerce now appeared all the year round, but there were early disappointments. Apples brought from Australia used to develop "brown heart," which was thought to be a disease, until it was realised that apples were alive and required to breathe, though less fresh air was needed if they were kept cool. At home 3 million cwt. were grown annually and 7 million were now imported. It was estimated that each person in this country ate 100 apples, 72 oranges, and 30 bananas every year.

Oranges came mostly from Spain, Palestine, California, or South Africa, the demand was steadily increasing and was supplied at all seasons. The navel orange resulted from no pollination, and similarly apples and grape-fruit could be grown without seeds, but the flavour suffered. Bananas were composed mainly of starch when green and might then be cooked like a potato, but as the banana ripened the starch turned to sugar. They grew chiefly in Jamaica and Central America and did not need to have the ground cleared for them, for once the timber was removed, the banana plants planted among the residual brush would clean the ground for themselves. It was in 1901 that Sir Alfred Jones, inspired by Mr. Joseph Chamberlain, began importing bananas from Jamaica, and the banana trade had now a volume of £7,000,000 a year.

Why, Mr. Taylor asked, had these fruits and vegetables become so popular of late years? Was it for their flavour or because they supplied some hidden need? They had little food value, most of them, though they furnished roughage, giving bulk to food. They also furnish vitamins, especially the tomato which was unusual among vegetables for its large content of vitamins A, B, and C. The orange provided chiefly the antiscorbutic vitamin C, and when in 1916 there was a shortage of potatoes in Scotland and in Manchester, scurvy developed. Further there were the salts of the fruit juices, of whose benefits we were not yet well enough informed. Clearly the vast development of cities had made these vegetable supplies of importance to the public health.

"NON-INFLAMMABLE" CELLULOID.

In considering the danger of celluloid in connexion with the Cleveland disaster we referred to the possibility of obtaining some less inflammable material with equally useful properties, and mentioned that the acetate of cellulose has replaced the nitrate in the preparation of plastic splints. It has come to light that an important recommendation to minimise the fire hazards of X ray films in this way appeared in an American paper[1] last year after a fire which nearly led to tragedy at the Memorial Hospital, Albany, N.Y. This fire arose, it is not known how, in a room on the first floor of the hospital used for the storage of films and X ray equipment the films being packed on shelves in ordinary cardboard boxes. Efforts to fight the fire were abortive, as the staff were forced back by the fumes from the burning films, and in retiring failed to close the doors between the corridor leading from the film-room and the open stairs leading to the upper floors, thus allowing smoke and fumes to permeate the building. In spite of all this occasion for disaster, no lives were lost. The paper, which is by Mr. R. D. Hobbs and is abstracted in the *Journal of the American Medical Association* for May 25th, deals with the methods of filing films so as to prevent the possibility of fire and contains the following significant passage:—

> "There is another and easier way to control this situation, although an inspection of hospitals indicates that it has not met with popular favour. There is a so-called non-inflammable film, made by treating cotton with acetic anhydride and acetic acid, and producing the same result physically but with the danger removed. The coating is similar to the other, and it is used in the same way. The price of acetic anhydride makes the film a little more expensive. The non-inflammable film is not unburnable as the name implies, but it is as safe as paper and rags, if not more so, for although its point of ignition may be a little lower than the others, its rate of burning is less, and, therefore, the spread of the flame is slower without the production of dangerous gases. It is unnecessary to require any storage conditions for celluloid acetate films; therefore this offers an easy solution to the entire problem when a hospital uses only one style of film."

Mr. Hobbs concludes with the remark that the chief objection to the use of the slow burning film is that it has a tendency to roll and is not so easily filed. Thus, he adds, property and lives may be endangered to facilitate handling and filing.

THE SWISS MEDICAL YEAR BOOK.

AFTER appearing for 50 years in a modest paper cover and a format less than 6 by 4 inches, the Swiss Medical Calendar in its 1929 issue has blossomed into a handsome cloth-bound quarto volume which compares favourably with the medical directory of any other country. The preparation of this Schweizerisches Medizinisches Jahrbuch, 1929, as it is now called, has been undertaken by Dr. Felix Barth, of Basle, Dr. Otto Leuch, jun., of Zürich, and Dr. Hans Trüeb, of Berne, the first two being doctors of medicine, the last-named a doctor of laws. The general scheme of the book consists of a medical guide to each of the 24 cantons in succession, in which is given the personnel of the cantonal health department and of the various sanitary commissions, a list of the hospitals and asylums with their staffs, followed by a topographical directory of the practising doctors, apothecaries, dentists, and veterinary surgeons. At the end of this section there is an alphabetical index of all federal practitioners, whether doctors, apothecaries, dentists, dental technicians, or veterinary surgeons. In the medical list a particular sign denotes those who are *not* members of the Association of Swiss Doctors, the exceptions being surprisingly few. There is also a list of 45 Swiss doctors practising outside Switzerland, scattered, it may be noted, from Japan to Mexico; their number, if it is in any way complete, bears testimony to the reluctance of the Swiss to leave for long his native hills. Five of the absentees hold chairs—at Bonn, Frankfort, Leipzig, Stuttgart, and Johns Hopkins Universities. The rest of the year book is occupied with notes on medical societies and institutions, the various medical faculties hospitals, sanatoriums and the like, followed by an admirably illustrated account of Swiss spas and health resorts. Thus far the volume is no more than an excellent directory, but the earlier 131 pages are occupied by a collection of monographs and original articles of a very high standard. Leon Asher writes on the progress of endocrinology, M. Cloëtta and H. Fischer on progress in pharmacology, C. G. Jung on problems of modern psychotherapy, W. Löffler on progress in practical therapeutics, M. Lüdin on new X ray methods of examination, to mention only a few: while a series of obituary notices (which are to be developed further in subsequent issues) includes an admirable sketch of the life of August Forel by Alex. von Muralt. The year book is published by Benno Schwabe and Co. in Basle at 11 Swiss francs.

SECOND-CLASS LIVES.

IT is a commonplace to those familiar with medical examinations for life insurance that to express an opinion on what are called first-class lives is easy enough. To assess the second-class or substandard life is a more difficult matter and yet one of the utmost importance to the various companies. Dr. Jehangir J. Cursetji, whose "Pocket Guide to Medical Life Assurance" has already been noticed in these columns,[1] has now compiled a pamphlet entitled "Substandard Lives and their Assessment in Life Assurance."[2] The author, who is the medical director of the Oriental Government Security Life Assurance Company, has a great experience of this class of life. He offers as a definition of a second-class or substandard life "one whose health and general condition are fairly good but who suffers from some disabling factor or "weak spot" in his personal or family history which exposes him to a certain amount of risk tending to shorten his probable expectation of life." With this definition as a working basis it is possible to evolve a classification of the different factors presented by substandard lives. After a chapter of introductory remarks the author considers the various systems and organs in which defects may be present. On such matters as cardiac murmurs, raised blood pressure, and rapid pulses, for example, in the section on the heart, he lays down elementary and commonsense principles based upon modern work which are essentially sound and easy of application. The difficult question of tuberculosis in the antecedents of a person presenting himself for life assurance is clearly discussed, but the author finds himself unable to recommend for adoption in India the more favourable views on the prognosis of tuberculosis gleaned from recent literature in America and in this country. On albuminuria he steers a clever middle course, taking into account all that is known about the orthostatic variety; as regards syphilis he is strongly of the opinion that even "cured" cases require careful "loading." An interesting sidelight in connexion with this disease is his observation, based upon large numbers of medical reports, that both an hereditary syphilitic taint and a personal history of syphilis are much less noticeable among Indian people than among the nations of the Western world. This excellent little book is to be incorporated in the next edition of the author's "Pocket Guide," and it will be a welcome addition, especially for the occasional examiner, to handbooks already of the first-rank.

A CASE OF ENURESIS.

To the Editor of THE LANCET.

SIR,—I am quite at sea with regard to a case I saw last week and wonder whether any fellow practitioner can help me. A professional man, 58 years of age, came to see me with a condition of occasional enuresis. The first time it happened was at 18 years of age, and since then at intervals of anything up to 12 months. There had been no "accident" for two and a half years up to last week, and he naturally thought himself safe, but now he is in despair. He is married, two healthy children, very active mentally and physically, and strong. No venereal history, one serious illness since pneumonia at 13 years of age, he smokes heavily, and is very abstemious. He has made notes and can associate it with nothing: it has happened in winter and summer, after an evening nightcap and without, on holiday, and in middle of hard work. He now wraps up scrotum and penis in two triangularly folded handkerchiefs and so saves most of the mess.

I am, Sir, yours faithfully,

June 10th, 1929. PUZZLED.

KING EDWARD'S HOSPITAL FUND FOR LONDON.

AT the annual meeting of this Fund on June 11th Sir Cooper Perry, chairman of the Radium Distribution Committee, presented a report on the allocation to various London hospitals of the radium purchased with £50,000 given for the purpose by Sir Otto Beit, F.R.S., last year. The procedure adopted was outlined in THE LANCET of March 9th (p. 511), and involves the loan of radium to approved hospitals for periods of one year. The present position is that specifications have been received for nearly the whole amount available. Specifications covering 3·405 g. have been approved, while others amounting to 0·595 g. are still under consideration. It will be some little time yet before any of the radium is actually in use at the hospitals, as the verification of the radium content of each container is a delicate and lengthy process. The detailed work in connexion with the allocation has been carried out by a subcommittee of the Distribution Committee, consisting of Dr. Eardley Holland (chairman), Sir John Rose Bradford, Sir Cooper Perry, and Mr. Leonard Cohen (hon. sec. of the Fund). Prof. Sidney Russ serves as a coöpted member. The committee's inquiries have brought home to them the great need for an increase in the supply of radium available for use in hospitals, and the advantages to be derived from the concentration of a large proportion of any additional supply in the hands of a central agency which can place it out on loan under conditions designed to secure its effective use. Loans of radium have been allocated to the following hospitals with medical schools: Charing Cross, 250 mg.; Guy's, Middlesex, and University College, 500 mg. each; St. George's, St. Mary's, and St. Thomas's, 150 mg. each. Other hospitals receiving loans are Prince of Wales's, Queen Mary's Hospital for the East End, Royal Northern, West London, Elizabeth Garrett Anderson, the Golden-square Throat, Nose and Ear Hospital, and the South London Hospital for Women, 150 mg. each; Central London Ear, Nose and Throat Hospital, Chelsea Hospital for Women, the Hospital for Women, St. Mark's Hospital for Fistula, and the Samaritan Free Hospital for Women, 100 mg. each; and the Marie Curie Hospital, 250 mg. The omission of certain important hospitals is accounted for by the fact that they were already found to have radium available or in prospect to supply the needs regarded by the committee as minimal.

THE AZUERO TREATMENT.

To the Editor of THE LANCET.

SIR,—Reports have been circulated in the lay press that the cures of paralysis of various kinds by the stimulation of certain (undescribed) zones in the nasal mucosa claimed to have been effected by Dr. Azuero, of Madrid, have been confirmed and repeated by other Spanish doctors. Since I have had numerous inquiries about this treatment I wish to say that Dr. Azuero has not made public his method, and that therefore no data exist on which his claims can be either confirmed or refuted. The public is in a state of exalted expectancy, and particularly liable to the influence of suggestion. In view of these circumstances I would suggest that no British physician should encourage any patient to seek this treatment. If, however, a patient desires to try it on his own responsibility, he should be advised to go direct to Dr. Azuero himself.

I am, Sir, yours faithfully,

A. G. GRAY.

Madrid, June 4th, 1929.

Croonian Lectures
ON
SOME CHEMICAL FACTORS IN THE CONTROL OF THE CIRCULATION.

Delivered before the Royal College of Physicians of London

BY H. H. DALE, M.D. CAMB., F.R.C.P. LOND., F.R.S.,
DIRECTOR OF THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH.

LECTURE III.*

LOCAL VASODILATOR REACTIONS.—HISTAMINE (*cont.*).—ACETYL CHOLINE.—CONCLUSION.

Histamine: Its Significance in Certain Pathological Reactions.

IT is, I think, in the field of the abnormal, pathological reactions of minute blood-vessels, and of certain tracts of involuntary muscle, that the greatest change and clarification of our conceptions is effected by the definite knowledge now available concerning the normal presence of histamine in so large a proportion of the cells of the body, and the ease with which it is liberated by injury of their protoplasm.

Anaphylactic and Allergic Reactions.

At the time when the activity of histamine was newly discovered and under investigation, the rediscovery of experimental anaphylaxis in the guinea-pig, and the dramatically fatal character of the shock in that species, had aroused fresh interest in the physiological details of the reaction, as seen, with such remarkable superficial differences, in different animal types. The knowledge was then new, that an artificial product of protein digestion, the familiar "Witte's peptone," when injected into a vein of the normal dog and of the normal guinea-pig, reproduced in each the characteristic and contrasted symptoms of the anaphylactic shock; in the dog, the tensely congested liver, hæmorrhagic intestinal mucosa, collapse of the circulation; in the guinea-pig, asphyxiating contraction of the bronchioles, usually fatal before any pronounced direct effect on the circulation had shown itself (Biedl and Kraus).[1] It was natural, then, to suppose that the anaphylactic shock was due to liberation of a protein cleavage-product in the circulation, by digestion of the reinjected antigen When the action of so simple a substance as histamine was found to produce the principal features of the shock with their characteristic contrasts in the different species, it was again natural that it should be identified with this hypothetical, circulating anaphylatoxin by certain continental writers. To me the theory, in that form, never appealed. Certain features of the anaphylactic reaction, such as the loss of the coagulability of the blood and the multiple small subserous hæmorrhages, were missing from the effects of histamine but reproduced in the action of substances like the Witte peptone. Later the investigations of a number of observers, including my own, convinced me of the correctness of the view which attributed the symptoms of the anaphylactic reaction, not to the formation of a poison in the blood, but to the reaction between the antigen and a precipitating antibody located in the cell protoplasm (Dale).[2] This theory of cellular sensitisation still seems to me to fit the known facts of anaphylaxis, in its original sense of an acquired specific sensitiveness to a soluble antigen. On the other hand, it was clear that the location of the reaction in the cells did not exclude the formation of a poison by protein cleavage; this might take place in the cells, and might there, indeed, be more rapid and severe in its effects than if it occurred in the blood. Abel and Kubota[3] definitely suggested the intracellular formation of histamine, by protein digestion, as the cause of the anaphylactic symptoms, and as accounting for their similarity to those produced by histamine directly injected.

It seemed to me that such suggestions went beyond the known facts. There was, and there is still, no convincing evidence, either of an immediate protein digestion resulting from the union of antigen and antibody, or of the liberation of histamine itself in the enzymatic cleavage of proteins. I suggested, indeed, on the facts then available, that the puzzling resemblance between histamine effects and the symptoms seen in the anaphylactic reaction might as logically find its explanation in the reverse direction; the effects of histamine itself might conceivably be due to its producing such changes in the state of dispersion of the protoplasmic colloids, as could be assumed to take place in the intracellular union of antigen and antibody.

Our present knowledge seems to me to have rendered all such speculations superfluous and obsolete. Lewis, finding that a local anaphylactic reaction in the human skin presented the familiar "triple response" of the blood-vessels to a local injury, concluded that the union of antigen and antibody in the sensitised cells acted, like any other injurious stimulus, by releasing the preformed H-substance. Such a conception appears to me to fit all the known facts, and to make clear the meaning of many which were difficult to interpret on any other theory. It was difficult, on our earlier conceptions, to explain why, in each species, only those cells should apparently become sensitive to the foreign antigen, and react to its reinjection, which had normally a special sensitiveness to histamine. There is now no necessity for assuming such preferential sensitisation of the cells which participate in the overt reaction. Cells of other types may be assumed to contain the specific antibody, and, as the result of its union in their protoplasm with the foreign antigen, to liberate preformed histamine; but only those cells which, in each species, are sensitive to histamine will exhibit the physiological reaction to it. The effect thus produced, and constituting in each species the central symptoms which determine the general aspect of the anaphylactic shock, could arise in one of two ways. The histamine might be liberated from, or in the immediate neighbourhood of, the reacting cells; on the other hand, anaphylactic injury of the cells of some large organ, such as the liver, might liberate histamine into the general circulation in such quantity as to produce its effects in the body generally, and thereby to cause a histamine-response in cells which are not themselves sensitised to the antigen, but are reactive to histamine. These alternative processes can actually be traced as the central features in the shock, as seen in the guinea-pig, in the one case, and the dog in the other. In the guinea-pig, in which death is produced by contraction of the plain muscle of the bronchioles, isolated samples of plain muscle give a direct response to application of the antigen in high dilutions; the histamine, we must suppose, is liberated from, or in the immediate neighbourhood of, the reacting cells. Isolated plain muscle from the anaphylactic dog, on the other hand, gives no significant response to the antigen, and the blood-vessels in the perfused limb of such a dog are but weakly affected if the antigen is added to the perfusing fluid. Yet when the antigen is injected into the circulation of the whole anaphylactic dog there is a general vascular and plain-muscle reaction, strikingly similar to that produced by histamine. As Manwaring[5] first showed, and others have abundantly confirmed, the sensitisation of the dog to the antigen is almost limited to the cells of the liver. If this organ is completely excluded from the circulation, injection of the antigen into the blood stream has little or no effect, though histamine, under such conditions, produces its usual general effects on small blood-vessels and plain muscle. If the blood leaving the liver of an anaphylactic dog is perfused through other organs of a second, normal dog, production of the anaphylactic shock in the first dog causes the vessels and plain muscle of the second to show responses such as they give to histamine. In the dog, therefore, the specific anaphylactic sensitisation by antibody chiefly affects the liver cells; when these are injured, by the immune reaction occurring in their protoplasm, histamine which we know them to contain, is released in such quantities as to produce its effects not only on the liver-vessels but on the histamine-sensitive cells of the body at large.

---

* Lectures I. and II. appeared in THE LANCET of June 8th and 15th respectively.

That these two types of reaction do occur in the guinea-pig and dog can hardly be doubted; but such actions of histamine, in the immediate neighbourhood of its release or distributed by the circulation, do not complete the picture of the anaphylactic reaction in either species. As I have already mentioned, the anaphylactic shock involves effects of a more injurious and lasting nature than any which direct injection of histamine can produce. A loss of the coagulability of the blood is a feature of the anaphylactic reaction in all species, but not of the reaction to histamine. It is an effect following acute injury of the liver cells by many poisons. The dog's liver, in the anaphylactic shock, becomes enormously distended with blood and lymph, the reaction being much more severe and persistent than that produced by the direct effect of histamine on the vessels of this organ. The injury, in other words, is a far more severe and disorganising one than would be necessary to produce a physiological release of histamine, and the loss of the coagulability of the blood would alone suffice to show that other constituents of the liver cells are in fact liberated. It is unlikely that the histamine, which the liver must pour into the general circulation under such conditions, will be free; it is more likely to be involved in colloidal complexes with the other cell constituents. Some of Manwaring's more recent experiments[6] suggest that such complexes involve the antigen, so that they are prevented, by some other kind of antibody, from producing the histamine action on other tissues of a dog which has been immunised to it; but the meaning of these observations is not yet perfectly clear.

The fact that in the guinea-pig, especially when death from the shock is delayed, the blood also shows a loss of clotting power, which histamine does not produce, may be taken as evidence that the liver is also involved in the injurious cellular reaction in this species. The occurrence of capillary hæmorrhages in the shock, which histamine again does not produce, may be taken to indicate that the vascular endothelium is itself sensitised to the antigen, and directly injured by the immunity reaction, in addition to being affected by release of histamine from other cells in its neighbourhood.

We may picture the anaphylactic shock, therefore, as the result of cellular injury, due to the intracellular reaction of the antigen with an aggregating antibody. Whether this is general, or localised in a particular organ, histamine will be released, and its effects will be prominent in the resulting reaction, imposing a general resemblance to the syndrome produced by histamine itself, on the symptoms seen in each species. The cell injury, however, is not limited to the degree required to produce a release of histamine, and involves other and more direct results. Such a conception is in accordance with all the facts as yet available, and it has the advantage of rendering intelligible, not only the striking resemblance between symptoms of the anaphylactic reaction and those produced by injecting histamine, but also the various and equally significant points of difference between the two syndromes.

Along precisely similiar lines we can explain the effects of the various "allergens" or "haptenes" on the subject of a natural or acquired idiosyncrasy. Whatever view be taken as to the similarities or differences between such conditions and artificial anaphylaxis, all certainly involve a condition of the cells such that a normally harmless substance is specifically injurious to them; in all cases the reaction to such specific injury involves symptoms like those produced by histamine, and for the reason that in all cases histamine is released by the injury.

Anaphylactoid Phenomena.

There is a large group of pathological reactions, some produced by natural infections and others by artificial injection of various substances into the blood stream in which groups of symptoms occur, more or less closely resembling those seen in the anaphylactic or allergic reactions. A large literature has grown up around the significance attributed to these resemblances. Intravenous injection into the guinea-pig of various chemically inert colloids and suspensions, with or without preliminary incubation with serum, produces symptoms showing a general similarity to those of the anaphylactic shock in that species. These facts have been used as the basis of more than one theory as to the cause of the symptoms of the anaphylactic reaction. When the symptom-complex is regarded as specific to anaphylaxis, the results of injecting some of these artificial mixtures are, indeed, so similar that the resemblance appears highly significant. When once it is realised, however, that any kind of general cell injury which leads to the release of intracellular histamine must be followed by symptoms of this type, this significance largely disappears. Hanzlik and Karsner[7] have surveyed the actions of a wide variety of agents, including organic colloids such as agar-agar at one end of the scale and ions of heavy metals at the other, the injection of which into the blood of the guinea-pig produces the "anaphylactoid" syndrome. It is perhaps significant that they find, as a common feature of the action of many of these, capillary embolism and thrombosis in the lungs. With the knowledge that lung tissue is peculiarly rich in histamine, and that the most prominent feature in the overt reaction of the guinea-pig to these varied substances is the closure of the bronchioles and consequent asphyxia, which histamine itself also produces in minute doses, it seems reasonable to look to the liberation of this substance from injured cells, of the lungs in particular, for that "common basis for the truly anaphylactic and the anaphylactoid reactions" in the guinea-pig, which Hanzlik and Karsner indicate as an aim of further investigation.

The matter, however, is not quite so simple as that. A number of chemically inert substances, when mixed and incubated with blood serum outside the body, impart to the latter the power of eliciting the anaphylactoid symptom-complex when injected intravenously. Such toxic serum does not itself contain histamine; it does not directly stimulate isolated plain muscle as histamine does; but from its effects when injected we obtain evidence of its directly injurious action on the blood cells and on the vascular endothelium (see Dale and Kellaway).[8] The effects, therefore, of injecting some of these foreign substances into the blood may be due to their direct mechanical injury of cells with which they come into contact, liberating histamine at various points by a process analogous to that causing Lewis's triple response of the skin vessels. Others, apparently by adsorbent action on the protein-lipoid complexes of the blood plasma, may cause these in turn to act as an injurious foreign substance, and may thus, at second remove, produce the histamine-liberating cellular injury. In the case of some substances, again, such as the artificial peptones, it may be difficult to decide to what extent they are acting directly, to what extent indirectly through cell injury. Witte's peptone, for example, has direct effects on plain muscle which suggest that it may contain histamine. The project of demonstrating the presence of that base in small proportions in such a complex mixture of peptides, by its actual isolation in a state of chemical purity, would, according to our experience with other materials, not be a very hopeful one. Short of this, Abel and his co-workers have put forward chemical evidence to justify the presumption of its presence. There are features of the action of such a peptone, however, which make it clear that this is not wholly due to histamine already present in it, but at least in part to an injurious action on the liver cells, like that seen in the anaphylactic shock, with ensuing indirect effects on other organs, and possibly also with some direct injury of endothelial cells outside the liver.

When once it is realised that symptoms having much in common can be produced, either by injecting histamine itself directly, or by injecting injurious substances which will cause its release in the body, you will appreciate the difficulty of disentangling the different parts of the total effect, in the case of a preparation which may contain both histamine and such other substances. It must be borne in mind, also, that general endothelial injury by itself, apart from the effects of histamine incidentally released, would directly produce a circulatory collapse having at least points of similarity with that produced by a toxic dose of histamine; so that again, in the case of some substances such as poisonous metallic ions, injected intravenously, it may be very difficult to decide what part of the total effect should be attributed to direct, irreversible destruction of the tone of the minute vessels, and what part to the secondary pharmacodynamic action of histamine released by the general cell injury.

These various considerations appear to me only to reinforce the suggestion that the syndrome of the anaphylactic shock has no special relation to that condition, and that the appearance of that syndrome, or of any of its constituent symptoms, as the result of any other kind of artificial intervention or natural, pathological process, does not warrant the presumption of a causal relationship or common basis, except in so far as general or local cellular injury is present in each case. A group of symptoms common to all these reactions is that which histamine will produce; and the release of this substance, from cells injured by a multiplicity of agents, would satisfactorily account for this common element in their effects.

Limitations of the Significance of Histamine.

If you have so far followed my argument, you will not suspect me, however, of suggesting that the liberation of histamine will by itself account for *all* the symptoms included in the group of phenomena which we have been considering. The point is of such importance that, at the risk of repetition, I must make it with more directness and emphasis. We have no justification for assuming that histamine is the only cell constituent which injury liberates. It is possible to imagine an injury so mild in degree, and so restricted to cells not concerned in the ensuing reaction, that only histamine might be liberated, or only its effects be visible. More severe injury, however, whether physical or chemical, local or general, might be expected to introduce other elements into the reaction; we have seen that it does so in the anaphylactic and anaphylactoid reactions; and it may do this, either by causing liberation of other and unknown cell constituents, or by directly affecting the physiological integrity of the endothelium of the reacting vessels. We may not know, in any particular case, which of these possibilities is the more important; but we do know that a fully developed, local inflammatory reaction involves much that histamine cannot reproduce, in the wandering of white and the leakage of red cells into the injured tissue, the thrombosis, and the resulting arrest of the circulation. Histamine can satisfactorily account for the evanescent response to mild injury, and for the initial physiological phase of the response to injury more severe in degree. As the reaction becomes frankly pathological, the effects of histamine fail more and more to fill the picture.

I can imagine that in some minds, and particularly in those accustomed to the detailed study of pathological blood-vascular reactions, this failure of the effects of histamine to cover the whole field may raise doubts of its real significance. On my own mind, which views the phenomena instinctively from the angle of physiology and pharmacology, the effect of this limitation is in the opposite direction. If histamine reproduced all the reactions to any kind or degree of cell injury it might merely be one of innumerable cell poisons producing a common set of vascular reactions, by liberation of an H-substance having no chemical relationship to any of them. That the action of histamine is not thus directly injurious, but a specific, reversible pharmacodynamic action on certain contractile cells, on which it acts in extreme dilutions, is to me a strong argument for its true, physiological significance, and for its identification with Lewis's H-substance. Its normal occurrence in living cells has now been chemically demonstrated in a wide range of tissues, and can be legitimately inferred from physiological tests in many others. I think that we have sufficient evidence for regarding it as the physiological agent of the relaxation of the tone of the small blood-vessels in response to irritation or injury of the tissues, whether local or general. Whether it is also concerned in the more strictly physiological relaxation of the minute vessels, in response to metabolic activity, the future may show; as yet we have no evidence of such a function.

ACETYL-CHOLINE.

I ask your attention now to the action of an entirely different type of vasodilator substance, which resembles histamine in certain features of its scientific history. The simple quaternary ammonium-base, choline, has long been known as a constituent of the tissues, where it enters into the constitution of the group of phosphatide lipins known as lecithins. Possessing an alcoholic hydroxyl, it can be esterified, and its acetic ester, acetyl-choline, was prepared by Nothnagel in 1894.[9] Like histamine, therefore, it was made in the chemical laboratory long before it acquired a physiological interest. Choline was already known to produce a depressor effect on injection into the mammalian circulation, when Reid Hunt and Taveau,[10] in 1906, observed that acetyl-choline produced the same kind of effect in about one-thousandth part of the dose. It had a choline-like action, but was a thousand times, or more, as active. Hunt and Taveau speculated on the possibility that such a substance might occur in the body, but found no evidence of it. At this stage they regarded its action as due to weakening of the heart-beat. My own interest in it[11] was first aroused, again as in the case of histamine, by the discovery of its presence in certain extracts of ergot, from which my colleague Dr. Ewins succeeded in isolating it.[12] On making a more systematic investigation of its actions on various organs, I was struck by the remarkable parallelism between its effects and those produced by stimulation of parasympathetic nerves. It showed an extraordinary instability when injected into the blood stream, presumably being hydrolysed with the liberation of the relatively inactive choline. Accordingly its parasympathetic effects were even more rapidly evanescent, as well as more powerful, than the sympathetic effects of adrenaline produced under like conditions. A striking feature of its action, and one in which the correspondence with parasympathetic effects appeared to fail, was the general dilatation of small arteries, produced by almost incredibly minute doses of this substance, not only in the areas receiving vasodilator fibres from parasympathetic nerves, but in organs such as the limbs, where the only known vasodilator nerve-supply to the arterioles was, and still is, that of the antidromic, axon-reflex mechanism of the sensory nerves. When Reid Hunt,[13] a few years later, confirmed this observation, of the predominantly vasodilator nature of the depressor effect of acetyl-choline in minute doses, he was struck with the resemblance, in character and distribution, between its effects on limb vessels and those produced by peripheral stimulation of the appropriate sensory nerve-roots. He was inhibited, however, from attributing any significance to the resemblance, by the observation that the effects of acetyl-choline were completely abolished by doses of atropine which left the antidromic effects unimpaired.

During more recent years the activity of acetyl-choline has gained interest in several directions. I had observed that, apart from its parasympathetic and vasodilator effects in minute doses, readily annulled by atropine, acetyl-choline, injected in larger doses after atropine, exhibited, like many other quaternary ammonium bases, a powerful nicotine-like action on ganglion-cells. This second aspect of the action of acetyl-choline has been found to extend to the production also of certain peculiar motor effects on voluntary muscle, which nicotine was already known to produce. Langley[14] had studied the slowly developed tonic contractions of frog's muscle, produced by applying nicotine, and Riesser[15] found that immersion of the muscle in dilute solutions of acetyl-choline produced similar effects. Heidenhain[16] had observed that the voluntary muscle of the dog's tongue, when deprived by degeneration of its motor fibres from the hypoglossal nerve, responded by a slow wave of contraction—he called it a "pseudomotor reaction"—to injection of nicotine into the circulation. Frank, Nothmann and Hirsch-Kauffmann[17] found that acetyl-choline, in relatively small doses, produced this contraction of the denervated tongue in a very striking form, and that other voluntary muscles, such as those of the limbs, became similarly responsive to acetyl-choline when deprived of their motor nerves. There was a tendency to speculate on these actions of acetyl-choline on voluntary muscle as implying a parasympathetic motor innervation, connected with tonus, in addition to the ordinary motor nerve-supply. Gasser and I,[18] however, were able to show, I think convincingly, that these effects of acetyl-choline on voluntary muscle were not directly related to its parasympathetic action, but were entirely concerned with that other aspect of its activity, which it shares with substances like nicotine.

Chemical Transmission of Parasympathetic Effects.

Two other lines of evidence which have lent new interest to the action of acetyl-choline concern its parasympathetic effects. Weiland,[19] working in the laboratory of the late Prof. Magnus in Utrecht, found that an isolated, sealed loop of rabbit's intestine, suspended in Ringer's solution, gave up to the latter a substance which stimulated rhythmic activity, when added to the solution in which another loop was suspended. Le Heux,[20] in the same laboratory, investigated the chemical nature of this substance, and succeeded in isolating choline. Testing the stimulating effects of pure choline on such isolated pieces of intestine, he found that it was greatly intensified if the warm saline solution, in which the tissue was suspended, contained acetates. He was led to suggest the formation of acetyl-choline in the tissue as a preliminary to the action of choline. In the same connexion we may note an observation made by Hoet[21] on the activity of such isolated loops of intestine. Magnus had found that part of the automatic rhythm of such a preparation was stopped by atropine, and had attributed it to choline. Hoet found that if, after the animal had been killed, but before the loop was detached from its natural connexions, the vagus nerve was strongly stimulated, this atropine-sensitive element in the rhythm of the subsequently isolated loop was much increased.

The clearest evidence, however, of the peripheral release, during stimulation of the vagus, of a chemical substance transmitting the characteristic effects of vagus impulses, has been provided by the work of Otto Loewi[22] and his co-workers on the frog's heart, and of others who have repeated and confirmed their results. In a series of publications from 1921 onwards they have built up an imposing structure of evidence, for the details of which the original papers must be consulted. Here I can only give the story in outline. Briefly, it has been shown that when an isolated frog's heart, containing a small volume of Ringer's solution, is subjected to inhibition by stimulation of the vagus nerves, a substance passes into the Ringer's solution which, on transference to another isolated heart, reproduces there the effects of vagus inhibition. In passing it may be noted that Loewi found, and others have confirmed the finding, that when the action of the sympathetic accelerator fibres in the vagus prevails, so that a stimulation of the rhythm replaces inhibition, an accelerator substance passes into the Ringer's solution. For the present, however, our concern is with the inhibitory vagus-substance and its properties. The quantities are minute, but the behaviour has been examined with great ingenuity. The substance is not free choline, though choline is present; for acetylation increases the activity, but not in nearly so high a proportion as it does that of pure choline. The activity of the "vagus-substance" can be annulled by treatment with a tissue esterase, and then not merely restored by acetylation, but increased beyond the original level.

Looking at the whole of the evidence, one fails to find any point of it which is incompatible with the supposition that the vagus substance is, indeed, a highly unstable and intensely active choline ester closely resembling acetyl-choline in its properties. The instability of such a substance would lead to the liberation of some free choline; so that, even if the substance were acetyl-choline itself, complete acetylation of the mixed residue would lead to the increase of activity in varying proportion, which is actually observed. The muscle of the frog's heart yields a similar substance to artificial extraction, even without vagus inhibition; but vagus inhibition, as a preliminary to extraction, increases the yield.

It should be noted that somewhat similar observations were made, many years before this recent series, on the mammalian heart. Dixon [23] observed in 1906 that the mammalian heart yielded to extraction a substance soluble in alcohol, and producing a muscarine-like inhibition when applied to the heart of a frog, and that the yield was greatly increased by stimulating the vagus up to the moment of extraction. The action of acetyl-choline was not then known, and Dixon's observation was not chemically developed. Later, with Hamill,[24] he gave a wider application to the conception, but no further evidence directly concerned with vagus action. A few years ago Plattner [25] made experiments of a similar kind, and, with the knowledge before him of the behaviour of Loewi's substance from the frog's heart, was able to obtain evidence of the presence of a similar substance in the mammalian heart, behaving like a choline ester, and increased during vagal inhibition.

Acetyl-Choline a Normal Constituent of the Body.

Altogether, then, there appeared to be a good body of evidence in favour of the view that the vagus produces its effects, not by direct passage of its impulses to the effector cells, but by liberation in relation to them of a substance having the effects associated with stimulation of the vagus, and in other respects having the properties of an unstable choline ester. Of the extensive series of choline esters which have hitherto been examined acetyl-choline stood out as unique in the possession of properties which would fit it for the rôle of the vagus substance. The temptation to assume the identification must have been experienced by many interested in this field of work. The chemical isolation and identification of the actual vagus substance, from minimal traces of material, was clearly not to be expected. To me it seemed that the one piece of evidence needed to justify such an assumption, and yet not wholly beyond credible attainment, was the discovery, in some organ of the normal animal body, of a substance having these physiological properties, its isolation and chemical identification. Less than a year ago the opportunity was presented to my colleagues and myself by a chance observation. In completion of our series of investigations on the distribution of histamine we were working on spleen extracts, using the spleens from freshly killed oxen and horses. Histamine was in due course isolated, in quantity sufficient to account for the type of activity which it represents. In addition to this, however, we found a surprisingly powerful action of the choline type. When we extracted the fresh organ with precautions learned by experience, this activity was sometimes of such intensity that, if due to choline itself, it would have meant the presence in the extract of some 20 to 30 g. of that base per kilogramme of spleen substance. Such a proportion was incredible, and a clue to the meaning of this activity was soon given, by the fact that it disappeared if the original extract, or its partially purified constituents, were exposed to an alkaline reaction. Chance had apparently presented us with an intensely active and unstable choline ester, naturally present in an animal organ, and in such proportion that the attempt to isolate it was a reasonable enterprise. The evidence, afforded by this instability to alkali, was reinforced and given very significant direction by the discovery that the extract lowered the arterial pressure, stimulated isolated intestinal muscle, and produced the abnormal, slow contraction of denervated voluntary muscle; and, further, that in each of these different actions it could be accurately matched against the same proportionate dose of acetyl-choline. The isolation and the chemical and physiological identification were completed by my colleague Dr. Dudley and myself only a few days ago, and we are able now for the first time to state that the substance is, indeed, acetyl-choline. The details of the evidence will be published shortly.

SOME PHYSIOLOGICAL IMPLICATIONS.

We do not suppose that the finding of acetyl-choline in the spleens of certain animals has necessarily any significance as regards that organ itself, or that its presence suggests its action as a true hormone. The extraordinary instability of acetyl-choline in the blood makes such a function highly improbable. We regard the identification as important, chiefly for the reason that acetyl-choline, which first came to notice as an artificial substance, and has hitherto been known only as such, or as a product of plant metabolism, and as having a remarkable action on certain animal functions when artificially applied, is now known to be a natural constituent of the animal body. Where we have evidence, then, in the animal body of a substance resembling acetyl-choline in all its detectable characteristics, but in quantities or under conditions which give slender hope of its chemical isolation, this new knowledge seems to me to create a strong probability that we are dealing with acetyl-choline itself, and not with some unknown substance having similar properties. It seems to me, further, that we obtain a powerful reinforcement of this probability, if we consider its bearing on the relation to one another of a number of hitherto disconnected physiological phenomena. I will endeavour to arrange them in a logical sequence.

In the case of the inhibition of the heart by the vagus the liberation of acetyl-choline in relation to the heart muscle seems to fit the known facts, including the annulment of both vagus and acetyl-choline actions by atropine. It would seem difficult, then, to suppose that the vagus produces its stimulation of intestinal movements by an entirely different process; but here we meet the first discrepancy, in the fact that atropine very readily annuls the effect on intestinal movements of acetyl-choline applied through the surrounding medium, but not the otherwise similar effect of vagus stimulation. This is a type of discrepancy which we shall meet several times. It must be frankly recognised, but I doubt whether it should be accorded the decisive significance, which some have been disposed to attribute to it. We do not know how atropine prevents the action of acetyl-choline applied to the cells from the surrounding fluid; and it may be that, in some cases, it is peripherally liberated by nerve-impulses in such an intimate relation to the reactive structures that atropine is relatively ineffective in hindering its action.

Proceeding a step further, if we accept the mediating action of acetyl-choline in vagus effects, it is difficult to imagine that other parasympathetic actions, such as the vaso-dilator effects of the *chorda tympani*, are produced by a different mechanism. We have here again the same discrepancy with regard to the action of atropine; but, on the other hand, the supposition that this vaso-dilator action is due to peripheral liberation of acetyl-choline brings an entirely different, and otherwise unrelated, set of phenomena into the picture. As long ago as 1863 Vulpian and Philippeaux[26] described a curious behaviour of the tongue muscle, when deprived, by section and degeneration of the hypoglossal nerve, of its normal motor nerve-supply. Peripheral stimulation of the chorda-lingual nerve, or of the *chorda tympani* alone, now caused a curious slow contraction of the voluntary muscle, lifting and rolling the tongue; whereas in the normal tongue such stimulation causes nothing but vaso-dilatation. Now we have already noted that, under the same conditions, the tongue muscle shows a new, abnormal sensitiveness to a group of substances having a "nicotine" action, among which acetyl-choline is conspicuous. On injection of acetyl-choline into the circulation the denervated tongue muscle responds with the same kind of long, slow contraction as it exhibits when the chorda-lingual nerve is stimulated. In the normal tongue, therefore, chorda-lingual stimulation and acetyl-choline injection produce only vaso-dilatation; in the denervated tongue both produce an abnormal tonic contraction of the voluntary muscle. The suggestion is inevitable, that, when the *chorda tympani* is stimulated, a substance is released at the periphery, normally concerned in the tongue only with parasympathetic vaso-dilatation, but capable of exciting the abnormal, slow contraction in muscle-fibres deprived of their motor nerve-supply. We now know one substance in the body, and only one, which could produce both these effects, and it is acetyl-choline.

One further step brings me to the point of most importance for the general subject of these lectures. In 1894 Sherrington observed that degeneration of the motor nerve-fibres to the muscles of the leg caused a new type of reaction. These muscles now responded by a slow, weak tonus-wave to stimulation of the sensory fibres left in the sciatic nerve. Here, again, we have seen that a new and abnormal sensitiveness of the muscle-fibres to acetyl-choline appears, at the same time as this abnormal reaction to peripheral stimulation of the sensory nerve-fibres. And again, in the sensory fibres, we are dealing with nerve-fibres the peripheral stimulation of which normally causes no discoverable effect but vasodilatation, closely similar in its character and distribution to that produced by acetyl-choline, and differing only in that, like that caused by the *chorda tympani*, it is insensitive to the paralysing effect of atropine. Again the suggestion is inevitable, that the vasodilatation produced by antidromic stimulation of sensory fibres, or by the axon-reflex through their terminal branchings, involves the liberation, in relation to the affected arterioles, of a substance causing normal arterioles to dilate, and exciting voluntary muscle, deprived of its motor nerve-fibres, to an abnormal, slow form of contraction. The only substance known to occur in the body, and producing both these effects, is acetyl-choline; and it is unique among all known substances, from any source, in its power of producing both.

There is yet another point of correspondence which is worthy of notice. Frank, Nothmann and Hirsch-Kauffmann,[17] who first described the action of acetyl-choline on the denervated dog's tongue, showed that its effect, and the similar effect of stimulating the chorda-lingual nerve, were both suppressed during the circulation of a moderate dose of adrenaline in the blood. This parallel annulment, of acetyl-choline effects on denervated muscle and those of vasodilator nerve stimulation, appears not to hold good for the cat's tongue; but according to Hinsey and Gasser[27] it does so for the "Sherrington phenomenon" in the cat's hind limb. This action of adrenaline is incompletely understood; Gasser and I concluded that in some way it prevented the access of acetyl-choline to the reactive structures in the denervated muscle. If this is a true conception, the similar interference of adrentaline with the effects of stimulating the nerves acquires a very direct significance.

The probability, created by these items of evidence, of the intervention in arterio-dilator effects of a peripherally liberated substance, which also stimulates denervated voluntary muscle, has not escaped previous recognition. Bremer and Rylant[28] hint at it, Hinsey and Gasser[27] suggest it as a definite possibility. With the knowledge now available, I am emboldened to give it precision, and to indicate acetyl-choline as the agent concerned. If this view is adopted, the local vascular reaction to stimulus or injury of the tissue, Lewis's "triple response," becomes, indeed, an interesting complex of pharmacodynamic effects. We have first the liberation of histamine from the immediately affected cells, directly causing vasodilatation of the minute vessels with which it comes into contact, and acting as a persistent stimulus to the sensory endings of the terminal axon-branching. So far we follow Lewis and the "H-substance." We must then further imagine that the nerve-impulses thus engendered, passing through the bifurcation to the ending of the collateral on the arteriole, there liberate, as the effective dilator, acetyl-choline. Such a conception may seem complicated; but in reality it makes for simplicity, in that it brings into coherent relationship a number of otherwise disconnected facts. The conception is, further, in harmony with the general tendency of neurological speculation to picture the intervention of a chemical agent, wherever an impulse conducted along a nerve-fibre becomes translated into excitation or inhibition of a cell, even at the synapses in the central nervous grey matter (cf. Sherrington[29]).

Other Possible Cases of Chemical Transmission.

For the autonomic system in general, this idea, that the arrival of nerve impulses at the peripheral endings may act on the effector cells indirectly, through liberation of a chemical agent, is not of recent origin. As long ago as 1904[30] Elliott suggested that the true sympathetic nerves might so act, by the liberation of adrenaline at their synaptic unions with plain muscle and gland cells. Such a conception is now supported, not only by analogy with parasympathetic effects, but by the direct observation, made by Loewi (loc. cit.) and confirmed by others, that the sympathetic, accelerator effect on the isolated frog's heart involves the liberation of an accelerator substance. We have no evidence, however, as to the chemical nature of this agent; and, likely as it may seem on general grounds, I think it would be rash to assume as yet, from the action alone, that adrenaline is the substance in question. The case made for acetyl-choline, as the transmitter of parasympathetic and sensory collateral vasodilator effects, is based partly on the chemical behaviour of the vagus substance, partly on the reproduction by the nerves of another aspect of its action, seen only on abnormal tissues, and quite unconnected with parasympathetic effects. There is no other such side to the action of adrenaline; and it remains a possibility that sympathetic nerves liberate peripherally another sympathomimetic agent, adrenaline being a special substance with properties fitting it peculiarly for the distribution of this type of action through the circulation. That other sympathomimetic substances may occur in the tissues is suggested by the effects of certain extracts recently described by Collip; but we have yet no knowledge of the chemical nature of the substance or substances concerned, nor any ground for connecting their existence with any known bodily function. Whatever be the nature of this suggested chemical intervener between sympathetic impulses and effector cells, it can serve only as the transmitter of centrally originated impulses. We have no evidence of any mechanism for the localised, peripheral release of adrenaline or of any substance acting like it; nor do we know of any normally functional peripheral-reflex mechanism concerned with sympathetic axons, or with nerves releasing any sympathomimetic agent. Broadly the contrast, indicated in an earlier lecture, appears to hold good; vasomotor effects, whether produced by nervous impulses or by hormones, are centrally originated and widely distributed, and are concerned with the upholding and mass-variation of vascular tone; vasodilator effects are largely, though not entirely, local reactions, chemically originated, and concerned with the finer adjustment of blood-supply to local requirements.

SOME GENERAL CONSIDERATIONS.

I have endeavoured in these lectures to put before you the evidence concerning the part played in the control of the circulation by four chemical agents in particular. I have restricted my attention to these, not only because I have, in different degrees, been personally concerned in the investigation of each, but because they seem to me to be the only ones of which our knowledge is yet sufficiently definite to warrant even provisional conclusions with regard to their normal functional significance. A large amount of evidence exists on the effects of extracts from various organs of the body, artificially injected, or applied to isolated preparations of cardiac or involuntary muscle. A great many of these data can, as yet, be regarded only as observations put on record for future interpretation. To take only one example, there is a large amount of evidence, among the prominent contributors to which Demoor[31] in Belgium and Haberlandt[32] in Germany may be mentioned, on the effect of extracts from the right auricle, or from the sino-auricular junction, on isolated heart muscle. The suggestion has been made that some of the stimulating or restorative effects of such extracts on the rhythm of this muscle may be due to the presence of histamine; it has also been denied. It appears to me that we have not yet sufficient evidence as to the chemical nature of the substances concerned, as to their normal liberation, or as to the manner in which their effects could be produced under natural conditions, to justify the assumption that such an extract contains a "heart hormone" or an "automatin." We really need a system of criteria or postulates, comparable to Koch's celebrated postulates dealing with the ætiological significance of a micro-organism—conditions which must be fulfilled before physiological significance is attributed to the effects produced by artificial application of an artificial organ, extract. There can be no hope, however, that any such criteria as could at present be suggested would be more generally applicable, or less liable to exception, than Koch's postulates have proved to be in their own sphere of application.

THE MECHANISM OF FILARIAL PERIODICITY.

BY CLAYTON LANE, M.D. LOND.,
LIEUT.-COLONEL, I.M.S. (RETD.).

THE difficult problem of filarial periodicity has puzzled and fascinated many since Sir Patrick Manson discovered its existence 50 years ago in *Filaria bancrofti*. Any attempted explanation must not merely account for the fact that the embryos of some filariæ are present in the cutaneous blood at all hours, of others by day only, and of yet others by night only, but must explain the established observation that the microfilariæ of *F. bancrofti* are in some parts of the world almost completely absent from skin blood by day, but in others can be found there throughout the 24 hours. A reasonable explanation of the periodicity, or of the lack of it, in *F. bancrofti* is obviously the key to the whole matter, and to the consideration of that anomaly this note is essentially directed; unless otherwise stated it is to this species that reference is made.

Periodicity in *F. bancrofti* is evidently produced in one of two ways. Either there exists in the circulation a fixed or almost fixed filarial population which shelters in some internal part of the body during the day and reaches the cutaneous capillaries at night only, or parturition is so timed that microfilariæ enter the blood stream at night only. The latter alternative implies: first, simultaneous cyclical parturition, using the term with the same loose regard to exactness as occurs in the reference to simultaneous cyclical sporulation in the tertian or quartan malaria parasites; and, secondly, daily death of the cyclical brood. The former conclusion was that reached by Manson, and it has held the day almost completely ever since. It seems well to reconsider it now in the light of the further knowledge which has been added to the subject particularly by the four expeditions sent out by the London School of Tropical Medicine which Manson founded, and by Prof. F. Fülleborn[1] whose recent survey of filariasis constitutes so remarkable an aid to all who would study this infection that without it the writing of this note might well have continued to be indefinitely postponed.

If microfilariæ merely retire to deeper parts during the day, what are those parts? Manson's[2] answer lay in their distribution in the organs after death in a classical case which during life had exhibited a very exact nocturnal periodicity, as proved by numerous examinations made during the previous nine months. During this period microfilariæ had been shown to disappear from the cutaneous circulation about 8 A.M. The man killed himself with prussic acid about 8.30 one morning in 1897. From the subsequent findings Manson concluded that "Filaria nocturna during its temporary absence from the circulation is present in the larger blood-vessels, particularly the arteries . . . but that the majority are lodged in the blood-vessels of the lungs." Now true filarial periodicity is marked by a swarm of embryos in the skin blood at night with their complete or almost complete disappearance from it by day; the difference is usually striking. If these microfilariæ shelter predominantly in the lungs by day, post-mortem examination should find them there in swarms when death occurs by day and in negligible quantities when it occurs at night. The difference should be a striking one if such examination can, as has been held, form a basis for conclusions. There is, at least, one such comparison reported. In British Guiana, where *F. bancrofti* shows nocturnal periodicity, Anderson[3] examined two cases who died of the acute septicæmia locally known as abdominal filariasis, one having died by day and one by night. Taking into consideration counts of microfilariæ found in those organs only which were examined in both cases, the percentage of the total which was found in the lungs was 23 for the day-time death and 10 for the night-time one. This difference in no way represents the loss of microfilariæ from the skin which occurs by day; it does not support a pulmonary habitat; and, quite reasonably, might be considered as fortuitous. Regarding the suggestion that microfilariæ retire by day to the large vessels, it is essential to remember that these creatures have no means of fixation. That they should be able to maintain their situation in the aorta or carotid artery seems as impossible as that a man should keep his position swimming against the current half way down the Niagara Falls. Moreover, Fülleborn has recovered enormous numbers of microfilariæ in the heart's blood after death, when puncture during life had recovered no more there than were present at the same time in skin blood. The post-mortem finding in Manson's case is not then evidence of microfilarial habitat during life, so far as the arteries are concerned.

Fixation in the Capillaries.

Fixation in the capillaries presents no such physical impossibility, and it has been held that during the period in which they are absent from the skin, microfilariæ retain their position in deep capillaries such as those of the lungs, either actively or passively. A retention, passive so far as the embryos are concerned, implies that during the period of their disappearance from skin blood the lung capillaries contract and retain the microfilariæ within them. But this means that such contraction maintains itself only at night when there is infection with *F. loa* in Africa, must be absent day and night when there is infection with *F. perstans* in Africa or with *F. bancrofti* in Fiji, and must be present only by day when there is infection with *F. bancrofti* in India or British Guiana. The corresponding constrictor effect of mixed infections on these vessels is too harassing to think out. Accordingly Fülleborn holds that *Mf. bancrofti*, in countries where it shows periodicity, takes up by day a slightly bent attitude and by this means holds itself for hours in deep capillaries and precapillaries, much as does a rock-climber in a cleft on the face of a cliff. Now such a "ratchet-action" posture is a commonplace in hookworm larvæ, but seems never to have been noted in microfilariæ. It is surely inconceivable that a posture adopted by the embryo for hours at a time in blood within the vessels should be absolutely abandoned in drawn blood. Moreover, Manson[4] aspirated by day the spleens of two filarious patients with nocturnal periodicity and drew off no microfilariæ. A small quantity of hæmoptysis blood passed by day was equally negative. W. W. Myers,[5] too, had negative results from both liver and spleen punctures in like conditions. During life, then, no secret day-time haunt of living microfilariæ has ever been detected. Furthermore, if one may so put the matter, what biological necessity could possibly induce the embryo to take up for many hours of the 24 an attitude which, on the supposition that it is long-lived, is entirely purposeless? That is the actual position. If embryos are long-lived and have already reached the blood stream they merely need to circulate there passively day and night till they die or are picked up by a mosquito. That microfilariæ must be passing through the skin capillaries during the hours when the insect vector feeds is essential for the preservation of the worm species; but that long-lived embryos should take the trouble actively to keep out of the skin at hours when the vector is unlikely to feed can advantage them in no possible way unless the mere fact of circulating damages them. That suggestion cannot be accepted for, assuming that *Mf. bancrofti* survives more than 24 hours, then in Fiji it enjoys no such respite from battering, and yet P. H. Bahr[6] holds that every embryo which reaches the Fiji vector, *Aëdes variegatus* var *pseudoscutellaris*, probably proceeds to develop; Manson had shown that the periodic and presumably protected form in China enjoys no such vitality in culex. The conclusion, then, seems inevitable that the temporary withdrawal of the microfilaria by its own activity from the skin during the day would be a biologically purposeless waste of energy subserving in no way the survival of the species and constituting a happening presumably impossible under natural selection. Yet it was just the presence of periodicity which led Manson rightly to implicate the mosquito as vector. The connexion must be in another direction. Again, microfilariæ are notoriously active creatures, and on the analogy, admittedly incomplete, of hookworm larvæ which are markedly altered in appearance after prolonged exertion, it is unexpected to find a complete absence from microfilariæ of any reported change in this direction, provided always that they live for long periods.

If periodic microfilariæ do not normally inhabit the large vessels during the day, how is their presence there after death explicable? If, as is by analogy reasonable, the female filaria in a dying host is apt to empty her uteri of microfilariæ, these, passing through the thoracic or left lymphatic duct, must later be found exactly where they have so frequently been reported after death, but as has been noted, not during life—in the lungs and large vessels.

Cyclical Parturition.

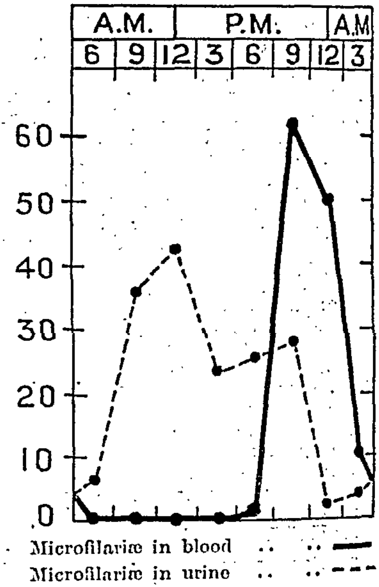
Passing to the possibility that periodicity in *F. bancrofti*, when it occurs, is an expression of parturition so timed that microfilariæ enter the blood stream at night only, it is clear that the necessary corollary is their complete destruction every day. The likelihood of periodicity by parturition was examined by Manson[4] in answer to certain observations by Myers.[5] Manson obtained and tabulated from the same man for six consecutive days and nights three-hourly counts of microfilariæ in smears of blood measuring 1½ by 1 in. and in the deposit from one ounce of chyluric urine. He then added together the counts from smears made at the same hour and wrote of the result: "If these figures are added together the results of this examination become more apparent. It seems to me that they indicate that filarial embryos are nearly always passing into the lymph stream. . . . Therefore filarial periodicity is independent of the act of parturition which is more or less a continuous process." The actual figures were as follows:—

Hour	6	9	Mid-day.	3	6	9	Mid-night.	3
Microfilariæ in—								
Blood	0	0	0	0	1	62	50	10
Urine ..	7	36	43	24	26	28	3	4

If this Table be plotted out it produces the accompanying graph which does not indicate a more or less even microfilarial content of the urine and so of the lymph. There did, in fact, exist urinary periodicity, marked though not complete, and timed differently to that of the blood. This is just what would be expected since, as P. A. Buxton[7] writes, "the larvæ which are counted in the blood come from a parent which is causing no physical signs," they take a direct and rapid route down the lymph stream into the blood stream. The larvæ counted in this case in the urine came from a female lying behind a grave lymphatic blockage. The lymph bearing them must have taken a devious, slow, and erratic course to the ruptured lymphatic vessel in the bladder, so that the curve showing microfilarial discharge must be a flattened one with its rise considerably delayed—such a one, indeed, as the chart shows to have been present in this case.

Direct evidence concerning cyclical parturition is scanty; faced with the adverse opinion of weighty authority few, perhaps, have cared or troubled to collect apposite evidence. Yet scattered observations support it. Bahr[6] in Fiji reported upon six full-grown female worms. Two of these were without embryos but with eggs, and measured 50 mm. and 67 mm. long, the latter, indeed, being the largest individual recovered, and clearly mature. Presumably, then, they had emptied their uteri of microfilariæ, and were waiting for their next cyclical parturition.*

Regarding their life span, he noted seven instances in which microfilariæ disappeared permanently from the blood while this was being regularly examined. In three cases this complete disappearance occurred within 24 hours of the onset of a febrile inflammatory reaction. Now Manson had noted, and O'Connor[8] has confirmed the observation, that mere fever does not cause microfilariæ to disappear from the circulation Bahr's observation implies, then, that the stream o newly born microfilariæ was abruptly cut off by the death or the complete inflammatory isolation of their mothers, and that those embryos already in the blood stream died within 24 hours. That the life span of microfilariæ in the body does not exceed a few hours is also suggested by another observation by Bahr. He found that in citrated blood they never survived for more than 12 hours at blood temperature, while his controls in the same citrated blood lived for three days at room temperature. Their survival at bench temperature for days is, of course, a commonplace, and is perhaps a necessity for survival in the mosquito.



Regarding the daily complete destruction of microfilariæ demanded by a simultaneous cyclical parturition which produces periodicity, microfilariæ have been injected into the blood of apes and have forthwith disappeared. Fülleborn[1] has, however, reported that *Mf. repens* injected into the dog has survived for two and three quarter years, and in one case doubled in size. These are biological unlikelihoods; and in connexion with larval longevity Myers[9] calculated, on the basis of Manson's investigations on *Filaria corvi-torquati*, that each female *F. bancrofti* poured 2,000,000 embryos into the blood daily. If these could survive for two years, the attempt to envisage traffic conditions in the blood and lymphatic vessels of a man parasitised by even a single female filaria for that period suggest that the term "unlikelihood" used above is a moderate one.

If microfilariæ are so short-lived, how are they disposed of? Evidence lies in two directions. Myers's[5] experiments, carried out with striking care and thoroughness, indicated that death and solution of microfilariæ (which showed periodicity and were evidently kept at the bench temperature of his China station) actually occurred in serum, and was much more rapid in morning than in evening blood. Manson[4] failed to confirm this, and the matter has evidently been dismissed as settled; but a positive finding from experiments as carefully executed as were those of Myers cannot be held cancelled by lack of confirmation from others carried through in unstated conditions. Moreover, this question of solution of microfilariæ can no longer be dismissed summarily as an irrelevance. Fleming's[10] showing—that 5000 million *Micrococcus lysodeikticus* are dissolved in a few moments by a tiny tear, and that the lysozyme which is the active principle concerned, and which is present in white of egg, still has lytic action when this last is diluted to 1 in 60,000,000—compels reconsideration of this matter.

---

* The suggestion is that in these non-periodic filariæ parturition cycles of different females fail to be simultaneous.

Actual destruction of microfilariæ in the body itself has been observed by E. Rodenwaldt[11] and by Anderson.[3] The former implicated the renal medulla where he found disintegrating embryos so plentiful that Fülleborn refers to these organs as constituting a veritable microfilarial cemetery—as the place where dead and dying microfilariæ are eliminated from the blood. Anderson found in the liver and spleen, and apparently in the lymph glands, dead microfilariæ without striation and in process of dissolution. These records are few enough, yet the doctrine of periodicity by visceral filtration is so venerable and carries such a weight of authority that regular investigation into possible massive destruction of embryos has never been conducted, so that the fact that such a condition has not been regularly reported is no necessary evidence that it is not regularly taking place. The matter at least merits deeper study.

Biological Support.

But the consideration which appeals most strongly to the writer as supporting simultaneous cyclical parturition as the cause of periodicity is biological. Speaking generally, two typical mosquitoes serve *F. bancrofti* as intermediate host, *Aëdes variegatus* var *pseudoscutellaris* in Oceania where it bites mainly, but as O'Connor showed, not exclusively by day, and where the microfilaria is non-periodic, and the night feeder *Culex fatigans* elsewhere where the microfilaria is periodic and nocturnal. Both these insects Bahr fed on the same filariated patient in Fiji where microfilariæ are non-periodic. The work was a model of control. In *C. fatigans* the infection in the majority of insects died out altogether; in no instance were more than two developing filariæ found in the thorax of one mosquito after the seventh day. On *A. pseudoscutellaris*, on the contrary, it was deemed possible, as already mentioned, that all microfilariæ which had been imbibed had proceeded to continuous development; at all events as many as 38 were found in the thorax of one mosquito on the sixteenth day, and feeds from strongly infected blood caused so heavy an infection that the mosquitoes died. As a secondary host *A. pseudoscutellaris* is then many times more susceptible than *C. fatigans*.

The influence of this susceptibility on the worm species will be much as follows. Infected aëdes will die in thousands from filarial infection, but this is biologically immaterial to the filaria, since the number of vectors which survive is so great and the output of microfilariæ so prodigal that the species will be maintained with ease by those other mosquitoes who happen to become lightly infected. Even with a heavy human infection, mosquito infection may be light, either because the insect happens on a moment when the circulating blood contains few microfilariæ (Bahr has shown that the microfilarial content of the blood may vary in Oceania from minute to minute), or because it secures a small meal only. Should such filariæ be carried by the migration of their human host out of the relatively restricted area of this optimum intermediate host into that of *C. fatigans*, where an increase of the microfilarial content of the cutaneous blood at night is essential, then, if the species is to maintain itself by means of this inefficient "nurse" when the human host is lightly infected, no juggling by retention of microfilariæ in deep organs can add to their number in the skin and perpetuate the worm species in these new and difficult conditions. Just the reverse. But if the female worms, without altering the number of short-lived microfilariæ produced daily, can learn under some stimulus at present unknown so to regulate their already varying rate of parturition as to concentrate cyclically in the blood, the great bulk of these embryos during the few hours when *C. fatigans* bites, the worm species will survive even with this inefficient intermediate host. While this sequence assumes that Oceania is the original home of *F. bancrofti*, there seems, if it is worked out mentally in detail, no insuperable biological reason against the process having been the reverse. Yet an optimum insect host and an unspecialised type of parturition seem to be primitive characters. That the contrary has been commonly assumed is, perhaps, due partly to the prior discovery of the periodic form, and partly to the knowledge that the trend of the "Archaic Civilisation," as W. J. Perry[12] calls it, emanating probably from Egypt, travelled thence eastwards by India right across the Pacific. Yet these pioneers went out for commerce and brought back west and north gold and pearl shell. And just as later the European civilisation searching America for gold brought back the potato and syphilis, so is there good reason to believe did the Archaic Civilisation not only carry the taro plant from India into the Pacific and carry it back to Egypt, whence it has spread across Africa, but also, it is here suggested, transport *F. bancrofti* westwards. The direction of transport is, however, for the purpose of this note, relatively unimportant. The essential point is the insistence that the trend of evidence supports, as the mechanism producing periodicity in *F. bancrofti*, simultaneous cyclical parturition and daily massive destruction of microfilariæ.

Conclusions.

The conclusions reached regarding the mechanism of periodicity are these. *If the embryos of F. bancrofti*, when absent from the skin blood, harbour elsewhere, it is physically unthinkable that they should do so in the overwhelming current of the large blood-vessels; they accumulate in these in numbers from the lymph trunks at or after death only. Nor are they being held back from skin blood by contraction of visceral capillaries, since these can hardly close on one species and open for another circulating in the same blood at the same time. If it were their posture which maintained microfilariæ for many hours daily in deep capillaries, posturing would not be completely discarded in drawn blood. Living microfilariæ have never been found congregated by day in any deep capillaries in numbers corresponding in any way to those demanded by this hypothesis of the mechanism of periodicity; no secret retreat of theirs has been discovered. If they were long-lived, old should be distinguishable from young larvæ by visible changes induced by their activity. Periodicity, then, cannot reasonably be explained as being due to a changed distribution within the blood-vessels of long-lived microfilariæ. Moreover, such a condition holds no biological advantage for the species.

The known facts have a cumulative weight in favour of the hypothesis that microfilariæ within the body perish rapidly, at least daily, and that periodicity is the result of simultaneous cyclical parturition. It is by this device alone that, except in optimum circumstances, the species is enabled to survive. Periodicity, then, is not a mere adaptation to the feeding habits of a particular intermediate host. It is an adjustment which produces that mean between failure to infect an insect and liability to kill it by hyperinfection which reasonably subserves the survival of the parasitic species. It is suggested that contentment with present beliefs on present foundations is no longer possible, and that the whole matter needs reinvestigation with an open mind.

PRIMARY GENERALISED HYPERTROPHY OF THE GUMS.

ILLUSTRATED BY A CASE.

BY D. PERKOFF, M.R.C.S. ENG.,
MEDICAL OFFICER, HOXTON MARKET CHRISTIAN MISSION.

THE entity of most rare conditions is difficult to establish and the case which I describe is no exception. Many authors, among them Grieg, Heath, Sleep, Parkes Weber, and Ironside, have pointed out the rarity of this condition. Heath says that the first case recorded in England was by S. J. A. Salter in 1859, occurring in a little girl aged 8 at St. George's Hospital under the care of Pollock.

Précis of Current Views.

There is some confusion in the literature about the existence of this condition as a separate entity from the rare unilateral hypertrophy of the gums which may be general or localised. The credit for giving us a clear picture is due to Grieg, who thinks that this form of hypertrophy does not constitute a disease, but an affection sui generis, a pure overgrowth of the gums, which is congenital, general, and bilateral, and only gives rise to discomfort after the eruption of the teeth, temporary and permanent alike. Many authors agree that the condition is congenital.

(*a*) Salter thinks it is congenital; although it occurs in children, it has never been known to occur at birth.

(*b*) Hutchison points out that the hypertrophy of the gums, in his case, preceded the appearance of the teeth which had never been able to force themselves beyond the gum surfaces; they were somewhat carious and would probably come out. If the condition were the result of sepsis of the gums or of pyorrhœa, one would expect it to be commoner. He compares it with macroglossia and—if the term were permissible—one could call it "gigantism of the gums."

(*c*) Sleep gives excellent reasons for assuming a congenital origin. He does not consider the lesions to be contingent on any exciting cause, but that the potentiality was contained ab initio in the germinal vesicle itself. As he says, "constitutional perversion is a developing force that precedes and accompanies the advent of the teeth germs from their genesis to their maturity." The teeth in his cases were normal in size and shape; there was no suggestion of any pathological process or excitement in the fœtal or infant life which might have induced hypertrophy of the formative epithelium constituting the enamel organ, or the submucous tissue of the papillæ forming the dentine. He therefore correctly infers that the aberrant process underlying the disease may precede the advent of the dental organs and grow with it and that they should not be suspected as the possible causes of the disease, either by or through their mere presence.

(*d*) Allbutt and Rolleston, discussing the causes of hypertrophy of the gums, mention that generalised hypertrophy may be due to widespread dental disease, especially when the organisms and pus form in pouches between the teeth and the gums, as in pyorrhœa. They are careful, however, to notice that there is a deep-seated general hypertrophy which is congenital, although it may only be noticed at the first dentition. They say that it is necessary to shave off not only the gums but also the portions of the dental alveolus from which it grows. I have no doubt that these authors have in mind the conditions which we are discussing.

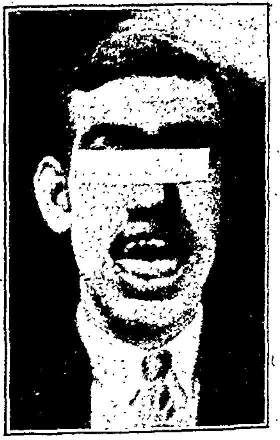
(*e*) Humphry, in his monograph on a condition which was unilateral only and associated with other abnormalities such as hyper-development of the left side of the face, tongue, and palate, thought the condition was a simple but spreading hypertrophy of the gum tissue, which was either congenital or began in very early life, perhaps at the cutting of the first teeth. He mentions that it commonly involves the entire gums of both jaws on both the buccal and the palatal side.

On considering the various views, I agree with Grieg that the condition is a congenital one which does not manifest itself until the eruption of teeth.

Association of Hypertrophy with Mental Deficiency.

In discussing hypertrophy of the gums many authors have, I think, copied each other slavishly, and reiterated the fact that hypertrophy of the gums is associated with mental deficiency. Hopson, for example, in his discussion of the ætiology of this condition, says "there is no defective mental condition in this case, as is so often associated with these cases of hypertrophy." Again, Canton showed a case of hypertrophy in a half-witted and strumous subject; he regards the patient's condition as the cause of the hypertrophy. It is true that in some of the cases reported mental deficiency was present, but the condition is not always associated with weakness of intellect. Sleep says that the real cause seems to lie deeper than mere constitutional debility, infection, or even intermarriage, though it is generally understood that the last-named is capable of awakening latent proclivities to disease and intensifying vicious tendencies, physical and psychical. Grieg, discussing the various views, is sceptical about Erichsen's opinion on mental deficiency and hypertrophy of the gums, and does not think his experience among the mentally deficient was large enough to enable him to draw correct conclusions. Grieg had 25 years' experience among the feeble-minded and he infers that no such hypertrophic condition can be noted as peculiarly associated with mental defect. Humphry quotes ten cases, of whom three—namely, the cases of Gross, Murray, and Waterman—possessed feeble intellect. He remarks that hypertrophy of the gums is often associated with other abnormalities, but he was discussing his remarkable case in which the hypertrophy was left-sided only and associated with hyper-development on the left side of the soft palate, tonsil, alæ nasæ, eyelids, pinna of the ear, eyebrows, papillæ of the left side of the tongue and of the face generally. He also quotes ten cases of general hypertrophy of the gums, among which three were of feeble intellect, one had stunted growth, an ill-shaped head, and a protruberant abdomen, two were epileptic, two had abnormal growths of the hair on the body, and one was deaf. Among the cases reported many such defects have been found associated with hypertrophy of the gums, but many of these do not come under the exact category of the case I describe. In the remarkable series of cases described by Murray in 1873, several children, members of one family who suffered from molluscum contagiosum, also had hypertrophy of the gums. I think the condition of the gums was primarily due to this molluscous fibromatous disease, secondary inflammatory changes causing the hypertrophy of the gums. Again, Erichsen's case was one of the same series of children, and the enlargement was part of a generalised disease, neuro-fibromatosis.

FIG. 1.



Photograph of the patient showing hypertrophied gums and dense growth of eyebrows.

Association with Abnormalities of the Hair.

One other abnormality which I think is associated with this hypertrophy has not been sufficiently emphasised. This is overgrowth and irregularity in the growth and distribution of the hair. As the teeth and hair are dermal appendages hypertrophy of the gums may well be associated with excessive hairiness and fibroid enlargement of the skin.

1. Hopson mentions the celebrated case of one Julia Pastrana, who was a member of a family in whom the gums were much hypertrophied and the hair on the whole of the body was very largely in excess.

2. Humphry noticed that the hair on the head was thick and coarse and the vibrissæ in the nostrils were exceptionally long. The hair on the eyebrows of the left side was coarse and abundant, and spread over the median line.

3. Parreidt's case was an Indian girl, aged 7, who had hypertrophy of the gums and very well-developed growth of hair.

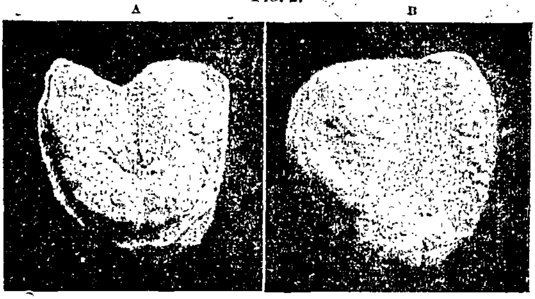
4. Waterman mentioned a woman of feeble intellect, who was exhibited by a Boston showman under the name of the "bear woman." She exhibited huge hypertrophied gums, and her body was covered with a remarkable hairy growth.

5. Pollock's case was noticed to have from birth an unusual quantity of hair on arms, legs, and head.

Description of Author's Case.

The patient, a french polisher, aged 20, came to me early in 1928 complaining chiefly of foul breath and bad taste in his mouth, and suffering from ulcerative stomatitis. He is the sixth member of a family of 11 children, all of whom are in good health, none of them suffering from bad teeth or showing signs of gingivitis. The parents are not consanguinous, are poor working-class people, and do not live under good sanitary conditions. The mother gives a history of three miscarriages, but has not suffered from any diseases except chronic rheumatoid arthritis. The father has fairly good health. The mother says: "The child never had teeth; at the age of 3 he was taken to the Metropolitan Hospital for that reason, and from there he was transferred to Great Ormond-street Hospital." Unfortunately, I have been unable to trace the history of the case at Great Ormond-street, the notes having been destroyed. According to his mother, his gums were there lanced top and bottom, to allow the teeth to come through, and she dates the hypertrophy of the gums from that date. The man asserts that he never had teeth from the age of 4 until the age of 19, and that he managed to chew on his enlarged gums. He never had rickets, or suffered from tonsils or adenoids or from enlarged cervical glands. He has had no other illness of any importance. He is a normally developed male, and is certainly not mentally deficient. He has no other physical defects. His hands and feet do not show any signs of enlargement, and the latter are in perfect proportion to his body.

FIG. 2.

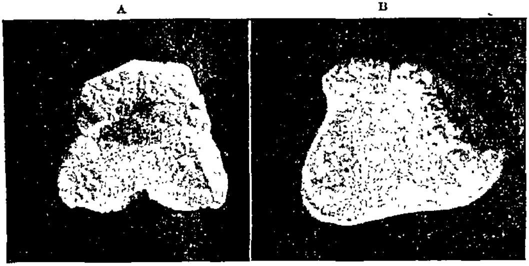


Model of upper jaw (A) before operation, and (B) after operation. (It was impossible to take a complete impression owing to the size of the masses filling the mouth.)

The growth of hair on his body is rather remarkable. It is thick and black, and the distribution on his arms and legs is much denser than that of the average hairy male. The hair on his legs, however, is remarkable in that it is evenly distributed over the whole of the leg and does not stop at the pubic region but is continued on the buttocks and well above the sacral region and tapers up his spine. The hair is long and coarse in texture. On his face the hair is coarse and dense, and the eyebrows are extremely dense and continuous over the bridge of the nose. The texture of the skin of the face is rather coarse, and he has a sallow complexion and suffers from slight acne. His mother asserts that as a child the whole of his body was covered with very fine hair.

He has huge hypertrophied lips, upper and lower, his mouth being so prognathous that his lips cannot be comfortably strained over the hypertrophied gum masses, the mouth being always kept half open. Between the lips the hypertrophied masses of gum tissue look, as Heath described in one of his cases, "like the mouth of a hippopotamus or a rhinoceros on a small scale." (Fig. 1.)

FIG. 3.



Model of lower jaw (A) before operation, and (B) after operation.

Inside of the Mouth before Operation.

The tonsils were slightly enlarged and ragged. The uvula was enlarged and lengthened, and was approximated to the dorsum of the tongue. His tongue gave the impression of being long and thin, owing to its confined position between the hypertrophied masses of gum; but when protruded it was seen to be normal in size and shape.

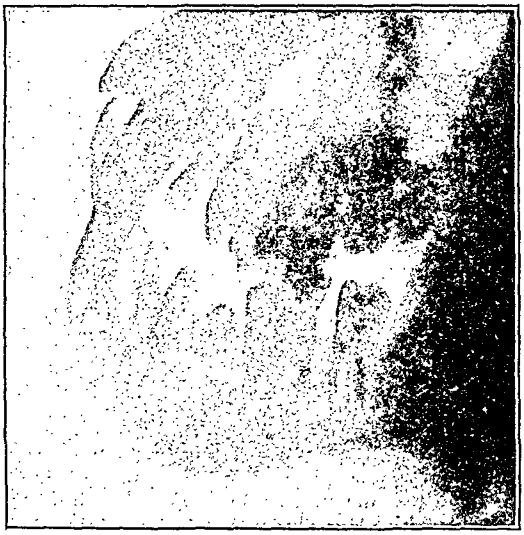
The lips were pushed forward by the hypertrophied masses and the lower mass of gum tissue protruded, everting the upper larger mass. The gum tissue was of normal colour, but rather firm and coarse in texture.

Upper Jaw.—The hypertrophied mass (Fig. 2A) consisted of two ill-defined masses, one extending from the posterior right extremity of the jaw to the region of the left canine or premolar, where there was a dip in the tissue extending from the palata to the buccal side; the other from the second premolar to the left posterior extremity. This latter mass extended across the mid-line of the palate, meeting its fellow of the other side. The proximity of the two masses gave the impression of a cleft palate, the cleft posteriorly admitting only the thickness of a visiting-card, and anteriorly widening out into a diamond-shaped impression 1·5 cm. in its greatest diameter. The mass in the anterior region was 2·4 cm. thick bucco-palatally, the mass in the right posterior region 3 cm. thick, and that in the left posterior region 3·3 cm. The depth of the mass anteriorly from the under-surface of the gum to the reflection of the buccal mucous membrane was 2·5 cm.

The only teeth present were the upper right first and second premolars and molars, and the left canine; only the tips of the cusps were showing, looking like an ivory island in a sea of pink flesh.

Lower Jaw.—This consisted of three ill-defined masses extending (1) from the right third molar to the right second premolar; (2) from the first right premolar to the left first premolar, where there was a dip extending to about the first molar: and (3) embracing the first to the third molars. (Fig. 3A.) The left mass in the anterior region was 1·9 cm. thick bucco-lingually, the left 2·2 cm. The right posterior mass was 1·9 cm. thick bucco-lingually, the left posterior mass 1·9 cm. bucco-lingually. The teeth present were the right second premolar, first right molar, left first molar and second molar. The teeth protruded to a depth of 1·3 mm. The buccal mucous membrane was raised in ridges, which partially covered the hypertrophied masses of gum tissue.

FIG. 4.



Skiagram of jaws.

At St. Bartholomew's Hospital Mr. J. E. H. Roberts resected a portion of the gum on the right half of the upper and lower jaws.

Right Side of Mouth after Operation.

The teeth are displaced either inwards or outwards by the hypertrophied masses of gum tissue. The only one missing is the first incisor, which was extracted at operation. The incisors and canines are all inclined outwards; the premolars and molars face inwards—that is, lingually. Intervening masses of tissue cause undue and irregular spacing of the teeth. The top jaw (Fig. 2B) is similar to the bottom jaw (Fig. 3B) in appearance, and all the teeth are present.

It is important to have a dental report on the teeth, which now appear for the first time, as it may be suggested that the hypertrophy was due to infection, in which case there should be pathological changes in these teeth. One suggestion made to me by a dental surgeon was that minute sinuses might lead down to the teeth and through these channels infection might occur, the reaction causing lymphatic obstruction; hence the elephantine dimensions of the gums. Mr. Evelyn Sprawson, dental surgeon of the London Hospital, examined the teeth, and found that they were apparently normal and healthy. Skiagrams of the jaws (Fig. 4) showed that the whole of the permanent dentition was present except the incisor which was removed at operation, and the lower third molars, which were both congenitally absent.

Comparison of the models made before and after operation shows an increase in the hypertrophy in the unoperated side. This is due, I think, to the fact that the pressure of the operated side was removed. There is also a tendency for the hypertrophy to recur on the operated side. This fact has been noted by Grieg in his case, and also in a case quoted to me by Mr. Sprawson.

The Wassermann and sigma reactions of the blood were negative. A microscopical report on the section shows that the nature of the tissue is difficult to determine, but it apparently consists of chronic infective hypertrophied tissue with much fibrous tissue. I have examined microscopically a section lent to me by Mr. Sprawson, taken from a case of general hypertrophy of the gums. This section gives us the same microscopic picture as my case, and suggests that it is a form of defuse fibroma.

As the milk teeth never appeared, there should be evidence of their presence in the jaw bones. From the mother's history "that the child was brought to hospital because he had no teeth, and after lancing no teeth were found," we have good reason to suppose that our subject was a case of a congenital absence of milk teeth; moreover, there is no history of their having been lost. This in itself is a very rare condition. The radiogram of the present teeth gives no evidence of the milk teeth ever having existed. The fact that this man was abnormally hairy as a child, to my mind, strengthens the suggestion of absence of milk teeth. Many cases have been recorded of deficiency of teeth associated with abundance of hair. Colyer quotes the case of Andrian Jeftichfen, in whom the whole of the face, nose, forehead, cheeks, and ears were covered with long brown hair, which also extended partially down the back. His son, Fedor, at the age of 3, showed the same tendency to hairiness. The father had no teeth up to 17 years of age, and eventually only erupted four teeth in the mandible and one in the maxilla. The son, Fedor, at the age of 3 possessed only four incisors in the maxilla. The Burmese family, consisting of grandfather, mother, and son, are said to have been deficient in the number of their teeth, but there is no reliable record. Again, cases are known where entire absence of teeth was accompanied by marked deficiency of hair.

Deficiency of Teeth and Hair Correlated with the Pituitary Glands.

From the foregoing cases it is evident that there is a co-relation between the hair and the teeth; in one class there is a deficiency in both structures and in the other deficiency of teeth is associated with redundance of hair. From this one can, I think, deduce interrelationship with the pituitary gland, knowing as we do that the secretion of the anterior lobe is connected with the growth of the skeleton, skin, and soft tissues. Cushing, in his book on the pituitary gland, mentions hypertrichosis due to excessive secretion of the pituitary. In acromegaly there is osteal hypertrophy of the maxilla and overgrowth of the soft connective tissues and periosteal ends of the fingers and toes. Sleep also suggested a relationship between the endocrine system and the hypertrophy of the gums. McNeill Love has this year described a case of hypertrophy of the gums in a boy aged 18. His case is, I think, one of the rare types we are discussing. Love states that the hands and feet are undoubtedly large, and X ray showed enlargement of the sella turcica, yet Love suggests acromegaly as the cause of the deformity, stating, however, that there were no other signs of the disease present.

On embryological grounds there is evidence of the relation between the anterior part of the pituitary gland and the buccal cavity. The anterior lobe is developed as a tubular prolongation from the epiblast of the buccal cavity, the embryological stomodeum, but the growth of intervening tissue soon cuts off all connexion with the mouth.

I put this hypothesis forward as a tentative suggestion, but in our present state of knowledge of the endocrine system we must leave it to further research to elucidate clearly the exact function of the co-relationship of this intricate system.

I must express my thanks to Mr. C. H. Fox for his skill in constructing the models, and to Mr. Evelyn Sprawson for help and advice.

A NOTE ON BLOOD TRANSFUSION.

WITH AN ACCOUNT OF A FATAL REACTION.

BY LESLIE J. WITTS, M.D. MANCH.,
M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, GUY'S HOSPITAL; LATE ASSISTANT TO THE MEDICAL UNIT OF THE LONDON HOSPITAL.

(From the Medical Unit of the London Hospital.)

IN the case now reported death was the direct result of a blood transfusion. The patient was not gravely ill before the operation and the preliminary tests were made with care. I am therefore publishing an account of the case and a few notes from the literature of the subject. Transfusion is a relatively simple and safe operation and the great majority of deaths are due to errors in technique. Nevertheless, the operation is not absolutely devoid of risks even in careful hands.

Clinical History.

A woman, aged 29, had been anæmic since the birth of twins three years before. The confinement was normal and there was no excessive loss of blood. Since then she had suffered from shortness of breath, dizziness, and occasional swelling of the feet at night. Her symptoms were alleviated from time to time and then got bad again. There was no obvious cause for the anæmia. Her nutrition and general condition were good and there were no physical signs of disease apart from the anæmia.

She was treated for five months with iron and ammonium citrate, grs. 10 three times a day, and made no improvement. At the end of that time her blood count was: red cells, 3,800,000; Hb, 44 per cent.; colour-index, 0·58; white cells, 7300; neutrophiles, 60·0 per cent.; eosinophiles, 2·0 per cent.; basophiles, 0·5 per cent.; lymphocytes, 31·5 per cent.; monocytes, 6·0 per cent.; the platelets, the fragility of the red cells, and the van den Bergh reaction were normal. A fractional test-meal showed a complete achlorhydria. The urine was normal. It was decided to give a transfusion.

The patient was found to belong to group II., and a donor of the same group was obtained. Immediately before the transfusion, both the cells of the donor and recipient's serum and also the cells of the recipient and donor's serum were matched in the usual way (Panton and Marrack).[11] No agglutination occurred in either specimen. The donor had given blood four times before and "all his patients had done well." The citrate technique was employed and the transfusion went smoothly. The patient complained of headache but nothing unusual was noticed. A few hours later she was sick, and she vomited at intervals during the next 48 hours. She did not have a rigor but the temperature rose to 102·6°F., falling to normal in 48 hours. There was no jaundice. Pain in the back was not complained of till 48 hours after the transfusion. It then persisted till death but was never severe.

A rectal saline was given on the day after the transfusion. On the cessation of the sickness the patient took water, soda-water and orange juice fairly freely by mouth. No urine was passed till the sixth day, when six ounces of very acid urine were excreted. It contained three-fifth volume of albumin, the urea concentration was 0·69 per cent., the deposit contained a few hyaline casts, red cells, many leucocytes, and many epithelial cells. A casual observer would not have realised that the patient was in extremis. Her colour and appearance were good, her mentality clear, the pulse was 64, the blood pressure 120/80. Nevertheless, the blood-urea on this day was 333 mg. per cent. Potassium citrate was given by mouth in drachm doses six-hourly, but the patient began to be sick again and it was omitted.

On the seventh day intravenous injection of normal saline was begun, a pint being given three times daily. Eight ounces of acid urine were passed. On the eighth day grs. 30 of potassium citrate were also given intravenously. Five and a half ounces of acid urine were passed. On the ninth day the blood pressure was 150/90. The patient was drowsy. Two pints of saline and grs. 30 of potassium citrate were injected during the forenoon. In the early afternoon the patient had tetany, but this disappeared after the intramuscular injection of one grain of calcium chloride in 40 minims of water. In the evening of this day one pint of saline and grs. 5 of potassium citrate were injected. Soon afterwards the patient shivered and Chvostek's sign was positive. She was therefore given another injection of one grain of calcium chloride and no tetany developed. Later in the evening 1½ pints of saline were given intravenously. Eight and a half ounces of acid urine were passed on this day.

On the tenth day the blood-urea was 354 mg. per cent., the plasma bicarbonate 33·6 volumes. A pint and a half of saline was given intravenously. The condition of the patient seemed fair. There was no visible œdema, but as there were signs of bronchitis no more saline was injected. The urine, which had previously been strongly acid, was neutral. Eight ounces were passed. There was one-tenth volume albumin, and the deposit contained granular and hyaline casts, red cells, leucocytes, and epithelial cells.

In the early hours of the eleventh day the patient, who had been sleeping comfortably, suddenly sat up in bed and fell back dead.

Findings at Necropsy.

A post-mortem examination (No. 575, 1928) was made by Prof. H. M. Turnbull, and the following is a summary of the findings:—

Examination showed "bilateral pleural effusion (32 oz. right, 12 oz. left), ascites (18 oz.), great œdema of the lungs, œdema of the brain and other organs, and a general anasarca which was relatively slight in the subcutaneous tissue so that the skin did not pit; greatly enlarged kidneys (16½ oz., body 114 lb. 7 oz.) showing a few petechiæ, a swollen, pale, yellowish-grey cortex with obscured pattern, and a dark red-brown medulla; a few petechiæ in renal pelves; general anæmia; hæmatogenous marrow throughout the neck and upper three-quarters of the shaft of the femur and in a few patches beneath."

Microscopic Examination of Kidneys.—"Most of the discharging tubules are filled with fine granules, large lumps or, occasionally, homogeneous masses of an isotropic substance of the colour of brown sugar. In addition to this substance there are frequently many desquamated epithelial cells and neutrophile leucocytes; less frequently there are areas of hyaline albumin. Where the cytoplasm of desquamated epithelial cells can be identified it is finely granular and of the same colour as the granules and lumps. Similar casts occupy numerous collecting and junctional tubules; but in these tubules, especially in the junctional, the brown substance is frequently replaced by deeply eosinophile granules or small spheres, amongst which one or two red corpuscles are occasionally present. The convoluted tubules contain albumin in the form of a net or multiple spheres; the remaining tubules sometimes contain the same or hyaline albuminous casts, but they are more often empty. Within the convoluted tubules there are occasionally one or two red corpuscles. Beneath the capsule in one section there is a small group of tubules filled with red corpuscles. All the tubules are dilated, particularly the collecting. The capsule of Bowman is usually only slightly dilated, and contains pale albuminous spheres. The glomeruli are large, and show no sign of collapse. The basement membrane of their capillaries is swollen, whilst the capillary lumina are wide and rarely contain any red corpuscles. The anæmia of the glomeruli thus contrasts very conspicuously with an engorgement of intertubular capillaries and a great engorgement of the vasa recta. The epithelium of the first and second convoluted tubules shows a very severe albuminous degeneration. Karyokinetic

figures in epithelial cells are frequent. The interstitial tissue throughout the medulla is greatly rarefied by œdema; the œdema in the cortex is patchy, but in these patches it is extreme. Round-cell infiltration is great round the vasa recta in the upper two-thirds of the medulla, and is considerable in the interlobar connective tissue, beneath the capsule, and in the adventitia of the vessels in the intermediate zone and in the cortex; it is occasionally present round discharging tubules filled with the characteristic casts. The infiltrating cells are chiefly plasma cells and large lymphocytes; small lymphocytes are less numerous; eosinophile leucocytes come next in frequency and in some foci predominate; histiocytes, neutrophile leucocytes, and large mononuclear leucocytes are relatively scanty. One or two myelocytes, myeloblasts, and normoblasts were found within capillaries on searching, but there is no myeloid reaction in the infiltration. There are interstitial hæmorrhages in the medulla round engorged vasa recta, in the interlobar connective tissue, and beneath the surface of a medullary pyramid. Fat, doubly refractive lipoid, and hyaline-droplet degeneration are absent."

The cause of death was suppression of urine following hæmoglobin infarction of the kidneys.

Discussion.

It is difficult to assess the inherent risk in blood transfusion. Most of the fatalities are due to faulty technique. Many of the patients are gravely ill and it may be doubtful whether death was due to the disease or the treatment. Much depends on the condition for which transfusion is given. In acute hæmorrhage severe reactions are rare. In the blood diseases reactions are more frequent and the blood group is sometimes so atypical that it is difficult to find a suitable donor. Severe reactions are so often encountered in the treatment of acute sepsis and acute leukæmia that transfusion is contra-indicated in these diseases. Bernheim,[3] in 1917, collected reports of 800 transfusions from 20 different surgeons. There were four deaths from hæmolysis. No tests had been made in three of these cases. In the fourth it was known that the donor's cells were agglutinated by the recipient's serum. There were six other deaths, four attributed to cardiac dilatation, and two to anaphylactic shock. Thus eight of the ten deaths were due to errors in technique. In the following Table I have summarised some of the more recent American figures, which show the results obtainable to-day. In over 4500 transfusions there were only five deaths, of which four—and possibly the fifth—were known to be due to errors in grouping.

Year.	Operator.	Preliminary tests.	Technique.	Total transfusions.	Deaths.
1919	Pemberton.[12]	Grouping.	Citrate.	1036	3
1923	Copher.[6]	Grouping plus cross-agg.	Citrate and direct	245	2
1925	Kordenat et al[9]	Cross agg.	,,	764	0
1928	Brines.[4]	Grouping.	Direct.	2500	0
	Total			4545	5

Agg. = agglutination.

Mr. P. L. Oliver has very kindly given me the figures for the Blood Transfusion Service of the British Red Cross Society, of which he is hon. secretary. This service has provided donors for 3430 transfusions. Five deaths have been reported. One of these was our own patient. Another was a man with advanced malignant disease who died of syncope during transfusion. In the third case the donor had been wrongly grouped, and in the fourth the patient had been wrongly grouped. In a fifth case the donor belonged to group IV, as was later confirmed by regrouping, but the patient, whose group is not given, died before the completion of the transfusion. It appears from these figures that the mortality of the operation of blood transfusion is of the order of 1–2 per 1000, and that the majority of the fatalities are due to inadequate compatibility tests. Members of group IV. can no longer be considered universal donors, as not a few deaths have followed the adoption of this simple "rule of four"; although the plasma of the donor is greatly diluted in the recipient, it is sometimes rich enough in agglutinating and hæmolytic principles to produce severe hæmolysis. There are few emergencies so urgent that it is not possible to do direct cross-agglutination tests with both donor's cells and recipient's serum and also donor's serum and recipient's cells. With this precaution severe reactions are exceedingly rare though they cannot be absolutely excluded.

In recent years, however, a number of fatal reactions have been described after transfusions although these preliminary tests had been carried out. These reactions are of two types, the hæmolytic and the anaphylactic. It is difficult to understand why hæmolysis should occur after a satisfactory cross-agglutination test. It is suggested (Doan)[8] that hæmolysin and agglutinin are not always present in proportionate amounts in the serum and a slight degree of hæmolysis may be overlooked in the test. Nevertheless, Percy,[13] in a series of 54 transfusions by the direct method, had three instances of severe hæmolysis and two of the patients died; in all three cases the blood of donor and recipient had been tested for hæmolysis before transfusion with negative results. A more probable explanation is that agglutinins are present in such low concentration that they are missed in the preliminary tests. Three instances of fatal hæmolytic reaction have been described in which preliminary grouping or cross-agglutination had been satisfactory, but on repeating the test after the development of the reaction the bloods were found to be incompatible (Baker and Dodds,[1] Copher,[6] Shera[15]). Schneider[14] has collected from the recent German literature an additional six cases in which fatal hæmolytic reactions occurred although there was no agglutination in the preliminary matching of donor and recipient. He is of the opinion that cross-agglutination is not a very sensitive test and that it is better to perform accurate grouping with high titre sera. There are great variations in the strength of agglutinin and agglutinogen in different bloods of the same group, and a blood may be allocated to the wrong group if the test sera are not fresh and active.

The effects of the transfusion of incompatible blood have been described by Pemberton.[12]

> "The clinical picture of these reactions is typical. They occur early, after the introduction of 50 or 100 cubic centimetres of the blood; the patient first complains of tingling pains shooting over the body, a fulness in the head, an oppressive feeling about the precordium, and later, excruciating pain localised in the lumbar region. Slowly but perceptibly the face becomes suffused a dark red to a cyanotic hue; respirations become somewhat laboured, and the pulse-rate, at first slow, suddenly drops as many as 20 to 30 beats a minute. The patient may lose consciousness for a few minutes. In one half of our cases an urticarial eruption, generalised over the body, or limited to the face, appeared with these symptoms. Later the pulse may become very rapid or thready; the skin becomes cold and clammy, and the patient's condition is indeed grave. In from 15 minutes to an hour a chill occurs, followed by a high fever, a temperature of 103° to 105°, and the patient may become delirious. Jaundice may occur later. The macroscopic appearance of hæmoglobinuria is almost constant."

The hæmolytic reaction may be directly fatal or it may lead to death indirectly from suppression of urine. Baker and Dodds[1] have demonstrated the factors which give rise to anuria by some very lucid experiments. Anuria is produced by the blockage of the renal tubules with precipitated blood pigment. Precipitation only occurs if the urine is acid and concentrated. A series of experiments in vitro proved that hæmoglobin is thrown out of solution when (*a*) the reaction of the medium is not more than about pH 6, and (*b*) the NaCl content is about 1 per cent or over. If the urine is alkaline, there is hæmoglobinuria but no suppression. Thus it seems that suppression of urine could be prevented by establishing an alkaline diuresis, a safeguard which could easily be adopted before transfusions which are not emergencies. In the case now reported there was no clinical evidence of hæmolysis; the actual transfusion was uneventful and there was no backache or jaundice.

The anaphylactic or foreign protein type of reaction is still less predictable than the hæmolytic. A fatal case has been described by Carrington and Lee.[5] The patient had pernicious anæmia. There was no history of asthma, hay-fever, or other type of protein sensitisation in either donor or recipient:

> "After very careful matching with a number of donors, the patient was transfused by the citrate method with 500 c.c. of blood without any immediate reaction. One half hour afterwards, however, he developed a typical anaphylactic protein reaction with high fever, spasm of the unstriated muscles, asthmatic symptoms in the lungs, involuntary voiding of urine, and several bowel movements. This subsided after one hour, but the man developed acute œdema of the lungs and died eight hours after the transfusion. During the reaction the urine was examined and no hæmoglobin found. The blood showed no hæmolysis or agglutination."

Severe foreign protein anaphylactic reactions seem to be very rare. In the majority of the cases the symptoms are limited to dyspnœa, cyanosis, swelling of the face, and urticarial rashes, and they respond to treatment with adrenalin or morphia. Doan[7] suggests that many of these reactions are due to incompatibility of the white cells. On exposure to an incompatible serum or plasma the white cells undergo vacuolation and disintegration. In Doan's series of 16 transfusions, there were 11 in which both red cells and white cells were compatible; no reaction occurred. There were four in which the donors were incompatible only as to the white cells; severe reactions followed, one proving almost fatal. In the remaining case the white cells were compatible but a severe reaction occurred; re-examination showed that the patient was an atypical group II., and ten different donors were tried before one could be secured with whose red blood cells there was not agglutination in vitro. Doan tests the white cells for compatibility by a modification of the "supra-vital" technique, and this requires much practice before reliable results can be obtained. Other factors which have been considered responsible for these foreign protein reactions are the use of new rubber tubing, excessive acidity or alkalinity and bacterial contamination of the diluting fluids, the presence of small thrombi in the blood, agglutination of the red cells, agglutination and degeneration of the platelets, and the presence of toxic substances in the plasma. Reactions are probably more frequent with the citrate technique than with the direct method. Some of the refinements suggested would remove blood transfusion from the sphere of practical medicine. There is no doubt that the frequency of reactions can be greatly reduced by familiarity with the method employed and rapid working.

The treatment of suppression of urine following hæmolysis is a difficult problem. The experiments of Baker and Dodds indicate the value of alkalis in the prevention and the treatment of this complication. Bancroft[2] has reported a case of anuria following blood transfusion in which recovery occurred after decapsulation of the kidneys on the tenth day. Osman[10] states that suppression of urine is usually accompanied by acidosis, and he has had good results by giving alkalis until the urine becomes alkaline. Very large doses of alkali are sometimes necessary. One of his patients received 1440 grains of a mixture of equal parts of sodium bicarbonate and potassium citrate in 24 hours. Where it is impossible to give alkali by mouth, he advises a drachm of the mixture in a pint of water intravenously. Our own experience with potassium citrate was not a happy one. It produced vomiting when given by mouth, and tetany developed after the intravenous injection of grs. 60 in 24 hours. As the plasma bicarbonate on the following day was only 33·6 volumes per cent. it is difficult to believe that the tetany was due to alkalosis. It may have resulted from the combination of the citrate with the calcium of the blood. It was easily controlled by the injection of calcium chloride. In concluding this report I should like to repeat that the experimental evidence of the value of alkalis in the prevention of suppression of urine after transfusion is so clear that, except in emergencies such as acute hæmorrhage, the operation should not be carried out until alkalis have been given in sufficient dosage to render the urine alkaline.

Summary.

(1) A fatal hæmolytic transfusion reaction is described. Preliminary grouping and cross-agglutination tests had shown no incompatibility. (2) The direct mortality of blood transfusion is about 1–2 per 1000. Accidents can be minimised by careful grouping and cross-agglutination, but a certain risk is unavoidable. (3) The commonest cause of death is suppression of urine from hæmolysis and hæmoglobin infarction of the kidneys. Alkalis are recommended for the prevention and treatment of this complication.

I wish to thank Dr. A. E. Clark-Kennedy for permission to publish this case, and Prof. H. M. Turnbull for the pathological details.

RECENT STUDIES IN THE BIOLOGY OF THE CANCER CELL.

BY PROF. A. H. ROFFO,
DIRECTOR OF THE INSTITUTE OF EXPERIMENTAL MEDICINE, BUENOS AIRES.

THE one incontestable fact that emerges from the vast bulk of cancer literature is that the cell and its products dominate the neoplastic process, and that physical chemistry will have to clear up the mystery of the cancerous cell. Every cell which uses energy at the expense of its nutritive material does so by oxidation or by excision. In the first case the process leads to the formation of carbon dioxide and water, while in the second case it causes the formation of intermediate bodies. In oxidation there is a complete utilisation of the energy contained in the molecule of the carbohydrate, while in the second case energy is not liberated. Warburg[12] showed that cancerous cells have a similar action on glucose to that of lactic ferments. Normal cells produce lactic acid only in asphyxia, while neoplastic cells always produce it even when freely supplied with oxygen. Warburg aptly compares the metabolism of the tumour cell with that of a normal asphyxiated cell. The lactic acid produced hourly by a piece of rat sarcoma in Ringer solution with glucose is equal to ¼ per cent. of the weight of the tumour. Glässner[3] showed that the injection of glucose into animals with tumours produces an elimination of lactic acid in the urine, which does not happen in normal animals. Freund and Revesz have proved that it is possible to modify the speed of production of lactic acid by insulin, while Woglom has accelerated the development of tumours by adding carbohydrates. These experimental results explain a very common clinical observation—the rapid development of tumours in diabetics. On the other hand, Correa and I[4] have observed the presence of insulin in tumours, a result which seems paradoxical.

The fermentative process, therefore, predominates in the carbohydrate metabolism of the cancer cell, and undoubtedly bears a close relationship to the cell respiration. Woglom and Russell[5] showed in 1921 that oxidation is less complete in neoplastic cells than in normal ones; the more rapid the evolution of the cell the more active its respiration. Neuschloss and I,[6] studying the influence of certain ions and venoms on the respiration, found that prussic acid and other similar substances which exercise an inhibitive action on normal cell respiration have no influence on neoplastic tissue. Adrenalin increases the reduction of the normal cells and diminishes that of the neoplastic; thyroidin acts in the opposite way. The ions Rb, SeO_3 and SeO_4 increase the respiration of adult tissues and diminish that of embryonic or neoplastic cells. We also found that the serum of cancerous animals and patients had an increased reducing power[7] proportionate to the evolution and development of the tumour. Catalysis was less in cancerous than in normal tissues, but the content of glutatium, a body which regulates the mechanism of organic oxidation, is greater in the tumour than in the normal organs. Robin[8] believes that cancer is the result of a ferment, which breaks up protein. Neuberg, Blumenthal, and Wolf mention that the endo-ferments of the neoplastic cell act not only on the protein of the tumour, but also on that of the surrounding cells. Abderhalden[9] and his school found that polypeptids of neoplastic cells are attacked differently from those of normal cells. Tumour tissues have greater lipolytic action on esters than normal tissues. Pregnancy, it may be noted, produces a physiological state with biological reactions similar to those provoked by tumours (Abderhalden).

The Ionic Composition of Neoplastic Tissues.

Investigations undertaken in this Institute[10] show a much higher content of lipoids and especially of cholesterin in neoplastic tissue than in normal tissues. This indicates an accumulation, which depends on various factors; a very important one is the accelerated development. Further investigations showed a disturbance of the nutritive metabolism of the cancerous cell. Cholesterin[11–17] is increased in the serum of cancerous animals and patients, and especially in the tissues of sarcomas and carcinomas, rising sometimes as high as 10 g. per cent. of dry material. The tissues of the animals show values which oscillate between 1 and 1½ per cent. Moreover, the metabolism is balanced by a greater activity of the cholesterinogenic organs. Even in precancerous lesions the cholesterin content is two or three times as great as in healthy tissue. The cholesterol and the water content were in many cases ten times as great in neoplastic as in normal tissues.

In consequence of these results we subjected animals to various kinds of lipoid-free diet. The animals fed on carbohydrates and small quantities of protein with absolutely no fats did not develop tumours, and tumours already present became necrotic in the first few days and later disappeared completely. It is obvious that destruction of such an important element as lipoid must profoundly alter the vitality of a cell. The cell membrane is a colloid, and cholesterin is an important regulator of the permeability of the membrane.

Meyer and Schaeffer[18] showed that in a mixture of lipoids and cholesterin the latter renders lipoids penetrable by water, and so diminishes the restriction of inbibition which determines the fatty acids. The more cholesterin there is in a gelalbuminoid mixed with lipoids the more water will it imbibe. This explains the enormous proportion of water—in certain cases 80 or even 90 per cent.—found in the tumours of rats, which are very rich in cholesterin. This percentage is only reached by embryonic tissues, which have such a close relation to neoplastic ones.[19] Is this hypercholesterinia a product of synthesis in accordance with the function of development, or is it a phenomenon of nutrition by absorption of the membrane of the cell? I have shown[17] that there is also a hypercholesterinia in embryonic tissues proportionate to their degree of development. In a culture of normal heart tissue we observed, after 48 hours, a depletion of the cholesterin of the medium by 2·06 and 8 per cent., while in cultures of neoplastic cells this diminution of cholesterin reaches very high values —59 to 83 per cent. These results show the close relationship between the development of the cells and the adsorption of cholesterin.

Certain ions,[20] [21] [22] especially potassium and calcium, act as regulators of the development of the tissues.[23] [24] [25] Wolf has obtained a retardation or acceleration of development of transplanted tumours according to which elements were in excess. Theis and Benedict found an increase of potassium in the blood of patients suffering from cancer with rapidly growing tumours. Our determinations on adult embryonic and neoplastic tissues have shown a relation between the potassium and the activity of development. We have observed a correspondence of the K/Ca relation[26] to the development of the tumour. If the value is 6·54 in tumours at the most active stage of their development it will be 3·56 in tumours in which the rate of development has decreased and which have zones of tenderness. The variations are almost entirely in the potassium; the calcium is present in nearly equal quantities in all cases.

We have observed variations which show that the conductibility of the normal and neoplastic tissues is specific and much greater in the tumour than in the normal spleen, liver, and other organs. We attribute those differences to the action of the electrolytes, especially the potassium, the amount of which varies according to the tissues. We have noticed a similar phenomenon with zinc, which Delezenne regards as an essential cellular constituent. The amount of it present in a tumour varies proportionately with the period of development. The zinc contained in these tissues is not dialysable, and must therefore be present in the form of a protein compound; this conforms with the investigations of Delezenne, who proved that the more proteins snake-venom contains the more zinc there is present.

We have demonstrated the influence of these ions on the development of tissues in vitro.[24] It was necessary to use very high dilutions of calcium to secure development. The results obtained by Zwaardemaker and Campbell and Wood suggest that potassium emits beta rays. The former noticed that the radio-active effect of calcium was to retard growth.

Summary.

The biology of cancer concerns two factors: one inherent in the cell and the other depending on the "terrain." The modifications in the evolution of the tumours in accordance with biological alterations of the "terrain," differences in the chemical compounds, the colloids, and so on, attribute special importance to this factor; but we must ask whether the chemical alterations of the tissues and their hormones prepare the "terrain," or whether the modifications are a consequence of the altered biology of the neoplastic cell. In the solution of this question lies the better understanding of the precancerous state.

Clinical and Laboratory Notes.

A CASE OF CEREBRAL SYMPTOMS FOLLOWING VACCINATION.

RAPID RECOVERY AFTER INTRATHECAL INJECTION OF POST-VACCINAL SERUM.

By Sir Thomas Horder, Bart, K.C.V.O., F.R.C.P. Lond.,

PHYSICIAN IN ORDINARY TO THE PRINCE OF WALES; PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

In the report of the Committee on Vaccination presented to the Minister of Health in July, 1928, are to be found these words (pp. 200–201):—

> "The occurrence of post-vaccinal nervous disease, however seldom it may occur, is of serious import and cannot fail to have an effect on vaccination both in its administrative and in its purely medical aspects. We have pointed out the extreme rarity of such manifestations, particularly after revaccination, and after primary vaccination in early infancy. Early infancy remains therefore the time of choice for primary vaccination.
>
> "We are of opinion that only publicity among medical circles of the knowledge and experience relating to such cases as might occur in the future, both in this country and abroad, will ensure the accumulation of clinical and epidemiological data and at the same time aid the prosecution of special researches devoted to the solution of this problem."

It is in deference to this injunction that the following case is now put on record.

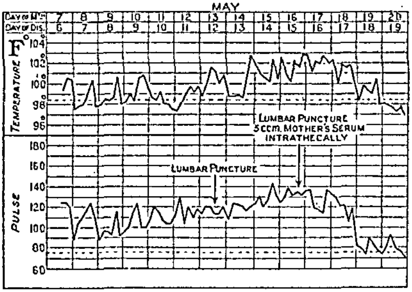
The Case Described.

A. B., a boy aged 4½ years, was brought to the casualty department of St. Bartholomew's Hospital on May 2nd, 1929. The mother stated that four days previously the child vomited, was puffy in the face and legs, suffered from headache and earache, and was found by the doctor to have a temperature of 100° F. The child was put to bed for two days, and then, seeming better, was allowed to get up, but complained of pain in the toes on attempting to walk.

In the room in which the child and his mother were waiting during the examination of the former there was also waiting another child found to be suffering from small-pox. It was therefore decided to vaccinate A. B. and his mother, and both, then and there, received four insertions of lymph. The child was then kept in an observation ward. At this time (May 2nd) there was no pyrexia. There was some general glandular enlargement, some petechiæ about the arms, legs, and back (? due to flea-bites), and the left elbow and left knee were tender on palpation and painful on movement. The tonsils were large and red. There was an apical systolic bruit and the apex-beat was displaced slightly outwards. The urine was free from albumin and blood.

The vaccination took well and the temperature rose on the sixth day (May 7th). On the eighth day the child became drowsy, and on the eleventh day he was stuporous. He vomited on this day. The limbs were entirely flaccid, but there were no pareses and no ocular palsies. (For temperature and pulse-rates see chart.) A lumbar puncture on the twelfth day yielded 10 c.cm. of cerebro-spinal fluid; Fehling reduction within the usual limits, total protein 0·03 per cent., red blood cells 52 per c.mm., white cells 4 per c.mm. (? a little admixed blood). The blood leucocytes were 8400.

The stupor and hypotonus continued on the thirteenth–fifteenth days (knee-jerks natural, flexor plantar response.) On the fifteenth day the lumbar puncture was repeated and, on Dr. Mervyn Gordon's suggestion, 5 c.cm. of the mother's serum was slowly injected intrathecally. The child's cerebro-spinal fluid was again normal on this occasion. On the seventeenth day the stupor lessened, and the child wept naturally. Hypotonus were still present. On the nineteenth day the child was more lively and the improvement in the mental state was thenceforth rapid. On the twenty-sixth day he talked for the first time since the cerebral symptoms began. A serum rash developed on the twenty-seventh day (twelfth day of injection). The subsequent course of the illness was uneventful save for a rise in the pulse-rate, which fell on getting the child up.



The mother's vaccination took well. She had been vaccinated once before, during infancy. She lost her sense of taste and smell for three weeks after the onset of her vaccinal symptoms, but she had no other nerve symptoms.

Discussion.

It is to be noted that in this child vaccination was undertaken during the late stage of some infection of unknown nature. There is therefore some suggestion that the virus of the vaccinia may have activated another virus, and that the cerebral symptoms may have been the result of the combined vira. If so, the case conforms to the third of the three possible explanations, offered by the Committee above referred to, of the occasional occurrence of encephalitis-like symptoms following vaccination.

It cannot, on the other hand, be safely inferred that the cerebral symptoms were due to the virus of the original disease alone, because the striking effect of the mother's serum suggests the operation of specific vaccinal antibody in this serum. Albeit the possibility that the good effects of the serum may have been non-specific must not be lost sight of. Should opportunity occur it may be that a trial of normal horse serum would lead to a similar good result.

This child received four insertions, and all of them took well. There is a suggestion here that, whether the Committee's recommendation in favour of one insertion only during infancy (with revaccination at 5–7 years and at 14–16 years), be followed or not, it should certainly be followed in all children who are suspected of recent infections of whatever kind, and in all persons at the time of their first vaccination.

A FATAL CASE OF "POST-VACCINAL" ENCEPHALITIS.

By John F. Taylor, M.D. Camb.,
PATHOLOGIST, ST. GEORGE'S HOSPITAL, LONDON.

The following case of a disease which is attracting considerable public attention at the present time seems worthy of record.

Story of the Case.

C. D., a maid-servant, aged 31, had for two or three years suffered from "anæmia, rheumatism, and menstrual trouble," but was able to carry out her duties. On May 22nd last she was vaccinated *for the first time.* "Government" calf lymph was used and it appears that 29 other persons, including C. D.'s mistress, were vaccinated from the same batch of phials without any ill-effect. C. D.'s vaccination "took" well and pursued its normal course, the arm was kept covered, and the dressing changed from time to time. On June 3rd, 12 days after the vaccination, she felt unwell on waking in the morning, vomited once, and stayed in bed, but as she had had similar attacks before no alarm was felt. In the afternoon she was found to be semi-conscious. On the following day, as she was unconscious and could not be roused, she was admitted to St. George's Hospital under Dr. Anthony Feiling.

On admission: Pallid, unconscious, but moved all limbs when pinched or pricked and resisted movement. The eyes were half open; pupils small and equal, reacted sluggishly to light; fundi not well seen. Reflexes: biceps, triceps, and supinators present, abdominal not obtained. Knee- and ankle-jerks brisk, plantar response flexor. Kernig's sign not present. No spasticity, no head retraction. Nothing abnormal detected in heart, lungs, or urine. Temp. 104·5° F. Pulse 120. Resp. 40.

On June 5th coma deeper. Complete flaccid paralysis of lower limbs. Incontinence. The eyes now showed a well-marked divergent squint. Right pupil larger than left and showed no reaction to light, left pupil reaction very sluggish. Knee-, ankle-jerks, and plantar response absent. Many coarse râles all over lungs. At intervals there was a fine chattering of the lower jaw with about 150 movements per minute. A diagnosis of acute encephalo-myelitis was made. Lumbar puncture was performed. The fluid was under pressure and opalescent; it was examined by Dr. E. L. Hunt who reported: "Slightly cloudy fluid containing a small contracted clot. Centrifuged deposit, blood present. An excess of leucocytes, not marked; polymorphs and lymphocytes (latter 40–45 per cent.). No organisms found. Sugar: Well marked reduction. Globulin: no excess. Albumin: opaque cloud. Cultures: sterile." Temp. 103°–104°. Pulse 100–110. Resp. 35–45.

On June 6th coma was still deeper but there was very slight response to pricks on arms and face. Biceps, triceps, and supinator reflexes present but all others absent. Slight cyanosis. Temperature, pulse, and respiration as before. Death occurred at 4.30 A.M. on June 7th, about four days after the first appearance of symptoms. Treatment had consisted of cold sponging, nasal feeding, and stimulants.

Post-mortem Appearances.

An examination made 8½ hours after death showed the body of a well-nourished woman. On the left upper arm were two healthy vaccination scabs with no local swelling or inflammation. The serous sacs contained no excess of fluid. Heart normal. Lungs: some early fibrinous pleurisy at the left base. Nodules of inactive fibro-caseous tuberculosis at both apices. Intense congestion and œdema with early hypostatic consolidation at bases. Liver congested. Spleen congested but rather soft. Kidneys: cortex cloudy, general congestion. Bladder distended with urine. Brain: some general swelling shown by flattening of the cerebral convolutions; a well-marked "pressure cone" on the cerebellum. No meningitis but the surface was everywhere intensely congested and of a cherry red colour. On section some increase of fluid in the ventricles was noted. The internal vessels were also intensely congested but no hæmorrhages were apparent to the naked eye. Spinal cord: intensely congested and somewhat softer than normal throughout its length. The other organs showed nothing abnormal.

A preliminary microscopical examination has been made of sections of the basal ganglia, crus cerebri, lumbar cord, and kidneys. No meningitis is present, all vessels are intensely congested. In all the sections foci of cellular reaction are seen. These are always related to vessels and form a scattered and rather widespread zone around them. No such foci are found apart from vessels. The cells resemble endothelial cells in size and shape and have fairly clear oval nuclei. The perivascular sheaths are as a rule empty but some contain a few cells of lymphocytic type. No polynuclear cells are seen. One very small hæmorrhage was noted in basal ganglia. In the more intense foci many of the ganglion cells show degeneration of varying degrees. Areas of demyelination of nerve-fibres were noted particularly in the section of the cord.

The kidneys showed intense congestion of the glomerular tufts and moderate congestion with a few small hæmorrhages elsewhere. The convoluted tubules showed well-marked degeneration of the epithelium in contrast to the deeper tubules which appeared healthy.

Commentary.

These findings appear to me quite consistent with those recorded in other cases of post-vaccinal encephalitis. The main points of difference from acute anterior poliomyelitis and epidemic encephalitis lethargica are:—

1. The distribution of the lesions throughout both brain and cord.
2. The foci of inflammation tend to be larger and are all related to vessels but the perivascular sheaths are practically free from cells.
3. The predominant cell is of an endothelial not a lymphocytic type.
4. The demyelination of nerve-fibres is marked.

The precise ætiology of these cases is not yet clear and I do not propose to embark upon a discussion of theories, but certain points seem to be established and to be supported by this case: (1) Encephalitis (with possibly very rare exception) follows primary vaccinations only. (2) It does not occur after unsuccessful vaccination. (3) There is no evidence that it is due to a secondary infection. (4) It is independent of the method or animal used in preparing the lymph. (5) Very young children seem to escape this complication.

I wish to express my thanks to Dr. Anthony Feiling for providing me with the clinical details of the case, and to Dr. E. L. Hunt for his report on the cerebro-spinal fluid.

ORAL IMMUNISATION AGAINST TYPHOID IN SOUTH AFRICA.

By Eustace Cluver, M.D., D.P.H.,
ASSISTANT HEALTH OFFICER FOR THE UNION OF SOUTH AFRICA.

Of the seven million persons resident in the Union of South Africa, five and a half million are non-European, the great bulk of whom are uncivilised. This large non-European population is the reservoir from which the towns and industries of the Union draw their unskilled labour. These people in general have little conception of hygiene, and unless carefully supervised will congregate in the towns under grossly insanitary conditions. Typhoid fever, so closely associated with insanitation, is therefore rife amongst them. It is prevalent not only among natives living under urbanised conditions in close association with Europeans in the towns, but also in the kraals, where conditions are also often grossly insanitary. Many of the smaller towns have primitive sanitary services, with badly conducted, single-pail night soil systems, abundance of flies, and exposed and untreated water-supplies.

TABLE I.

Year.	Typhoid notifications.	Year.	Typhoid notifications.
1923 ..	4163	1926 ..	4454
1924 ..	3859	1927 ..	4018
1925 ..	4390	1928 ..	5787

The Union Health Department is actively engaged in improving sanitary conditions by a system of health inspections, general advice, and other propaganda. But in the meantime typhoid continues to take a heavy toll. Notifications of this disease during recent years in the Union are shown in Table I.

The actual incidence of the disease is probably very much higher than indicated by these figures. Only a small proportion of natives living in country districts consult a doctor during typhoid; and unless some circumstance, such as exceptional severity, attracts the attention of the magistrate or district surgeon such cases go unnotified. On the gold mines of the Witwatersrand the annual incidence of typhoid per 1000 natives employed, except on well-conducted, sewered mines, is seldom below unity, and on sanitarily unsatisfactory mines it is generally over 5.

Vaccination.

Although sanitation is making steady progress throughout the Union, the high incidence of typhoid has called for more direct action. Inoculation by the injection method is impracticable on a general prophylactic scale, owing to the fact that a skilled process, which can only be carried out by members of the medical profession, is involved, and to the resistance offered by natives to a somewhat painful proceeding. Natives in general are, however, curiously willing and even eager to absorb medicines ("Muti") by mouth. The method devised by Prof. Besredka of orally administering the vaccine in combination with a gall pill presented a method of general prophylaxis very acceptable to the native.

The vaccine is being prepared on a large scale by the South African Institute for Medical Research. At first it was supplied only as a suspension of killed *B. typhosus*, *B. paratyphosus* A and *B. paratyphosus* B (in much greater concentration than that used in the ordinary T.A.B. vaccine), together with pills of of ox-bile, coated with keratin in order that they might pass through the stomach undissolved and prepare the intestine for the absorption of the injected vaccine. A teaspoonful of the vaccine (well shaken before using) is administered along with one of the bile pills on each of three successive mornings before any food has been eaten. The Institute first started the routine manufacture of this vaccine in April, 1925. The suspension is still being produced and is being used for mass prophylaxis on certain mines. Since May, 1928, the vaccine has also been put up in the form of pills, and it is in this form that it is being issued to medical practitioners and local authorities. Twelve different strains are used in its preparation. Each strain is cultivated separately in broth medium for about 24 hours at 37° C. To the broth culture 0·5 per cent. formalin is added and allowed to act overnight. The medium is then centrifugalised and the sediment is dried in the incubator, after which it is ground in a grinding machine. From the powder the pills are prepared, each pill containing 0·015 g. of dried bacilli which is approximately equivalent to 45,000 million organisms per pill. Vaccine for oral administration is also being prepared, put up in pill form, by at least one private laboratory. Altogether the number of triple doses of this oral vaccine issued by the South African Institute for Medical Research up to the present is, in the form of suspension, 31,141, in the form of pills 17,154.

Experience on the Mines.

The first large-scale experiment with oral vaccine in this country was made on a Mine "A" in the Germiston area.[1] This mine has two compounds about a mile apart, one housing 1850, the other 1750 natives. A typhoid outbreak (probably fly-borne from unknown carriers, the mine using the conservancy system) commenced on the mine in November 1922. Oral vaccination was performed between Jan. 4th and 12th, about 3500 natives being vaccinated and about 100 being missed. The total number of cases admitted to the mine hospital during the outbreak was 53. Of these, 33 were admitted previous to Jan. 4th, and 20 between Jan. 4th and Feb. 24th. After that no further cases were admitted for several months. Of the 20 cases admitted after vaccination had commenced, four had not been vaccinated. The remaining 16 were admitted late in the disease, which suggests that they were in the incubation stage when vaccinated. The great bulk of the natives employed on the Witwatersrand gold mines serve a contract of a year or less. At the end of 12 months very few of the vaccinated natives were left on this mine; and in October, 1923, another typhoid outbreak occurred in the same mine. The natives were again vaccinated and the outbreak brought to an end. Since that date all recruits arriving on this mine have been vaccinated by the oral route, and the annual incidence per 1000 has dropped from 23·3 in 1923 to 10·4, 10·1, 5·2, 4·0, and 4·7 in the succeeding five years. Though typhoid still occurs on the mine its incidence during the past three years has been low for a mine with an unsatisfactory conservancy system and generally very unsatisfactory sanitary conditions. Its present typhoid incidence compares very favourably with that of a mine ("B") in the neighbouring municipality where conditions are in every way comparable, except that routine oral vaccination is not carried out.[2]

TABLE II.—*Typhoid Incidence on Two Mines on the East Rand.**

Year.	Mine.	Cases.		Deaths.		Average number employed.
		Admissions.	Per 1000	No.	Per 1000	
1927 ..	A B	13 127	3·98 11·57	4 30	1·22 2·73	3,291 10,978
1928 ..	A B	16 115	4·74 9·72	4 46	1·19 3·89	3,373 11,826

* With similar conditions except that at mine "A" all native recruits are treated with oral vaccine.

Oral vaccination is being very strongly urged by the Union Health Department on all mines where the sanitary removal system continues to be unsatisfactory. On sewered mines typhoid has virtually disappeared, and its incidence on mines with a satisfactorily conducted dual pail system is very low.

Routine oral vaccination on sanitarily unsatisfactory mines has not caused the disappearance of typhoid, but the incidence has been very greatly reduced.

Experience of Local Authorities.

As mentioned above, sanitary conditions in some of the smaller towns of the Union, particularly among the native populations, are often grossly unsatisfactory. In such towns sanitary improvements are being urged by the Department; but in the meantime, especially in the face of an epidemic of typhoid, mass vaccination is being recommended.

In three municipalities in which the typhoid incidence was high during the year ended June 30th, 1928, mass oral vaccination was introduced early in 1928, and by the second half of the year the typhoid incidence had fallen to relative insignificance. (Table III.)

TABLE III.—*Typhoid Incidence in Three Towns in which Mass Oral Vaccination was Introduced during the First Half of 1928.*

Municipality	Cases during 12 months ended June, 1928.	Cases during 6 months ended December, 1928.
Heilbron ..	97	0
Ermelo	120	3
Bloemfontein ..	48	13

Similar results have been obtained in other municipalities where it was been possible to inoculate the bulk of the population at risk. Very good results have been obtained in Pretoria.[3]

Conclusions.

The experience on the mines and in urban areas of the Union of South Africa, although observations have not been made on strictly experimental lines (no satisfactory control experiments having been practicable), would yet appear to indicate very definitely that the degree of immunity established by the oral method of administration of the vaccine is at least equal to that obtained by subcutaneous inoculations. The immunity appears to be established more quickly. Oral vaccination has two very important advantages; the subjects, particularly natives, are generally much more willing to take "medicine" by mouth than by injection with a needle; no malaise follows oral administration, whereas unpleasant sequelæ often occur with subcutaneous inoculation.

NORTH OF ENGLAND GYNÆCOLOGICAL AND OBSTETRICAL SOCIETY.

A MEETING of this Society was held at Leeds on May 24th.

Vaginal Examinations and Puerperal Infection.

Dr. A. M. CLAYE read a paper on the Puerperal Morbidity-rate in Cases Delivered Normally; a Comparison between Cases Examined Vaginally and Cases not Examined Vaginally. He said that a series of 1546 normal cases at the Leeds Maternity Hospital had been investigated, the following being excluded from the normal category: (1) all cases requiring intra-uterine manipulation or instrumental assistance during labour; (2) all cases where there was any obvious predisposing cause of puerperal sepsis—e.g. ante- and post-partum hæmorrhage; and (3) all cases of puerperal pyrexia due to definite extragenital causes. Cases with perineal tears were classed separately to avoid confusing the issue. Cases admitted to the hospital in labour from outside sources were excluded owing to lack of definite information about vaginal examinations before admission. The morbidity-rate in this class was abnormally high.

The remaining normal cases had been classified according as they were examined vaginally or not, and the puerperium had been described as:—(1) *morbid:* Ministry of Health standard of puerperal pyrexia; (2) *submorbid:* where the temperature reached 99 °F. or more at least twice during the 21 days following delivery; and (3) *normal:* all apyrexial cases, cases where the temperature never reached 99°, and cases where the temperature reached or exceeded 99° on one occasion only. The temperature was taken in the axilla in all cases.

The vaginal examinations had been done in almost all cases by pupil midwives under the supervision of the labour ward sister in order to comply with the existing rule of the Central Midwives Board, which required pupils to perform a certain number of vaginal examinations. The patient's vulva was shaved on admission, the examiner wore boiled gloves, and antiseptic precautions were observed during the examination. The results were as follows:—

CASES WITHOUT PERINEAL TEARS.

Cases Examined Vaginally, 309.

(*a*) Number morbid..	7	or 2·3 per cent.
(*b*) Number submorbid	21	or 6·8 ,,
Total (*a*) + (*b*)	28	or 9·1 ,,

Cases not Examined Vaginally, 778.

(*a*) Number morbid..	10	or 1·3 per cent.
(*b*) Number submorbid	41	or 5·3 ,,
Total (*a*) + (*b*)	51	or 6·6 ,,

The above figures showed that the total morbidity-rate was one and a half times as great for the cases examined vaginally.

CASES WITH PERINEAL TEARS, 459.

(*a*) Number morbid	12	or 2·6 per cent.
(*b*) Number submorbid	50	or 10·9 ,,
Total (*a*) + (*b*)	62	or 13·5 ,,

Probably in cases examined vaginally the increased morbidity-rate was due to the finger moving infected matter from a comparatively safe position in the vagina to a dangerous position within the cervix rather than to the introduction of new organisms. Dr. Claye thought that rectal examination could replace vaginal examination except in the following groups: 1. Cases of antepartum hæmorrhage. 2. Cases where it is important to know the exact size of the os, and this cannot be gauged by the rectum; these are mainly breech presentations. 3. Cases where the doctor has been called in during labour to a patient whom he has not seen before where he cannot decide on the proper treatment without vaginal examination—cases of incompatibility between the head and the pelvis. 4. Cases where the doctor is about to resort to operative treatment. He maintained that the amount of dilatation of the os could nearly always be determined from rectal examination and that this method could also determine the presence of the bag of membranes, prolapse of the cord, and a face presentation. As far as midwives were concerned, their duties under the four indications given above (of which numbers 3 and 4 did not apply) were clear. In antepartum hæmorrhage they had to summon medical aid. In breech presentations, unless uncomplicated, they had to summon medical aid, and no one could be certain that a breech would be uncomplicated until delivery was in progress. He therefore held the opinion that it was not necessary for midwives to make vaginal examinations and that they should be forbidden to do so.

Prof. CARLTON OLDFIELD said that he considered most severe infection was conveyed from outside. He had rarely seen a case of severe infection where no vaginal examination had been made and could not recollect a case of infection where rectal examination only was used. He considered that the main danger lay in doctors and senior nurses who did general work and made vaginal examinations.

Mr. WILLIAM GOUGH said that in Leeds Maternity Hospital they had given up lysol for biniodide and only allowed rectal examinations. In Berne it had been found that this halved the morbidity-rate in the Berne Maternity Hospital, and this institution refused to admit patients who had been examined vaginally outside.

Dr. W. W. KING (Sheffield) said that he had analysed 457 of his own cases. Fifty-five had been examined vaginally and of these one was morbid (1·9 per cent.), but this patient had had a manual removal of the placenta. Four hundred and two had been examined rectally only; of these two were morbid (0·5 per cent.). He considered this group of vaginal examinations too small to be of much value, but using Dr. Claye's classification the one morbid case in this group would be excluded on account of the interference necessary and therefore there would be a higher morbidity-rate with rectal examinations. He pointed out therefore that figures alone could be made to show anything.

Mr. WILLIAM GOUGH showed a specimen of

Hyponephroma of the Ovary.

The patient was a married woman aged 25. She had been normal as a child. When seen she had a deep bass voice and had to shave daily. The menses had appeared at the age of 13 and were regular up to the age of 20 when they ceased, and the changes in secondary sex characteristics began to appear. Her sexual feelings were normal. A mass, separate from the uterus, was found in the left iliac fossa and there was some free fluid. On August 25th, 1928, abdominal section was performed. Two or three pints of straw-coloured fluid escaped and a tumour of the left ovary, which had no adhesions, was removed. It was of a bluish colour with pinkish orange excrescences on its surface. The right ovary and uterus were normal and there were no swellings in the kidney regions. The tumour was reported as a typical hypernephroma.

Twenty-eight days after operation (said Mr. Gough) the menses appeared. They next occurred a fortnight later and thereafter were regular. As the patient had last menstruated on April 6th, 1929, she might now be pregnant.

Dr. **Clara Stewart** said the tumour was a simple benign hypernephroma exactly similar in structure to an adenoma of the adrenal gland.—Dr. **Leith Murray** (Liverpool) asked if male characteristics occurred with unilateral renal hypernephromas, and said that he thought Glynn asserted that they only occurred with bilateral tumours. He (Dr. Murray) had seen a case of sudden change in sexual characteristics in a woman aged 25 in whom no abnormalities in pelvis or renal areas could be found. He asked if the cells in this case could be paralutein cells.—Dr. **Stewart** said she did not consider that the cells showed the characteristics of paralutein cells. It was not necessary for the tumours to be bilateral to cause changes in sexual characteristics.

Miss ***Ruth Nicholson*** *recorded two cases of*

Pyometra.

The first patient was a single woman, aged 49, whose chief complaint was a constant vulval irritation for four to five years and more recently a vaginal discharge. She had had cystitis as a child. The periods commenced at 14 and had always been irregular and scanty. She had not menstruated at all for the last five years. On bimanual examination thickening and fixation of the appendages was felt and a diagnosis of tuberculous salpingitis was made. At operation very marked adhesions were found. The tubes were nodular, closed, and adherent to the ovaries. Panhysterectomy was performed. When the uterus was opened the cavity was found to be filled with a thick yellow pus. Microscopical sections showed typical giant-celled systems.

The second patient was a woman, aged 70, who had had a high amputation of the cervix eight years previously. She complained of a yellow discharge, partial rectal obstruction, and some vaginal hæmorrhage. A mobile, solid mass about the size of an orange was felt continuous with the cervix. At operation the uterus broke away, at the point where the previous amputation had been done, as soon as the vessels and cellular tissue had been cut across. The specimen showed the uterine cavity distended with pus and lined with granulation tissue. Microscopically there was no evidence of malignant disease.

Dr. D. W. E. **Burridge** recorded a case of

Puerperal Infection with Bacillus welchii.

The patient was a primipara, aged 39, admitted to hospital with a diagnosis of prolonged labour and vomiting. Labour began on March 21st, 1929, and on admission on the 25th her general condition was good (temp. 98·4° F., pulse 88). Vomiting had ceased, no pains were present, and the uterus was not tender. No fœtal heart sounds could be heard. The cervix was 5 shillings dilated but not fully taken up.

There was no change on the 26th, but by the morning *of the 27th she was seriously ill, restless, of toxic appearance,* and with a rising pulse. By noon the pulse was 120, the abdomen was distended, and the uterus tender. Preparations were made to assist the uterus to empty itself. The cervix was now half dilated and an unsuccessful attempt was made to dilate it manually. This manipulation allowed the escape of a quantity of highly offensive gas, and some foul, frothy brown fluid. As immediate evacuation of the uterus was inadvisable axis-traction forceps were applied and a weight of 7 lb. was attached to the traction rods over a pulley. Pituitrin, 4 minims, was given at ¼-hourly intervals for five doses. These measures were successful and by 5 P.M. the child's head was born. There was considerable difficulty with the delivery of the trunk owing to the enormous gaseous distension of the abdomen. After delivery there was a free escape of browny frothy fluid and much gas but no hæmorrhage. Swabs from the interior of the uterus, umbilical cord, and fœtal abdomen gave a good growth of *B. welchii*. The patient stood delivery well but in the evening restoratives were necessary. On the next morning *she was a little better but the placenta was still in the uterus.* It was left alone as it was not causing symptoms.

On March 28th 10 c.cm. of Weinberg's anti-gas-gangrene serum and 40 c.cm. antistreptococcal serum were given. Further doses of anti-gas-gangrene sera were given on the 2nd, 3rd, 4th, 5th, 6th, 8th, and 11th days of the puerperium. Attempts to express the placenta on the 4th and 5th days of the puerperium were useless but very painful. The patient remained in extremis for four days after delivery and a change was then noticed; once this was manifest the progress towards recovery was remarkable, despite a vesico-vaginal fistula which became manifest on the 6th day. By the 17th day the uterus was down to the pubis and the lochia were scanty and non-offensive. The patient was sitting up on the 21st day and walked a few steps on the 35th day.

The main points of the case (said Dr. Burridge) were: (1) the absence of hæmorrhage; (2) the fact that the placenta was never recovered would suggest that it was liquefied; (3) the retained placenta might have prevented the spread of infection; (4) the value of anti-gas-gangrene serum.

Dr. E. O. **Croft** remarked on another case in which a weight and traction rods were used to secure delivery.

Prof. **Oldfield** mentioned a case of full term ectopic pregnancy in which the child was extracted but the placenta never came away. Later this patient had an operation for ventral hernia and no trace of the placenta could be found.

Dr. J. E. **Stacey** (Sheffield) commented on the method of delivery as being useful in cases where there were no pains, and a dead child, in the presence of infection of the mother.

Dr. **King** had had three cases of *B. welchii* infection, in none of which the patient had recovered. He thought the conduct of labour in this case had been admirably conservative. The idea of forceps plus a weight was valuable, but it had its dangers, as witness the vesico-vaginal fistula in this case. In his opinion labour ceased because there was an œdema of the uterine muscle which caused paralysis. He had had a case in which he left the placenta in situ and on the 10th day a piece about the size of five shillings was passed and that was all. He considered that in the presence of a gas-forming organism tissue destruction must be much more rapid.

Dr. **Murray** had seen two cases of gas-gangrene infection both of which were fatal. The distressing feature he noticed was that the patients were acutely conscious to the end.

Dr. **Bailey** had seen a number of cases of retained placenta. He always left the placenta alone in the absence of symptoms. Altogether he had had about 30 cases and quoted some in which the placenta came away at varying intervals from 30 hours to 6 days, and one case where the woman would not allow him to examine her or see the lochia. In this case, to the best of his knowledge, the placenta never came away. She was seen in his surgery two months after her confinement, quite well.

Prof. **Carlton Oldfield** reported two cases of

Entero-vesical Fistula.

The first patient was originally seen in 1914, when a diagnosis of diverticulitis was made and a pelvic abscess drained by posterior colpotomy. In 1928 the patient had three attacks of pain at different times, and after the third attack began to pass fæces and flatus from the bladder. This made the speaker still more certain that the condition was diverticulitis. The patient now had so much trouble that something had to be done. No information was obtained from cystoscopy. Abdominal section was performed and very dense adhesions found. Eventually the bladder, uterus, and sigmoid were separated, and a stony hard swelling was found adherent to the uterus and sigmoid. This was eventually separated, leaving a hole in the sigmoid and a track lined by granulation tissue was found leading down to the bladder. The track was scraped and the hole in the sigmoid closed. The patient later developed obstruction which was relieved by a cæcostomy and thereafter she made a good recovery. The report on the nodule was "typical, caseating, active tuberculosis; some parts of ovary, and plain muscle are present." Prof. Oldfield thought that the original lesion must have been tuberculous salpingitis. The second case was one in which a vesico-vaginal fistula followed a Wertheim's operation. The fistula was repaired and a few days later urine was being passed per rectum. No further treatment was undertaken for this patient and she remained quite well. Her only disability was the necessity for frequent bowel actions to pass urine.

in the text illustrate the habitat and associations of the plants described. The English botanist will find included a large proportion of his native flowering plants and grasses as well as the alpine and sub-alpine species with which he meets on his holiday tours. Obviously no public library would be complete without a copy of this work, and to any lover of flowers it will afford a never-ending source of enjoyment. The total cost up to date of the twelve volumes in paper covers is 369 marks, or bound in linen boards 406 marks, and it is understood that the price will be raised as soon as publication is complete.

PEDIATRICS FOR THE GENERAL PRACTITIONER.

By H. M. McCLANAHAN, M.D., Professor of Pediatrics, University of Nebraska. London: J. B. Lippincott Company. 1929. Pp. 606. 25s.

THIS book differs in some respects from the majority of pediatric text-books of similar size; it is written for general practitioners rather than students, and deals fully with practical points of diagnosis and treatment while little space is devoted to pathology. It is profusely illustrated by photographs and radiograms. A praiseworthy amount of attention is paid to the characteristics of the normal child, and to the details of breast feeding. The author believes that the degree of attention which has been focused upon complicated methods of artificial feeding has led to some neglect of breast feeding. He includes a short description of percentage feeding. The common disorders of childhood are treated clearly and practically, though the distribution of space is somewhat uneven. Rickets, for instance, is treated too briefly, and no mention is made of irradiated drugs. On the whole the book is satisfactory.

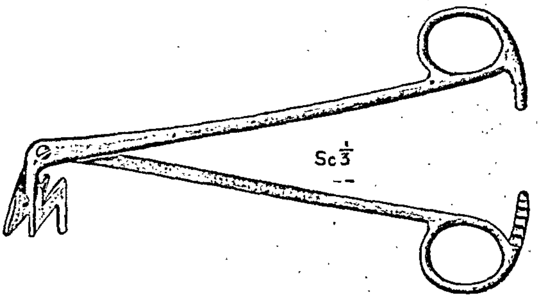
JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE.—Various aspects of the cost of illness to industry are considered in the issue for April. The first paper is by E. W. Phillips dealing with tuberculosis in an industrial group. Free medical service without special attention to prevention and detection of tuberculosis did not control the disease. The group of workers concerned were railroad employees, among whom the annual tuberculosis rate was about 1 case in 800. It costs on an average 4600 dollars to put an advanced patient in condition to resume work; a moderately advanced case costs about 1050 dollars, and an early case about 450 dollars. At the same time the mortality in the advanced cases, within four years of detection, was nearly 40 per cent.; while all the moderately advanced and early cases recovered and were able to return to work. The occurrence of nervous illness in industry is discussed by Millais Culpin, who points out that such industrial neuroses as cramp among telegraphists, which he has specially studied, and miners' nystagmus are really only particular manifestations of the existence of a large mass of nervous individuals. A paper by him on Nervous Disease and its Significance in Industry has appeared in THE LANCET (1928, ii., 897).—The third aspect is the relation between lead absorption and compensation, which is presented by M. R. Mayers. It is based on a physical examination of 381 lead workers. Of these, 149 were suspected of lead absorption, but when laboratory methods were applied in 39 cases no basis for the clinical diagnosis was found. On the other hand, among the 232 cases free from any clinical suggestion of lead absorption, laboratory research showed that in 112, or almost half, active lead absorption was taking place. The conclusion drawn is that when laboratory research supports clinical symptoms the case is undoubtedly one for compensation. When there are no clinical symptoms, even though laboratory research indicates lead absorption, there is no disability, and so no case for compensation. The doubtful cases are those where laboratory research shows no absorption, but where there is disability on clinical grounds ascribable to lead. Most of these cases probably are not associated with lead poisoning, hence compensation should not be awarded.

New Inventions.

PERITONEAL TETRA-TOWEL FORCEPS.

THE use of tetra cloths is now regarded as almost an essential in the technique of abdominal operations. The difficulty is suitable forceps. The forceps shown in the figure overcomes many difficulties. It lies flat under the tetra cloth as it has an abdominal curve. Its bite is also horizontal and dips vertically into the wound over the skin edge. The fixation of the towel to the peritoneum is broad and does not damage or tear the peritoneum, and the instrument is sufficiently large to prevent possible loss in the abdomen. Two forceps on each side are required for the average wound—the proximal two are attached by the operator with the assistant holding the peritoneal edge and towel edge in apposition, and the distal two are controlled by the assistant. These instruments are of particular help in Cæsarean sections.

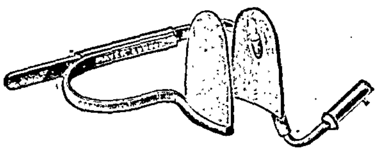


The forceps are made by Messrs. Allen and Hanburys, Limited, Wigmore-street, London, W.

W. McK. H. McCULLAGH, M.B., B.Ch. Belf., F.R.C.S. Eng.

ELECTRICALLY ILLUMINATED NASAL SPECULUM.

THE accompanying illustration shows a simple electrically illuminated nasal speculum. The light-carrier is of the Jackson type, set at an angle through the blade of the speculum, and can be removed for cleansing. The instrument is useful for bedside examination, when it is difficult to obtain a satisfactory light. The same principle could be applied to the Thudichum type of speculum.



The instrument is made by Messrs. Mayer and Phelps, Chiron House, New Cavendish-street, London, W.

JOHN E. G. McGIBBON, M.B., B.S. Lond., D.L.O. Eng.

Radon in Cancer of the Œsophagus.—Mr. Musgrave Woodman calls attention to an inaccuracy in our report of his remarks at the Royal Society of Medicine (THE LANCET, June 15th, p. 1250). When speaking of the external approach to the œsophagus by the operation of thoracotomy, he mentioned that few patients would be suitable for this treatment, but in contrast to this, almost all patients were suitable for the simple operation of introduction of radon through the œsophagoscope.

THE LANCET.

LONDON: SATURDAY, JUNE 22, 1929.

IE MEDICAL PROFESSION IN THE NEW PARLIAMENT.

HEN the last Parliament assembled early in 1925
ere able to publish the portraits of 12 members of
nedical profession who had become members of
House of Commons. We are happy to do the same
he new Parliament which meets on Tuesday next
the profession will have 18 representatives,
ding those in the House of Lords. They
ag to each of the political parties; they also, for
first time, include members of either sex. The
go of Government has caused Major WALTER
IOT to lay down his responsibilities for Scottish
rs in an office which he has discharged with
ked ability and enthusiasm and to the satisfaction
of his political opponents. But medicine has now
ger share of ministerial appointments than before;
ongratulate Dr. DRUMMOND SHIELS on his advent
he India Office where his experience of the not
imilar problems of Ceylon may be useful; and we
come the return to office of Dr. ADDISON, the
Parliamentary Secretary to the Ministry of
iculture.

he incoming Cabinet's programme of legislation
not be officially revealed until the KING's *Speech*
ead at the opening of Parliament. In the present
nce of parties we can expect no major measures
pt by way of compromise and consent. Parlia-
tary time in July must be devoted to completing
year's financial arrangements, of which last
ion's Finance Act was only a brief instalment. Un-
loyment, foreign affairs, and the mining industry
likely to demand full discussion. The Ministry of
lth will be busy with administrative changes due to
recent Local Government Act. Here our medical
bers will watch with special concern the effect
institutional facilities and upon our existing
m of voluntary hospitals. Shall we hear news at
f a new *Factories Bill? This project, so often*
ioned in previous King's Speeches, was the one
ted failure in the late Government's claim of
es fulfilled. Undoubtedly the past five years
seen several useful measures, of particular interest
medical profession, placed upon the statute-book
on the initiative or with the aid of medical
ers. The list includes the Public Health Act
5, the Therapeutic Substances Act, an important
l Deficiency (Amendment) Act, attempts to
te the smoke nuisance and lead paint poisoning
h these efforts fell short of what many desired),
roners (Amendment) Act of 1926, and the
ement of the law of death registration linked
ith, provision for the registration of nursing
amendment and consolidation of the Food
ugs Acts, and a re-statement of the poor-law
already demands a further revision. This
in itself an indication of increasing popular
in public health, was attained in a Parliament
ted by a docile and substantial majority such
not be seen again for several years. These conditions of party government have made us forget the difficulty of legislating in the absence of such support. Private members' Bills may have better *chances of success if both Houses of Parliament* decide to pursue recent suggestions for carrying over a Bill from one session to another. A great opportunity occurs in the field of local legislation for progressive health measures, some of which—as in a recent Edinburgh Corporation Bill—raise acute problems of medical treatment. One topic on which Parliamentary action is long overdue is the control of patent remedies. A Select Committee examined the evidence thoroughly and reported in 1914, but nothing has been done since. Other topics which demand attention are rivers *pollution and atmospheric pollution. Most important* of all, perhaps, is lunacy reform. Parliament has ignored the views of expert advisers and too little is done to combat the early stages of mental disease or to provide treatment for the cases which fall short of certification. Nor must the fact be ignored that certification itself, the key to the present processes of institutional treatment, will break down if the certifying practitioner, upon whose evidence a judicial order is made, is to be exposed to litigation and to such huge awards of damages as have been recorded in recent years.

The medical M.P. is elected, we all know, to represent a constituency, not to press the sectional claims of a particular profession; but he does not divest himself of *his special knowledge* when he goes to Westminster, nor will his contributions to debate on technical or professional subjects, if delivered with reason and moderation, fail to command respect. Some of these subjects will be controversial. Health insurance, vaccination, vivisection, the position of the unregistered practitioner—here are instances of past controversies from which the medical M.P., whatever side he takes, *could hardly stand aloof. Such instances will recur in* plenty; if it be only to conciliate the army of new feminine voters, Parliament must give increasing attention to the health of the family and to public hygiene.

◆

TRIAL LABOUR FOR THE SECOND CHILD.

A TRIAL labour is a labour experimentally allowed to proceed, though the obstetrician has reason to doubt whether a living child of normal size can be delivered at full term. The practice has arisen in recent years as an expression of the reaction which has followed the advocacy of induction before term or of Cæsarean section in all cases where grave disproportion between mother and child is suspected. The expectant attitude now adopted by many obstetricians must not, of course, be confused with the hearty optimism which moved practitioners of an older generation, when a patient came to book her confinement, to note in a diary the probable date, and to dismiss her with the cheerful assurance that all would be well. The essential feature of a trial labour is that it involves more anxious watching than any other method. It should never be conducted in the patient's home, but in an institution equipped and staffed for all emergencies. Its purpose is to save the individual patient from unnecessary interference, not only in her first but in subsequent labours.

Why are the devices for coping with disproportion, *which were held up as triumphs of obstetric art* not so long ago, being superseded in many clinics now by expectant tactics? Is it because serious drawbacks to these methods have lately become apparent or because experience has shown our criteria of measurement or our means of estimating the forces in labour to be unreliable? The new teaching postulates that in doubtful cases—and a good many fall into this category—the patient should be admitted into an institution where her labour can take place under supervision but with no interference in the early stages. If no progress is being made after a period to be determined by the observer and, in respect to which no directions appear to be laid down to guide the less experienced, Cæsarean section is to be performed, since high forceps are now universally condemned. It is claimed that in practice the operation is often found to be unnecessary, because the moulding of the head is so great that a live child is often delivered naturally when this outcome seemed most unlikely. We need seek no further reason for an alteration in obstetric tactics. We have all of us heard of infants emerging per vias naturales, even while preparations were being made for a Cæsarean section, and of the birth of a healthy, large child to a mother whose earlier pregnancies were artificially terminated at the eighth month; but we have assumed that the previous examinations had been conducted by an inexperienced or timid obstetrician, or that the cases were exceptional. Evidently, however, obstetricians have good reason to believe that in a considerable proportion of cases in current practice a prognosis founded on measurements and estimates is too gloomy, though they are unable to state precisely and quantitatively what extra allowance should be made in any given circumstances. It is possible that observation of large numbers of women whose trial labours have been uneventful will give a standard of probabilities which will save their sisters from uncertainty.

Has the point of view of the individual patient been sufficiently considered by the protagonists of trial labour? It would be interesting to learn the views of the educated prospective mother whose pelvic measurements are not normal on the proposal to subject her to a trial labour of uncertain duration or discomfort, which may possibly end in an abdominal operation. If the issues were plainly put before her, she would probably far prefer an induction after the eighth month for her first child, though she might be willing to try experiments for her second should the induced labour show considerable margin. The obstetrician may claim that the conduct of a labour is his responsibility, which cannot be shared with the patient. But her coöperation must be enlisted, not only because her consent to a confinement in an institution must be obtained, but because on her fortitude and patience the issue will largely depend. The desirability of submitting to a test which, even if it fails, will give information guiding the conduct of future pregnancies, is not likely to be considered at a time when the mind is concentrated on hopes and plans for this first child. The emotions aroused can hardly be expressed in terms of stress and strain, but the woman is conscious that if her first child is lost or spoilt the shock and distress may have a profound effect on her subsequent life. This anxiety for the first child is not the prerogative of educated women, whose sisters in other classes differ from her not in emotion but in articulateness. It is a point worth considering whether induction should not be continued as a routine for primiparæ with contracted pelves, reserving the trial labour for the second pregnancy should there have been an encouraging margin when the first child was delivered. Even more useful information would thus be obtained, and the patients would be more likely to face the ordeal without dismay.

VACCINATION DANGERS.

Headlines in daily papers during the past week have contained such phrases as The Death Roll of Vaccination; A Number of Poison Deaths after Vaccination; and Sleepy Sickness Opens New Controversy, which have instilled fear into such newspaper readers as are still susceptible to suggestion of this kind. A Society leader has publicly announced her satisfaction that none of her seven babies has been vaccinated, and the responsible chairman of an Irish Board of Health, when called on to deal with vaccination defaulters, is reported to have said, "I would not advise that proceedings be instituted against them at present in view of the reports that are current about sleepy sickness as a result of vaccination." While parents are still obliged to have their children vaccinated against small-pox, the gap left by conscientious objection has become so wide that in the town of High Wycombe, for instance, exemption was claimed for 93 per cent. of babies born in the last year on record. Is it possible, one may well ask, for the still small voice of preventive medicine to make itself heard above the noise and turmoil of the jarring elements? Prevention is always at a disadvantage, for it is continuously destroying the object-lessons which render its teaching effective. The Anti-vaccination League says that small-pox in England has for many years been a less fatal disease than chicken-pox, and invites us to conclude from this that vaccination is futile. But we may equally well regard the facts as evidence of its success. Vaccination would certainly be futile if small-pox were not a potentially killing disease, but the Registrar-General's figures for the last quarter, which have been regularly quoted in our columns, are a reminder of what punishment severe small-pox when it is reintroduced inflicts on the unvaccinated.

What are the incidents which have given rise to these scare lines? One is recorded by Dr. John Taylor, pathologist to St. George's Hospital, on another page of our present issue, where a healthy woman, 31 years of age, vaccinated on May 22nd, died on June 7th with post-mortem findings consistent, as Dr. Taylor writes, with those recorded in other cases of post-vaccinal encephalitis. Inquests have also been held in London on girls aged 10 and 14 years, in each of which death was regarded as due to encephalitis following primary vaccination. It was quite plain, as the Coroner for Westminster (Mr. Ingleby Oddie) pointed out in one of these cases, that there was nothing unsatisfactory in the lymph or in the method of vaccination or in the treatment of the arm. Whatever view may be taken by pathologists about the exact nature of the infecting agent, unhappily there is no reasonable doubt that these deaths must be regarded not only as post-vaccinal but to some extent as propter vaccinal. The main facts of this risk, as we now know it, were set out with care in a report by the Commission on Small-pox and Vaccination presented to the Health Organisation of the League of Nations at Geneva last August. The problem has arisen in consequence of the events of the last few years in the Netherlands and Great Britain. In the Netherlands 139 cases of disease of the central nervous system following vaccination were described during the period 1923–27, of which 41 were fatal; and in England and Wales during the two periods covered by the reports of the Andrewes (1922–23) and Rolleston (1926–27) Committees, 87 similar cases occurred, of which 48 were fatal. The period between vaccination and the onset of symptoms was usually between 9 and 13 days. In both countries a predilection of the disease for children of school age was noted, only 8 of the English series of 87 being under two years of age. Most of the cases in both countries occurred in children whose vaccination, judging from all ordinary signs and cutaneous reactions, had run a normal course. The Geneva report suggested further inquiry into the existence of post-vaccinal encephalitis in countries other than the Netherlands and England as an essential preliminary to the proper understanding of the causes which have operated to produce this disease in these two countries. Our own Ministry of Health has asked to be kept informed of all cases of central nervous disease in which vaccination had been performed within four weeks of the onset. If, however, the fact of recent vaccination were made obligatory on the certifier, a retrospective investigation of fatal cases would still be possible. The Commission spoke of the minute risk of encephalitis in proportion to the vast numbers of normal vaccinations, a point emphasised in the Rolleston Report by the statement that 51 deaths were reported in a period during which approximately two million vaccinations and revaccinations were performed at the cost of the rates and more than three million charges of Government lymph were issued. Crucial indeed is the fact that disease of the central nervous system is a complication of the utmost rarity among infants vaccinated under the age of two years and of equal rarity after revaccination of older children or adults. In the Netherlands primary vaccination at school age was the rule, but the experience of 1923–27 was sufficient to shake official satisfaction with this method and to occasion a temporary suspension of the administrative measures on which vaccination at school age rested.

Infancy is a dangerous adventure but vaccination happily is not one of its major risks, and the inconvenience it produces might be mitigated. The Rolleston report made a suggestion, warmly endorsed by Mr. ODDIE at one of the recent inquests, in favour of limiting the number of vaccine insertions at each operation. It does not appear to have been determined on any adequate scale what is the smallest amount of virus sufficient to produce immunity, but the report regarded the probable loss of duration of individual immunity, being the result of substituting a single for multiple insertions, as fully compensated by the readier acceptance of vaccination. Dr. G. H. HART and other medical officers of health have long protested that it is a mistake to insist on four insertions, believing that the practical difficulty in obtaining consent to vaccination would largely disappear if the milder method were permitted. But public vaccinators, it seems, have not yet been given discretion in the matter as a sequel to this recommendation. The argument for infant vaccination has been immensely strengthened by the immunity it gives not only against small-pox but against the worst danger (rare though it is) of primary vaccination later. It may be that in the years immediately following on infancy encephalitis, if it should occur may take on a milder aspect. The interesting case recorded in our columns this week by Sir THOMAS HORDER gives some hope in this direction. A boy, 4½ years old, who became drowsy on the eighth day after a primary vaccination and was stuporous on the eleventh, recovered rapidly after intrathecal injection of 5 c.cm. of the serum of his mother who was vaccinated on the same day as the child. This child, who was suffering from a febrile disorder of four days' duration at the time of vaccination, received four insertions of vaccine, and Sir THOMAS remarks that whether the Committee's recommendation of one insertion only during infancy (with revaccination at 5–7 years and at 14–16 years) be followed or not, it should certainly be followed in all children who are suspected of recent infections of whatever kind. The position of small-pox vaccination is unique. As the sole established instance of the use of a living virus as an immunising agent it presents difficulties. We have much sympathy with Mr. ODDIE's view that the recommendations of the Rolleston Report should receive the attention they merit.

Annotations.

"Ne quid nimis."

RIVERS POLLUTION.

LAST month's conference on the pollution of streams and rivers by town sewage and trade refuse did something to press upon public attention a subject too easily forgotten. Just as it is lamentable that, while one Government department is interested in smoke abatement and a purer atmosphere, another department sanctions the establishment of a fresh source of pollution in the Battersea power-station, so it is lamentable that some of our administrators should have imported a great continental industry like sugar-beet cultivation without forethought of the effect of the trade wastes from sugar-beet factories upon streams of which others of our administrators are concerned to secure the purity. A fresh threat to rivers where salmon still abound is to be noticed especially in the County of Devon. The multiplication of garages, usually swilled out every morning, sends oil in ever greater quantities into public sewers or storm-water drains; if it does not actually destroy the fish in the rivers, or drive them back to the sea, it spoils the gravel banks and sedges where the immature fish find their food. On the bigger issues other questions arise. Are we devoting enough time and money to research? Are we solving the problems of particular trade effluents, trade by trade? Cannot more be done to fix standards and enforce them? Can we not make up our minds what is the duty of the local authority in respect of providing means of disposal, and whether the trader is or is not to have a right to discharge his waste into public sewers? To turn a topic over to examination by a Royal Commission is notoriously a process of postponing action. Almost a generation ago the Royal Commission on Sewage Disposal made its recommendations, yet little or nothing has been done. Some say the law is sufficient if it were only administered effectively; others say the law is useless in itself. Several instances of expensive and protracted litigation have probably discouraged local authorities from further effort. When the Joint Advisory Committee on Rivers Pollution had reported, the Ministry of Health urged the formation of Joint Watershed Committees. Is it because of jealousies among the local authorities or because of other preoccupations at the centre that results are so slender? Should the central authority be armed with fuller powers to give final decisions without reference to the law-courts, and should that central authority be the Ministry of Health or some other body old or new? The public knows that the state of its rivers is getting steadily worse, though pollution seems to be successfully combated in particular cases. In spite of the necessity of not hampering commercial undertakings, the public wants its rivers clean. If the demand is not yet very loud, it will grow louder, for there is increasing interest in the preservation of the country's amenities. When the demand is loud enough, something will have to be done. The task will be easier if tackled now.

COMPARATIVE ANATOMY OF THE CEREBELLUM.

THE Herter Lectures at the Johns Hopkins Medical School were given last winter by Dr. Iven Ingvar[1] of the University of Lund in Sweden. The first was entitled the Phylogenetic Continuity of the Central Nervous System, the second was devoted to a discussion of the function of the cerebellum, and the third dealt with the pathological changes underlying the phenomenon of the Argyll Robertson pupil. The chief interest undoubtedly centres in the first lecture. Phylogenetic continuity is an established principle of anatomy, but while the discovery of homologies in different species is often regarded as an end in itself, the principle is capable of being used as a means of elucidating obscurities in human anatomy, and Dr. Ingvar has thus used it in an endeavour to discover the primary anatomical divisions in some difficult parts of the central nervous system, particularly in the cerebellum and in the thalamus.

His comparative studies of the cerebellum were already well known to neurologists. In the human cerebellum the old anatomists found various divisions to which, without any knowledge of their significance or relative importance, they gave fanciful and picturesque names—vermis, pyramis, tonsilla, nidus avis, and so on—with which our memories are still burdened. Yet these names were for centuries only veils to cover ignorance and hampered rather than assisted the understanding of the organ's nature and function. In the nineties of last century the embryological studies of various English workers—Stroud, Bradley, Elliot Smith—brought a new knowledge of cerebellar anatomy, and with Bolk's comparative studies yet another advance was made. Bolk's merit is that he revealed in the cerebellum throughout the mammalian class a constant morphological system; he taught that in all mammals it was formed on the same uniform principles. In all mammals the deepest of the transverse fissures of the cerebellum is the "primary sulcus"—the sulcus which is the first to appear during embryological development, the mass in front of this sulcus Bolk called simply the anterior lobe and all that developed caudal to it he called posterior lobe. The anterior lobe is subdivided in all mammals into four lobules. The posterior lobe presents more difficulty; its rostral (or anterior) portion has the same plain pattern as the anterior lobe and Bolk called it the lobulus simplex. Behind the lobulus simplex two sagittal fissures divide the main mass of the posterior lobe into a medium portion (the inferior vermis), which Bolk called the lobulus medianus, and two lateral portions, the lobuli laterales (the cerebellar hemispheres of the old terminology). Ingvar has endeavoured to carry Bolk's work a stage further. Surveying the cerebellum throughout the vertebrate phylum he concluded that another sulcus separating off the most posterior part of the vermis, with its attached flocculi, was an elemental one. He consequently gave the name posterior lobe to the portion separated off by it, and the structures between it and the primary fissure he called the middle lobe. We may observe that Elliot Smith, from a study of the embryology of the cerebellum, had made a similar division nearly twenty years earlier. Ingvar's division, whilst nearly identical with Elliot Smith's, assigns the pyramis to the posterior lobe, whereas Elliot Smith's assigns it to the middle lobe; when we consider the difficulty of deciding among the neighbouring fissures which corresponds to a particular one in other animals, we may find guidance in the connexions between adjacent parts; the pyramis is connected on each side with the lobulus biventer (digastric lobe) which both authorities assign to the middle lobe, and if this connexion is at all intimate it seems probable that the pyramis also belongs to the middle lobe. That, however, is a relatively small matter and on the main lines there is substantial agreement. Supporting evidence for the division of the cerebellum in this way is afforded by the fact that the fibres which enter it are distributed according to the lobes thus described—those from the spinal cord to the anterior and posterior lobes, those from the pons to the middle lobe, and those from the labyrinth to the posterior.

Encouraged by the evident services of phylogeny to the study of the cerebellum, Ingvar went on to examine by the same methods the manner of division of the thalamus. Again giving his attention largely to the brains of birds, he recognised in them all the thalamic nuclei of mammals, the greatest difference between the two classes being the much stronger development of the lateral thalamic region in mammals. The most conspicuous formation in the avian thalamus is the nucleus rotundus and this in Ingvar's view corresponds to the nucleus ventralis of the mammalian thalamus; the homology, he finds, is again supported by the similar fibre connexions of the parts. That there should be such correspondence in the structure of the thalamus in the two classes and yet such enormous difference in the development of the cerebral hemispheres suggests that the thalamus is largely independent of the cerebral cortex and that its nuclei are laid down and developed without regard to cortical formations. The lecture concludes with a few paragraphs on phylogenetic continuity as seen in the cerebral hemispheres, but these are not based on Dr. Ingvar's own work and he scarcely develops the subject. Such a method of anatomical study is a fascinating one, and if it is rigidly controlled by every available means it is certainly likely to yield valuable results.

ICTERUS NEONATORUM.

THE pathology of jaundice occurring in the newly-born has been subjected to close study in recent years and its classification has been greatly improved. When syphilis, sepsis, and excessive fragility of the red blood corpuscles have been excluded, three ætiological possibilities remain to be considered. The case may be an example of "physiological icterus"; it may belong to one of the more severe familial forms, such as icterus gravis neonatorum; or, finally, the so-called congenital obliteration of the bile-ducts may be responsible. In the last-named group it has been well known for many years that a cirrhosis of the liver is also present, and Sir Humphry Rolleston is inclined to regard this as the initial lesion with obliteration of the extrahepatic ducts as a subsequent development. Following this teaching several cases have been reported in which congenital obliteration of the bile-ducts was diagnosed on the micropathology of the liver, though the extrahepatic ducts were quite patent. The condition known as physiological icterus neonatorum which occurs in about half the infant population has been attributed to the destruction of the excessive number of red blood corpuscles with which every infant is born. The difficulty of accepting this view has been the fact that every infant does not suffer from jaundice. Lately an attempt has been made to elucidate the condition by comparing the blood groups of the mothers and infants, and in a recent paper[1] Dr. G. Lenant and Dr. S. Biró enlarge on this question and also on the occurrence of isoagglutination phenomena in the blood of the newly-born. As far as a study of 100 cases by these authors will permit of generalisation, it seems to be established that severe icterus neonatorum is twice as likely to be present where agglutination between the mother's and the child's blood occurs as when this is not present. In another communication[2] to the same journal, Prof. C. de Lange, with the coöperation of Dr. A. K. W. Arntzenius, gives a very interesting account of familial "icterus gravis neonatorum," or as it is here called "icterus familiaris gravior." In these cases several children in the same family are born with an intense jaundice and usually survive only for a few days. Those who survive longer often develop curious nervous symptoms consisting of head retraction, spasticity of the limbs, and sometimes tonic contraction of the upper extremities. At autopsy there is no evidence of any fibrosis in the liver, and very little of degenerative or other changes in the liver cells. Most of the organs are deeply bile-stained, but in the brain there is especially deep staining of the basal nuclei. The blood picture shows signs both of gross destruction of blood and of regeneration. Three theories have been advanced to account for this rare condition—it might represent a disease of the blood-forming apparatus of the child, it might result from toxins acting in utero and arising either from the mother or from the fœtus itself, or it might be due to hæmolysis of the child's blood caused by the interaction of agglutinins and isoagglutinins. Some support is lent to the toxin theory by a case of severe congenital œdema, "hydrops universalis fœtus," described by Prof. de Lange. The mother was very œdematous with albuminuria, and corresponded to the "toxæmia of pregnancy" type of case. The blood picture of the infant and the section of liver obtained at autopsy were exactly similar to those seen in the cases of icterus gravis, and, moreover, a connecting link is found in reports from the literature of children born in a condition of generalised œdema to mothers whose previous infants had fatal icterus. This sequence suggests that icterus gravis neonatorum is due to some toxin transmitted from mother to child. Dr. W. Scholtz[3] reports a family in which the two first children were slightly jaundiced at birth; in each the jaundice became intensified on the fourth day and both infants died a few days after. On the assumption that the intensification of the jaundice on the day after the secretion of milk started was more than a coincidence, two children born later to the same parents were artificially fed. These showed only a mild transient jaundice and progressed favourably. A family history of asthma and of intermarriage was noted. Unfortunately the cutaneous reaction of the surviving children to the mother's milk was not tested. The obscurity surrounding various types of congenital jaundice is lifting; if further study of the new views leads to their confirmation, light may be thrown on the pathology of certain other congenital abnormalities.

NICOTINE IN CIGARETTES.

THE practitioner is handicapped in forming an opinion of the clinical effects of smoking by the lack of scientific data concerning the actual toxicity of tobacco in the various forms in which it is taken. Some useful work has lately been done by Dr. A. Winterstein and Dr. Ernst Aronson, of the Department of Agricultural and Physiological Chemistry at the Technical High School of Zürich, on the actual and effective nicotine content of various kinds of cigarettes.[4] They point out that previous estimates have been compromised by the absence of a satisfactory method of measuring nicotine, but that Fühner's method gives readings of great accuracy; he estimates with a cymograph the muscular contractions of a leech under the influence of nicotine. They found that the toxicity of a cigarette is determined not only by its nicotine content but also by the variety of its tobacco, and its humidity, shape, and density. Those who inhale absorb three times as much of the poison as those who do not. Short, thick cigarettes produce twice as much nicotine as long and slender ones, and loosely rolled cigarettes 30 per cent. more than those which are rolled tightly. The nicotine given off by damp cigarettes is 30 per cent. less than that produced by dry ones. The quantity of nicotine which reaches the mouth therefore depends on the resistance offered to the smoke in its passage through the tobacco; if this resistance is low the amount passed will be high. Dark and strong tobacco yields more than light. An important feature of the investigation was the discovery that "hygienic" or "denicotinised" cigarettes contain just as much of the alkaloid as ordinary ones, and that a cotton-wool filter does not diminish the quantity in the smoke. It was found impossible to reduce the output of nicotine by chemical means. The authors suggests that legislation should be passed to restrict the use of the term "nicotine-free" or "low nicotine" to tobacco containing not more than 0·8 per cent., which would deliver at the mouth not more than 0·4 mg. of nicotine per gramme of leaf. They point out that so far it has not been possible to produce a tobacco with this low content that has an acceptable aroma, but that selective cultivation should solve the difficulty. It is, they say, a fact that certain tobaccos contain only one-third to one-seventh of the quantity of nicotine present in a high-nicotine brand, and they hope that propaganda will encourage a demand which will make the necessary research worth while. They make no mention of other toxic bases in cigarettes, such as pyridine, and presumably their method of measurement gives the mass result of all the toxic constituents. Nevertheless their tables, which are very full, will provide valuable information for those interested in this question.

TREATMENT OF PULMONARY TUBERCULOSIS WITH SANOCRYSIN.

IN November, 1923, before Prof. Möllgaard had published his investigations into the effects of sanocrysin on tuberculous animals, Dr. K. Secher began to test this drug in human beings. Since then he has continued to study its effects in man, and his latest publication, in *Nordisk Medisinsk Tidsskrift* for June 1st, includes a summary of the results achieved in the 322 patients hitherto treated. He classifies them in three groups, according as they (1) became well, (2) became better, or (3) showed no change or became worse. Among the 191 patients in the first group, there were 53 whose disease was slight, as many as 45 of these 53 being sputum-negative. There were also 41 whose disease was severe, but even among these cases there were as many as 19 sputum-negative patients. In the same group were 70 cases of pleurisy, 14 of glandular tuberculosis, and 13 of tuberculosis in children under the age of 15. In the second group, which contained 68 cases, there were 55 in which the disease was severe, 47 of these 55 being sputum-positive. There were also 6 cases of very severe disease, 3 of pleurisy, and 4 of tuberculosis in children under the age of 15. In the third group, which contained 63 cases, every case was classified as one of very severe disease. Dr. Secher has come to the conclusion that this class of case is unsuited for chemotherapy. In several of these cases the treatment was attempted as a therapeutic essay or as a consolatary expedient. "This group," he says, "can be entirely eliminated in the future." An unsatisfactory feature of Dr. Secher's material is the lack of controls. Of his 73 patients suffering from pleurisy, 70 were cured, and three became better—a happy sequel, the significance of which must, however, be judged in the light of the fact that the overwhelming majority of such patients get well and keep well with nothing more specific in their treatment than prolonged rest and fresh air. The same criticism is applicable to the 53 sputum-negative patients whose disease was slight, and whose recovery, it is implied, was connected with their treatment with sanocrysin. More convincing than Dr. Secher's statistics are his records of isolated cases, and no doubt his continued advocacy of this treatment depends chiefly on his clinical evaluation of a large number of individual cases. His discussion of the dosage resolves itself into a criticism of the timid procedure which is "a tuberculin therapy and has nothing to do with sanocrysin treatment," and of a rule-of-thumb schematic procedure. He recommends the most cautious individualising, the graduation of the dosage according to the patient's weight, the character and extent of the disease, and the nature of the reaction following the previous injection. He usually begins with a dose of 0·5 g.—i.e., approximately 0·01 g. per kg. of body-weight. At the second and third injections, 0·75 g., or 1·0 g., is the usual dose. The intervals between these three first injections are usually two clear days, the later intervals being from five to six days or even longer if the reactions point this way. The injections are continued until what Dr. Secher calls "effective doses" no longer provoke a reaction. The usual number of injections is five or six, but he sometimes gives up to ten, the average dose—"a really effective dose"—in one series of cases being 0·0167 g. per kg. body-weight. Dr. Secher's review of the results achieved by various clinicians suggests very explicitly that pessimism may be correlated with timidity of dosage, the curve illustrating the transition from pessimism to optimistic confidence in sanocrysin running parallel with the rising curve of the dosage.

SCARLET FEVER CARRIERS.

SEVERAL outbreaks of scarlet fever ascribed to carriers have recently been described by Dr. Ruth Tunnicliff and Dr. T. T. Crooks.[1] In the first epidemic the infection was introduced into the ward of a children's hospital by a boy who was admitted apparently during the incubation stage of the disease for he developed scarlet fever three days afterwards. Another case was noted on the same day and still another nine days later. The usual measures were enforced with regard to quarantine but further cases nevertheless appeared in the same ward on the twelfth and thirteenth days after the last case. Throat cultures were now taken from everyone in the ward, including doctors, nurses, and wardmaids, and hæmolytic streptococci, said to be specific for scarlet fever, were isolated in almost pure culture from a doctor and a nurse who had had a sore throat about a fortnight before. Further examination showed that at the end of five days the streptococci had disappeared from the throat of the doctor, but the subsequent history of the nurse is noteworthy. She was allowed to remain on duty in the same ward and about a month later three new cases developed among the patients, although face masks were now being worn by the nursing staff. On the occurrence of these cases she was still found to be harbouring a hæmolytic streptococcus and was taken off duty from the ward and given work which only permitted contact with other nurses. At the end of about another month a colleague who had been in the habit of visiting her room developed scarlet fever, and at this stage her throat was examined by an ear and throat specialist. Chronic tonsillitis was found and the specific streptococci were isolated from the tonsils when they were removed. After operation throat cultures failed to reveal the presence of hæmolytic streptococci and no more cases of scarlet fever appeared in the ward. Tunnicliff and Crooks's paper also gives details of two family outbreaks of scarlet fever in which the only possible contact of the children with the outside world was by means of the father, who was in each case found to be harbouring a hæmolytic streptococcus of the type specific for scarlet fever. Their whole argument clearly rests on their claim to be able to distinguish this specific strain, for this is the basis of proof that the persons described as carriers were accurately so determined. Epidemiological evidence is overwhelming in favour of carriers, both healthy and convalescent, being responsible for the spread of scarlet fever, and since the streptococcal ætiology of scarlet fever was established the epidemiological indications have fitted in very accurately with what we know of the distribution and habitat of the hæmolytic streptococcus. Absolute proof awaits better classification of the streptococci, but in this connexion it may be noted that Miss Tunnicliff[2] has previously described a method using the opsonic technique for differentiating the scarlatinal streptococcus. It does not seem difficult to carry out and she says that it is as quick and accurate as the cultural diagnosis of diphtheria. If this work can be confirmed it will go far to simplify the diagnosis of the disease and the determination of carriers, and will thus give good ground for administrative action which is at present based largely on strong suspicion.

COLLOIDS IN MEDICINE.

THAT branch of science which is concerned with the properties and behaviour of colloids originated in biological investigation and many of its most notable advances have been made by those engaged in such work. This is not surprising if we consider how great a part is played in the life of animal and vegetable organisms by systems which are essentially colloidal. On the one hand, the microscope reveals the intricate organisation of the tissues, and on the other, chemical and biochemical studies show the complexity of the continuous changes in them. These changes, often bound up with the microscopical structure, are nearly all incompletely understood, and at present it is seldom possible to reproduce them independently of life. This is particularly true in the vast field of enzyme action, which is held to account for many of the vital processes, and seems to be much more complex than even the most intricate example of inorganic catalysis. Despite a wealth of brilliant research into its nature, the great problem remains unsolved—namely, the way in which the various groups of enzymes act so specifically, each promoting only one type of chemical change or synthesis and each attacking only a certain (often highly specialised) type of chemical compound, leaving unchanged other substances which may be almost identical chemically. New evidence has accumulated of late; comparison with organic catalysis has yielded many suggestive analogies; but the problem is so intimately connected with the peculiar properties of various groups of colloids that it seems clear that advance in the knowledge of enzyme action must go hand in hand with the advance of colloid chemistry.

The theory of enzyme action, though exceedingly important, is only one aspect, however, of the biochemistry of colloids. The ubiquity of colloidal phenomena in the body is indeed remarkable. It would, of course, be absurd to assign to colloids the position of being the sole factors of life, but they are nevertheless concerned, more or less, in every manifestation of life. In a recent book[3] some of the applications of colloids to biology and medicine are reviewed by a number of biologists, chemists, physicists, and bacteriologists who have for the most part made a special study of colloids as applied to some branch of medicine or of its allied sciences. Biology and medicine, and botany also, are fundamentally concerned with cell behaviour, involving the study of the "permeability of the membrane" and the properties of protoplasm. A great number of investigations bearing upon these questions have been made, outstanding observations beginning with those of Pfeffer and De Vries and their original concept of the osmotic nature of the living cell. Some of the difficulties of this concept were known to its authors, for by producing precipitation of tannin in certain cells by diffusion into them of various substances they showed the untenability of the simple concept of the cells as a small sac of fluid enclosed by a semi-permeable membrane, impermeable to all dissolved substances but permeable to water. Indeed it was soon clear that the original view of the strict osmotic construction of the cell would have to be abandoned, for on this view the cell could not take up food or rid itself of its excretory products. As an alternative it was often suggested that the term "semi-permeable" must be allowed a more flexible meaning, and must be supposed to be "permeable" to the things necessary to life or permeable only in one direction. As Martin Fischer remarks in the book to which we have referred: "A living cell is, however, capable of taking up and giving off water and of taking up and giving off dissolved substances and these two things may occur at different times or at one and the same time, and with the solvent and dissolved substances moving in the same direction or in opposite directions." To explain these phenomena is by no means easy even to-day. Many of the theories proposed are based on the idea that "imbibition" might play some part in the process. Fischer, who has thrown much light on water absorption by living cells under physiological and pathological conditions (œdema), thinks that there are two main factors quite distinct from osmosis—namely, the reaction of the fluid and its salt concentration, taking into account the nature of the particular salt involved. The exchange of water is largely reversible, and urea, pyridine, amines, and certain other substances increase the hydration capacity in a way quite distinct from the action of acids and alkalis.

[3] Colloid Chemistry: theoretical and applied. By selected international contributors. Collected and edited by Jerome Alexander. Vol. II. Biology and Medicine. New York: Chemical Catalog Company. Pp. 1029. $15.15.

These few examples show that the facts are being accumulated, though very slowly. There are theories to explain some of the facts but none to explain them all. Undoubtedly the slowness of advance since the days of Pfeffer is due to the need for a new science in the form of colloid chemistry, and this is now being developed to explain the phenomena.

THE TREATMENT OF POLYCYTHÆMIA.

NOT long ago Dr. W. Mackay drew attention in our columns[1] to the uses of phenylhydrazine in reducing the red cells of the blood in polycythæmia. In both his cases nothing but good came of the treatment, but toxic effects have been from time to time reported by other observers. In this country cases of polycythæmia are so rare as to make it hard for any one person to gain enough experience to lay down rules about dosage and general management. In America the diagnosis seems to be made more often, either because the disease is commoner or because diagnosis is more lax. The fact that certain cases have been recorded with red cell counts of only just over 5 millions favours the latter alternative, but in any case phenylhydrazine has been used on the human subject a good deal more frequently in America than in this country. As a result of their own experience and that of others Dr. H. Z. Giffin and Dr. H. M. Conner,[2] of Rochester, Minnesota, have laid down certain general principles to be followed in giving this drug. They point out that a very common cause of disaster after its administration is thrombosis, either of the mesenteric vessels or elsewhere, and on this account they lay stress on the importance of doing everything to prevent stagnation of the circulating blood. To this end the treatment is preferably ambulatory; if in hospital the patients should be kept out of bed as much as possible, or if this cannot be done, they should be given massage and passive movement. For the same reason the treatment should be used with caution in patients showing signs of advanced arterio-sclerosis. They consider that large doses are unnecessary and suggest an initial dose of 0·1 g. three times daily. This may be continued until from 1·5 to 3·5 g. have been taken according to the degree of blood destruction. Thereafter the drug should be given in short courses at intervals determined by the rate of red cell production. It is stated that patients soon learn the dosage which suits them and are able to judge for themselves when further courses are necessary. The treatment has its dangers, but has until lately offered almost the only satisfactory method of combating a disabling and dangerous condition. The newly introduced treatment by spleen extract promises to be less dangerous, but it remains to be seen whether it is equally effective.

RENAL STONES.

IN submitting a detailed analysis of cases of renal and ureteric calculus, Mr. A. R. Thomson[1] says that when he was appointed chief of the genito-urinary department of Guy's Hospital in 1910 he decided not to publish results until the department had been in existence for some time. As a basis for his report he has collected the post-mortem records at Guy's from the year 1890–1900, inclusive, and in order that "a curb might be placed upon any unfair opinions gathered from the records of one hospital," he has read through the case-sheets of nearly 13,000 cases treated at the Victoria Hospital for Children and at the London Hospital. His investigation has, therefore, been extremely thorough and his conclusions may be accepted with complete confidence. Among them are the following: (1) The incidence of stone is about equal in the two sexes, but in elderly people more males are affected than females. (2) There is a slightly greater number of stones on the right side than on the left. (3) The large number of bilateral stone formations, which is about one-third of the total number of cases, points to the seriousness of this condition. (4) Bright's disease is not uncommonly diagnosed when there is a renal or ureteric stone present, and a stone is often the cause of Bright's disease. Bright's disease following on stone formation is more common in males than in females, but bad kidneys, such as bilateral pyonephrosis, are more common in females than in males. (5) Stone may form in the urinary tract as a result of some wasting disease. (6) The commonest place for a stone to be found is the pelvis of the kidney. (7) Compensatory hypertrophy of one kidney, when the other is diseased, is not nearly so common as is generally supposed. (8) Stones may recur after operations for their removal, but this, Mr. Thomson thinks, may be due to carelessness on the part of the operator.

VACCINE THERAPY IN AMERICA.

IT is a little unfortunate that the one word "vaccine" should be employed in different senses. It was applied to the great and established discovery of Jenner in the prevention of small-pox; it was used to denote Wright's contribution to the prophylaxis of typhoid and allied infections; and it is used in relation to the treatment of infections by dead organisms. These three clinical methods do not stand on the same footing, but they have all given rise to extravagant claims at one time or another. The treatment of infections with vaccines, which is still in the experimental stage, is particularly open to abuse at the present time because so many conditions of unknown origin are put down to focal sepsis. When we hear of a case of soft corn of the foot treated with a streptothrix vaccine, and a case of lymphadenoma treated with a polyvalent fæcal vaccine, we feel that the patient is entitled to know that his medical adviser is putting his money on an outside chance, to say the least of it.

The question arises how far clinicians do, in fact, make use of vaccines is one to which no answer can be given in this country, although the price-lists of commercial firms show that there is a constant demand. In the United States, however, Hektoen and Irons[1] have taken the trouble to write to over three thousand medical men in the hope of finding out. Their report is surprising, for the percentage employing vaccines, usually less than five, does not exceed 25 in any of the four groups into which the respondents are divided, and in furunculosis alone is that figure reached. The replies show almost complete unanimity in refusal to use *Bacillus coli* vaccines; only 0·25 per cent. treat colitis with vaccines, and no one employs them for tuberculosis or epilepsy. Hektoen and Irons point out that from 1906, when Wright introduced his vaccine treatment, to 1912, there was a large output of papers on the subject. Since then the papers have been fewer and apparently the method has fallen into disfavour. In the latest edition of Kolle and Wassermann's handbook, although much is written on it, significantly little is claimed. On the whole, however, it seems to be in greater disrepute in America than in this country or in Germany where questions are not uncommonly set in qualifying examinations on the "proved" values and methods of vaccine therapy. "Non-specific" or "shock" therapy is not considered in Hektoen and Irons's report, but the country in which Petersen has worked may be said to be the originator of this method, and we may suppose that it is widespread there. The use of such preparations here is undoubtedly spreading, and Ledingham has expressed the opinion that, where vaccines in treatment are efficacious, the result is due to non-specific reactions. Few would deny that, in staphylococcal skin infections, vaccines are often of value, but preparations of manganese give very similar results.

[1] THE LANCET, April 13th, 1929, p. 762.

[2] Jour. Amer. Med. Assoc., May 4th, 1929.

[1] Guy's Hospital Reports, April, 1

The exaggerated statements often made on behalf of vaccine therapy make this questionaire of interest, but it is unlikely that such an investigation will be made in England, and, after all, what the American doctor does is no more evidence of scientific fact than what the soldier said. It is, however, a straw showing which way the wind is blowing in the United States, and there are those who hold that a wind from the same quarter would not be disadvantageous over here.

MATERNAL MORTALITY.

Dame Janet Campbell, who has accepted an invitation to go out to Australia to give the benefit of her experience to the Commonwealth Government, was entertained on June 17th by the President and Committee of the United Empire Circle. Replying to Viscountess Elibank, who spoke of the widespread appreciation of her services, and expressed a hope that her mission would bring lasting help to Australia, she pointed out that maternity and child welfare was not a new subject in that country, and said she hoped to gain more from her visit than she expected to be able to give. In Australia, as in this country, maternal mortality was one of the most pressing problems, and it was a complex problem which could not be solved by any single line of approach, but only by the united action of all interested. A great deal of educational work was needed among the mothers themselves, and also among medical students and midwives, to equip them to meet the difficulties they might have to face. It should always be possible to summon the help of a consultant in time of need, for many maternal deaths would be avoided if the mother could have skilled attention at the right moment. Increased education and coördination would tend to bring about a reduction in the death and damage-rates among mothers, and also in the early infant mortality-rate associated with childbirth. Children between the ages of 1 and 5 years were at present somewhat neglected because no official body was responsible for them, and we must consider how best to watch over those children so that they might arrive at school age in a healthy condition. In the course of subsequent speeches the Countess of Birkenhead said that at the General Lying-in Hospital in the last ten years 26,198 confinements had been attended in the hospital and on district, the maternal mortality-rate being 1·6 per 1000; and Viscountess Erleigh paid a testimony to the invariably wise and far-seeing advice which Dame Janet had given in regard to plans for day nurseries.

CHEMISTRY IN CZECHO-SLOVAKIA.

Bohuslav Brauner has for many years been known by name to chemists as a professor at the Bohemian University of Prague, as well as an authority on atomic weights and general chemistry. It is, therefore, with interest that we welcome as fruits of his labours the appearance of an early number of the first annual collection of Czecho-Slovak chemical communications, published under the patronage of the Regia Societas Scientiarum Bohemica. The number contains eight papers by workers at the Charles University and the Polytechnic at Prague and at other similar institutions. Written in French or English, they include records of sound work in inorganic, physical, organic, and analytical chemistry. Not only the papers themselves but even the advertisement columns afford evidence of the intense desire of a country recently made autonomous to tell the world in languages better known than Czech that it is taking its place among the learned nations.

A MEDICAL "TALKIE."

Mr. Swift Joly will preside at the last meeting for the present session, of the Section of Urology of the Royal Society of Medicine, to be held on Thursday, June 27th, when Sir John Thomson-Walker will give a cinematograph demonstration showing a "talkie" film. This is a demonstration by way of experiment, but we may have here the beginning of an important development in teaching. We understand that the film showing the operation will explain itself audibly as the operation proceeds, but that this does not imply that it will be a "close up" of the operator. The innovation is sure to attract a large audience.

The Cavendish Lecture of the West London Medico-Chirurgical Society will be delivered at 8.15 P.M. to-day, Friday, June 21st, at the Kensington Town Hall, by Prof. Cl. Regaud, of the Radium Institute, Paris, his subject being Progress and Limitation in the Cure of Malignant Disease by Radium. A reception will be held from 7.30 P.M. onwards, and at 8 P.M. the Society's triennial gold medal will be presented to Sir Ronald Ross, F.R.S.

The University of New Brunswick has conferred the honorary degree of Doctor of Laws upon Sir Charters Symonds, consulting surgeon to Guy's Hospital, who was born at Saint John. Sir Charters, who was prevented from attending the Encænial proceedings, signalised the occasion by founding a prize to be known as the James Symonds prize in history in honour of the original English settler at the mouth of the Saint John River.

National Campaign against Rheumatic Diseases. At a conference held in London last November an executive committee was appointed to draw up a constitution for a national campaign against rheumatism. This executive committee, of which Sir Thomas Horder is chairman, invites members of the medical profession to attend a meeting to be held at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W., on Wednesday, June 26th, at 5 P.M., when a report on policy and constitution of the campaign will be received and a council will be elected. The hon. secretary of the committee is Dr. M. B. Ray, 6, Bentinck-street, W. 1.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXXIV.

THE INTERPRETATION OF MENTAL TESTS.

I.*—PRELIMINARY CONSIDERATIONS.

PROBABLY very few of the problems of diagnosis and prognosis presented to the busy practitioner fill him with so profound a sense of his own limitations as that which faces him when he is asked by an anxious parent to give an opinion upon the mentality and the future prospects of a child or a young adolescent. General medical education, which provides the student with some knowledge, more or less vague, of the idiot and the imbecile, which he groups in his mind confusedly and erroneously with the insane, has omitted to inform him to any degree regarding the much larger class of the feeble-minded. In his general work after graduation he has but occasional opportunities of becoming acquainted with the type, in contrast to the children's specialist and the school medical officer, and as the feeble-minded generally do not present so marked physical traits as the idiot and the imbecile, he may be tempted to express favourable opinions regarding children who, before many years have passed, will demonstrate by their failures how uninformed the medical opinion had been.

At the outset the practitioner should beware of the temptation to utter comforting platitudes about "late development." One does not deny that late development occurs, but in the writer's experience it is extremely rare, and when there is a clear history of lateness in teething, sitting up, walking, talking, control of bladder and bowel, together with obvious signs of a mentality from 2 to 3 years below the normal for the child's age—we are assuming a child of about 7—it is safe to anticipate that there is a permanent lateness, becoming later every year, a permanent subnormality, that is to say, with all that it implies.

One of the practitioner's difficulties is that in these cases, as in the insane, he has almost entirely to abandon the search for physical signs which are his sheet-anchor in his routine daily work. There are, of course, a few definite types of deficiency which can be diagnosed by physical signs—the microcephalic, the hydrocephalic, the mongol, and the cretin being the chief of these. Their physical description does not concern us here, and in any case prognosis regarding their mental possibilities need give but little difficulty. The microcephalic rarely rises above the level of the low-grade feeble-minded. The mongol is always an imbecile, but mongoloid types exist with less marked physical features, who may rise a little higher. He is not always the last child of a mother exhausted by numerous pregnancies of the text-books. Of the cretin it should be said that while thyroid treatment may transform him physically into at least a semblance of normality, no such transformation mentally need be expected—he remains a defective. Hydrocephalics vary very greatly in their mental capacities. These special types constitute but a small percentage of defectives.

The physical "stigmata" on which at one time so much emphasis was laid as signs of inherent mental or moral degeneracy may also be passed over with but brief mention. Their significance singly is negligible, for their single occurrence is not infrequent in normal persons, but when they occur in any number from three upwards, they assume significance, not so much for diagnosis of the individual as for that of his family as probably degenerate. Our main reliance for guidance must, then, be found elsewhere than in the physical, and it will be convenient to pursue our lines of search in the order of: history, observation, and tests. Further, as consultation on mentality is most frequent either at the early ages from infancy to 7 years, and at the period of early adolescence, these two periods require to some extent separate treatment.

THE EARLY YEARS.

History.—By history is meant individual history. Family history, however valuable, when obtainable in reliable form, as indicative of the presence of lunacy, deficiency, epilepsy, paralysis, functional nervous conditions as hereditary factors, is of no more value for a diagnosis of the individual than a plurality of stigmata. To appreciate the significance of individual history, it is necessary to keep before our minds certain norms of development as a guide to interpretation. Some of the main stages of physiological growth may be briefly epitomised.

Stages of Physiological Growth.—Within the first three months after birth a child, besides showing normal activity of the reflexes essential to life, should begin to take notice of objects affecting his various senses—noises, bright lights, tastes, and in some vague degree the more immediate objects in his environment—with, at the end of the period, some capacity to follow a bright object or turn towards a sound. The following three months sees considerable development of the power of seizing and grasping objects, with, towards 6 months, some little perception of their relative distance. At 6 months he can sit up, but will still require support, and his mother or nurse is now a fairly well-recognised entity. At 9 months a normal child can sit up without support, and will be crawling or otherwise propelling himself along the floor, and may even stand and try to step. About this time also are the first beginnings of imitation, but it is not a marked trait until the end of the year. Muscular coördination is now more reliable, both as regards grasp of objects and control of his own body movements. At 12 months he should walk with help, he will play with a spoon and a saucer and with blocks, but cannot construct; eye accommodation is now under control.

At 18 months he can walk alone, and even try to climb a stair, try to put on his shoes, and attempt to feed himself with a spoon. Bowel control should now be fairly reliable, followed at 2 years by bladder control. By 2 years he will build up a tower with three or more blocks. He can put on his shoes at 3, carry a frangible object, and open a door. At 4 he is mastering certain of the elementary processes of dressing—buttoning clothes and fastening shoes.

Language and Articulation.

Coincident progress in speech must be noted. After the early babbling stage comes, among other imitations at 8 or 9 months, the imitation of sounds heard, at first with no idea of meaning. Before 12 months a child should begin to understand what is said to him and to obey commands. Of use of actual words by himself at 12 months we expect little but "mama" and "dada" and a few other common baby words. A few months later he is appreciating the meaning of more words, but up to 18 months his own spoken vocabulary is extremely limited. The next six months, however, sees great extension in this direction, coupled with greater understanding. By 2 years he may have acquired as many as 200 words, and is a persistent imitator, so that echolalia is a marked feature at this stage. From this time the interaction of language and intelligence upon one another becomes more definite, and in the third year he is becoming acquainted with first the similarities of different objects, later their differences, and developing concepts consequently of wider and wider significance. Short sentences in place of single words, negatives, plurals, pronouns, parts of verbs make their appearance, and by the end of the third year that most significant of all mental advances, the use of the pronoun "I" is, in a normal child, well established. At the same time—and this is of importance—articulation should be nearly perfect.

---

* Part II., the Significance of Accepted Tests, will appear next week.

Abnormalities in Development.

With these norms before him the assessor of intelligence has a fairly satisfactory basis for a diagnosis, provided that he can obtain approximately reliable data for the individual child before him. Retardation of teething, sitting up, and walking may only indicate rickets, of which there will be other signs, but when all these are combined with lateness in "taking notice" in infancy—a point soon discovered by an experienced mother—with absence of the normal babble, retardation of early efforts at speech, with, for a prolonged period, great difficulty of articulation, and lateness of other normal activities described, with late control of bladder and bowel, then there is a strong a priori case for a diagnosis of deficiency.

In the case of any child up to 3 and a markedly subnormal child to 5 (or even later) practically no other method of diagnosis but this and the observational is available, but at those early ages diagnosis must always be guarded. Idiocy and imbecility may be readily recognised then; such a child would probably not be talking at 3, and not very much and not distinctly at 5—to take only one sign as an example. But feeble-mindedness at these early ages is not so readily diagnosed. At any age up to 6 or 7 to say that a child who started to walk at 18 months and is only just beginning to talk at 2 to 3 years is not feeble-minded, and will be all right later, would be dangerous. Indeed, we may go further and say that a quite definitely feeble-minded child may only show a retardation of a few months in each of the activities above mentioned. More usual, perhaps, is a slight retardation in some and a marked retardation in one or two—say, talking or acquisition of cleanly habits. These inequalities are common in the feeble-minded, and the practitioner would be well advised to adopt a "wait and see" policy, a policy which, after all, he has to adopt in reference to many other diseased conditions. It is seldom indeed that a certifying officer will commit himself to say of any doubtful case until the age of 7 that the child is not feeble-minded.

With children of older ages the questionaire may be extended to present conditions—the child's ability to dress and wash himself, to bring a number of errands correctly by memory only, his play activities and hobbies, his propensity to play with children of his own age or younger, to be led by others, to defend himself against others. And, above all, a comparison either from the parents' own information or by actual testing, between him and a younger member of the family (if any) may be illuminating. In obtaining all this information, the practitioner—if he is the regular family doctor—has an advantage over the official certifying officer in that he has probably had opportunities of observing the growth of the child, and cannot, therefore, be so readily imposed upon by a parent anxious to cover up the facts.

Observation.

Much may be learnt by careful observation, and in the case of very young or very low-grade children it is practically the only method of examination that is possible. A vacant expression, a slouching posture, a clumsy gait are readily noticed. So also are rocking movements, biting nails, sucking the thumb, and other habitual purposeless movements, but they are not very common above the imbecile grade. Alertness and quickness to "take notice" or the opposite are usually obvious, and the child's ability to walk and to articulate clearly; his own attempts at spontaneous speech are often of significance. An abnormal amount of fidgetiness and restlessness in such degree that the child is on the move all the time, handling everything he sees, but only for a moment, distracted by the slightest interruption, is characteristic of one type of defective—the unstable. At the other extreme is the stolid type whom it is difficult to rouse to any activity, physical or mental. It is, of course, in the mass that all such signs find their meaning. They are, however, never all present—articulation, for example, is sometimes almost perfect even in a young imbecile.

H. HERD, M.A., M.B., Ch.B. Edin.,
Senior Assistant School Medical Officer,
Manchester Education Committee.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. F. Cock is placed on the Retd. List with rank of Surg.-Capt.

Surg. Lt. J. K. G. Way to *Victory*, for R.N. Infirmary, Portsmouth.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. J. O. Clyde to be Surg. Lt.

Proby. Surg. Sub-Lt. C. Seeley to *Victory*, for R.N. Hospital, Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. H. H. Leeson, R.A.M.C., Res. of Off., to be Maj., whilst re-empld. under Art. 507 (b), Royal Warrant for Pay and Promotion, 1926, and relinquishes the rank of Lt.-Col.

The undermentioned Capts. to be Majs.: W. Bird, D. Cran, A. R. Ross, O. D. Jarvis, A. C. Taylor, R. Johnson, P. R. O'R. Phillips, T. H. Twigg, A. H. Clarke, D. J. H. Jones (prov.), J. K. Holland (prov.).

Lt. F. Welsh resigns his commn.

G. R. M. Apsey to be temp. Lt.

ARMY RESERVE OF OFFICERS.

Lt.-Col. J. D. Kidd to be Lt.-Col.

TERRITORIAL ARMY.

Lt.-Col. A. P. Watson to be Bt.-Col.

Capts. E. R. Woodroofe and A. H. Richardson resign their commns.

H. V. Ingram to be Lt.

Lt. E. White to be Capt.

2nd Lt. A. T. B. Dickson (late 7th Bn. H.L.I., T.A.) to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. N. R. Rawson, from Active List, to be Capt.

INDIAN MEDICAL SERVICE.

Capts. R. S. Aspinall and Gangadrum Venkataswami Ram Mohan to be Majs.

P. J. Walshe, A. M. Sheridan, and J. H. Boultbee to be Lts. (on prob.).

Col. A. Spitteler and Lt.-Col. G. Fowler retire.

As will be seen from our advertisement pages the Secretary of State for India proposes shortly to make a certain number of appointments to permanent commissions in His Majesty's Indian Medical Service.

ESSEX PUBLIC MEDICAL SERVICE.—The fifth annual report (for the year 1928) of this Service shows that it provides increasingly for medical attendance on the families of insured persons. The number of subscribers rose from 14,594 in 1927 to 16,040 (7454 adults and 8586 children) in 1928, and their payments from £9427 to £10,446. The number of new books issued to subscribers during the year was 1904, and at the end of the year there were 8048 books on which payments were being made. The maximum remuneration of individual doctors during the year was £371 in a metropolitan district, £720 in an urban, £244 in a semi-rural, and £231 in a rural area. The balance-sheet affords more cheerful examination than in any previous year for the excess of liabilities over assets is now only £132, with a prospect of disappearance next year. The loan from the National Defence Trust (originally £400) has been reduced from £400 to £300, and the doctors' loan from £100 to £55. The Service, whose offices are at 108, City-road, London, E.C. 1, has all the signs of a going concern.

Special Articles.

THIRTY YEARS OF SANATORIUM LIFE.*

BY ESTHER CARLING, M.D. BRUX., L.S.A.,
CHIEF MEDICAL OFFICER, BERKS AND BUCKS JOINT SANATORIUM.

THE coincidence of the Reading Pathological Society's visit to the Berks and Bucks Joint Sanatorium with the completion of 30 years of its existence suggests a backward glance and an inquiry as to how far the system still merits the confidence of the profession which feeds it.

The First Phase.

Systems of treatment develop from small flexible experiments into the hard concrete of the established order of things; with the acquisition of property, the appointment of officials, and the fencing around by legal documents an organisation comes into being which is very resistant to change. We have seen in the question of poor-law reform that, even when a Royal Commission has recommended action, over 20 years can elapse before the established order can be shaken. We see also how very slowly the structure of administration concerning mental disease is becoming modified. It is therefore surely wise to consider periodically the actual and relative values of any part of a system that has been on trial for a reasonable time, particularly if it happens to be a costly and exacting part.

Few practitioners will now remember the wave of interest that caught both the profession and the reading public when, late in 1898, a chemist named Gibson published in the *Nineteenth Century* an account of a cure for consumption which he had undergone in the Black Forest. This was followed by the experiences of several English medical men, and a rapidly spreading cult began for treatment on so-called Nordrach lines. Certain extravagances of Teutonic origin were at first included, and the overfeeding and lack of nursing of the Black Forest progenitor were part of the earlier English institutions. In 1899 several private sanatoriums were started, mostly by doctors who had themselves undergone the cure. The common-sense of a great deal of the system gained rapid support, and in a few years demand was forthcoming that the working classes should share the benefits. Here and there a specially wide-awake borough council or board of guardians made application to private institutions to start an industrial branch; employers asked for treatment for their servants or workpeople, and the demand for beds became insistent. Thus a very small experiment, started here in 1899, grew steadily by ones and twos. Patients were housed in huts and shelters with a minimum of capital expenditure, and year by year more and more pressure was made to extend the accommodation. There were certain dramatic moments when interested callers left cheques for £500, or when a deputation from a county council urged on us "sell your boots but provide beds." The stage of struggle and building up is ever the most vital and interesting. I often wonder whether the results which seemed so much better then than they do now were really so, or whether it was the youth and freshness and enthusiasm of all concerned and the newness of the system that gave such impetus and caused such quick developments.

The Edinburgh Dispensary and the Sequel.

The next step came with the development of the dispensary system organised in Edinburgh by Sir Robert Philip. The voluntary model so provided was rapidly copied and paved the way for the system which became a part of the public medical service with the National Health Insurance Act of 1911. From thence onwards local authorities, acting singly or in groups, have been building up their systems of antituberculosis work. As always in British procedure, a wide range of difference has marked the development. Some authorities have themselves developed a complete equipment with orthopædic provision, advanced hospital beds, and industrial colony, open-air day and boarding schools, after-care organisations, X ray plants in dispensaries, and "all the luxuries." Others have done little but farm out a few patients to voluntary institutions and spend as little as pressure from the Ministry of Health would allow. The sanatorium, which in early days was the star of first and greatest magnitude, has gradually become but one point in a constellation and there are signs that its brightness is still on the decline. As it is, however, by far the most costly single item, its relative value is worth determining.

An institution, such as the Berks and Bucks Joint Sanatorium for example, with 180 beds, costs the public something over £20,000 a year to run—and this amount represents an almost exact mean in the average cost of similar undertakings. The public asks very few questions, so also with the medical profession; the sanatorium just exists in the established order. Annual reports find their resting-place in the waste-paper baskets of county councillors; so long as no scandal occurs a deathly dullness envelopes it. Such lack of interest is unhealthy, but that is ever the trouble with public and official institutions that do not have to fight their way into the limelight.

The Basic Idea.

The basic idea of the sanatorium was that it afforded an opportunity for the "cure of consumption," and though this optimism has been modified by time presumably it should still offer some very definite values in return for the cost of upkeep. What these values amount to are best known by the body of general practitioners in the area which it serves, but probably it rarely occurs to them to criticise or consider the question as a whole, though they may have their general impressions. They would perhaps allow that a stay at the sanatorium does "some good," is "useful for a change," "gives the relations a rest," "teaches habits of hygiene," &c. We who live and work at the sanatorium hope it fulfils these functions and perhaps a few others, but we are also increasingly imbued with certain aspects of wastefulness and misdirection in the working of the scheme. For instance, we see repeatedly patients who have left the place full of hope and fitness returning in a year or two as physical wrecks, and we ask ourselves "was it worth while?" We realise often also that the short interval of health and working life that the sanatorium gave to these people has been the means of adding other handicapped lives to their families. This factor indeed is a problem which I think we have shirked far too much. The Parisians have faced it by a system of "placing out" the children born of tuberculous parents, but infant life is even yet more precious in France than in this country.

On the economic side comes the question: Is it worth while to give *so much* for a few weeks or months and *so little* for the remaining months and years of a very protracted illness? At the sanatorium is given a thoroughly ample, even generous, diet for example, and the patient is impressed that as he has lived at the sanatorium so should he "carry on" at home. He perhaps does not return to work, so the income is diminished. Yet he feels if he drops the generous feeding to which he has become accustomed his chance of maintaining the benefit gained is endangered, so he feeds up, and the healthy children have less that the invalid may have more.

Some of the Prospects.

A gradual development of late years calls also for comment. The average length of stay at the sana torium has steadily increased; in 1914 it was 12 weeks, in 1928 it was 28 weeks for adults (43 weeks children). This fact points to a change in the scope of the sanatorium. It has largely taken the place of the poor-law infirmary in dealing with chronic cases. This has some advantages: the life is on brighter, more vigorous lines; occupations are organised, crafts are taught, there are committees and interests, there is more coming and going. But there are also disadvantages; the buildings are not planned for the feeble chronic case. The advanced chronic patient is unnecessarily uncomfortable in winter and is a real anxiety to the staff lest harm should ensue. Some provision has recently been made here for "acutes," and it has been very helpful, but an entirely separate section would be a better way. Only rarely does the early case seek institution care, but the advanced should be encouraged to take it for the sake of others, and the middle cases for personal ends. Yet the sanatorium buildings are still planned on the lines which only the vigorous can reasonably profit by. If the sanatorium is sweeping all types into its net, what is it doing for them and what advances are recorded?

---

* A paper read at a meeting of the Reading Pathological Society held at the Berks and Bucks Joint Sanatorium.

The sanatorium can always offer a helpful and educational "change," it can frequently initiate or carry through a useful course of special treatment; it can sometimes serve a moral or psychological purpose by altering a patient's outlook from invalidism to a more normal view, and there are indeed definitely some cases of a turning point to health again. It therefore seems to hold its own at present despite the degree of disillusionment which has been expressed.

In 30 years no specific treatment has arrived, and we are reminded of Tennyson's words:

> "Our little systems have their day
> They have their day and cease to be."

Tuberculin has had its day—and in some quarters it has still not ceased to be; serums have come and gone; vaccines have been tried and faded; heavy metals have still their advocates; surgical procedures have been in and out of fashion. Of late years the sun has come forth like a bridegroom from his chamber and has run a race with his ultraviolet derivative. Of all these one treatment at least has really been of lasting value in its own rather limited field, and that is the successfully established artificial pneumothorax. Some 253 cases have been undertaken here since 1911, and though the results are not sensational, they have meant a good deal in various ways.

1. The treatment offers a definite line of attack which, failing anything else, has a moral value. The old Devonshire saying "do good if you can but do zummat" has much wisdom in the treatment of a long disease like tuberculosis.

2. A pneumothorax course involves a régime of rest for a longer time than patience might hold out without a definite treatment.

3. When fairly complete compression can be established it has a really remarkable value. We have, indeed, on our staff to-day ex-patients treated by this means whose living and working seemed absolutely impossible four or five years ago.

The developments of the future seem likely to lie as much in the field of surgery as of specifics, and for this reason I hope that a "surgical side" will either become the rule at all large institutions or an alliance with the surgical departments of general hospitals. There is much to be said for grouping orthopædic and pulmonary cases on one area in different blocks as well as for dealing with all grades and types and ages. Just as in mental work the trend is towards larger units, so it might well be in tuberculosis. A more vigorous life for the staff is possible, and the larger the numbers the more efficiently and economically can a variety of needs be catered for. Another point is that the wider the range dealt with the less should the bogy of "infection" prevail. This is still a real hardship and disadvantage, yet a tuberculosis colony, wind-swept, sun-washed, and efficiently managed is a remarkably healthy spot in which to live.

The Tuberculosis Colony.

The sanatorium idea should move with the times, but at present it shows a tendency to stasis which is undesirable. From the first the idea of the colony has cropped up in varying forms—the "Nordrach colony," the farm colony, the industrial colony, all have had good examples and have shown certain possibilities. Finance generally wrecks them after a time; they can *not* be self-supporting. But the colony may come again, by wider groupings, by bolder planning, and by the welding of official and voluntary effort.

There is one element of "the colony" idea which is capable of very useful development—viz., the inclusion of a wide variety of children. It is very surprising that so few county units contain this provision; experience here shows that there is everything to be gained. The life of the children is quite separate, but they give brightness and vigour—they can be seen at play and heard shouting, and they make the place more homely. The teaching staff they need can give valuable help to the adults, and the medical resources called for in the diagnosis of their more indefinite symptoms also help the provision for the whole place. The criticism is often made, "But are they really tuberculous?" This is a nice point and one that I personally find increasingly difficult to determine. At any rate they are the weaklings of homes where tuberculosis has taken toll of adult members and they are wisely sent as a preventive measure. They yield naturally a fine harvest in immediate results, and I believe the tuberculosis officers who watch their later development are satisfied that these results are lasting. Certainly they very rarely return in adult life as patients. Whether they should be subjected to the label of notification as cases of phthisis is to my mind an important point, but it is a lesser evil to notify them than to withhold treatment. In looking back over the years, one feels that the children have been infinitely worth while. So also has been one other factor—the employment of patients as members of the staff. This has been done from the beginning wherever possible, and we are proud of the fact that some 40 per cent. of our staff are ex-patients. The advantage has not been all on their side—their presence is an encouragement to the patients, they bridge the gap that separates the worker from the invalid, and, further, they bring to the work conviction and enthusiasm engendered by their own success. If the fully fledged tuberculosis colony is an economic gamble too risky for public bodies to embark upon, the employment of ex-patients can at any rate be encouraged. Any technical difficulties they present as to insurance problems are worth overcoming. The mingling of normal and pathological workers calls for thought and care, but can be accomplished without harm resulting. On the economic side, if an institution can show about 40 per cent. of ex-patients on its staff and still keep a middle place on the cost list of comparative institutions, there cannot be much wrong.

I have perhaps said little on the strictly medical side, and my apology for this would be that in the long struggle with a disease like tuberculosis the medical side is less than the human, as the darkness of disease is less than the dawn of health.

KING EDWARD VII. HOSPITAL, WINDSOR.—Rapid progress with the rebuilding and extension of this hospital was reported at the annual meeting recently. The south wing will contain three wards in place of the former two; one of them is already occupied, and the other two will be available during the present month. Sir Edward Stern is adding an additional wing to the north ward, and the Lady (Gomer) Berry Hostel, which will be completed shortly, will contain nearly 100 rooms, about 80 of which will be occupied by the nurses. When this hospital is completed there will be 180 beds.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Corporal Punishment.

THE question of corporal punishment having been raised before the Edinburgh Education Authority, a motion was made that, whenever corporal punishment was resorted to, appropriate particulars should immediately thereafter be recorded in an official record kept for the purpose. A committee on day schools and attendance considered this motion and disapproved of a recommendation by a subcommittee that the clause be inserted in the regulations. After discussion at a meeting of the authority the motion was defeated. Another motion was made that the regulation, "the Education Authority are very desirous that the infliction of corporal punishment should be avoided during the time set apart for religious instruction" should have added to it "and at all times in infant departments." This was also defeated. The intention of the first motion was to bring about a gradual abolition of corporal punishment, and there is in the procedure of the Central Board of Lunacy in Scotland, now the Board of Control, strong precedent for the method suggested. For here a special register having been instituted which required an exact statement of the particular reason, the nature of any restraint enforced, the length of time of the restraint and other particulars had the effect that the strait-waistcoat ceased to be used in the asylums of Scotland. No steps were ever taken, so far as I know, to abolish any form of restraint required; the recording of the details ended in the disappearance of this particular method. And it is probable that a register of corporal punishment in schools would have a parallel history.

The Scottish schoolmasters of former days were certainly not famous for their leniency in the use of the tawse, but possibly the belief in the disciplinary efficacy of an inflicted pain is a survival of the "possession" theory of wickedness, and those that accept that theory are becoming extinct. At the Edinburgh discussion, it was admitted by one supporter that the teachers of exceptional "personality" did not need to inflict corporal punishment, which is a comment of the first value.

The Glasgow Small-pox Outbreak.

In the bulletin of the Glasgow Public Health Department it is pointed out that only one case of small-pox was recorded last month. "This case was associated with the former outbreak in respect that the patient was a painter on the ship on which the infection occurred. He worked on board that vessel from April 20th to 23rd and was diagnosed on May 11th. He had been at work on another vessel from the date of his sickening on May 5th. All possible contacts were kept under observation and no further cases of the disease have arisen. It would now appear that the outbreak is definitely at an end." It is a matter of interest that no deaths have occurred among the cases which have arisen in Glasgow, but four small-pox patients remain under treatment. The case of the ship's painter forms an illustration of the variation in infectivity. The late Dr. John C. MacVail, whose knowledge of small-pox was extraordinarily extensive, used to tell with great humour the story of the Kilmarnock registrar who divided the population into two classes—those that had had small-pox and those still to take it! The story marks the difference between the administrative resources of those days and of these. Glasgow Public Health Department is to be congratulated on the rapid arrest of a rather serious outbreak.

Dundee Royal Infirmary.

At the annual meeting the chairman stated that, while over £80,000 had been added to the Endowment Fund, the income alone being used for administration, there had been a surplus in the reserve fund only in one year. This is the fund available for the general purposes of the institution. From that fund, which stood at £109,765 in 1918 and towards which £103,305 had been received during the intervening years, it had been necessary to draw a total sum of £161,663 to meet annual deficits, leaving the fund at Dec. 31st last at £51,407. This, he said, was face value, not actual value, and in view of the large additional commitments of the infirmary, it was clear that a large addition was required not to the annual income alone but to the total funds required for extraordinary expenditure. The infirmary is one of the finest general hospitals in Scotland and within the last few years many enlargements and improvements have taken place in it. In fact Dundee as a whole is peculiarly favoured in the number of public institutions supported by generous men of wealth, and the infirmary, from time to time, has shown great public spirit in taking on fresh burdens.

Presentation of Portrait to Sir Alfred and Lady Ewing.

On his retiring from the Principalship of Edinburgh University, a portrait of Sir Alfred Ewing was presented to the University and accepted by the Lord Rector, Sir John Gilmour, late Secretary of State for Scotland. A second portrait of Sir Alfred was presented to Lady Ewing. The Chancellor of the University, the Earl of Balfour, could not be present; but there was a large gathering representative of every phase of University work and interest in Edinburgh. The artist is Mr. Lintott, R.S.A.

Child Neglect.

The Scottish Society for the Prevention of Cruelty to Children does admirable work and it is no reproach to the "Children's Charter" that prosecutions successfully instituted by it may produce a situation which appears to render all effort nugatory. Here are four cases. A labourer, aged 33, pleaded guilty to having neglected his four children between Dec. 1st and May 20th and was sentenced to three months' imprisonment; a miner, aged 48, pleaded guilty to neglecting his three children and was sentenced to three months' imprisonment, admitting one previous conviction; a pit-head worker, aged 38, pleaded guilty to neglecting his six children between March 28th and June 3rd, admitting two previous convictions, and was sentenced to four months' imprisonment; another miner, age not stated, pleaded guilty to a charge of neglecting his wife and six children, and was sentenced to three months' imprisonment. Evidence of extreme laziness on the part of the fathers was forthcoming, and it is known that prosecutions are only instituted in the worst examples. In these cases the family, during the imprisonment of the father, has to be provided for by the poor-law authorities or by the Society, and the break-up of the family and the boarding out of the children may either or both be necessary. When the father comes out of prison, he resumes, whether he wishes or no, responsibility for his wife and children, and though kind efforts may be made to give him a fresh start he frequently returns with no work or wages to his family and the same results of laziness and incapacity follow. Many years ago, the Local Government Board for Scotland, then the central authority for poor-law, had to stop the inspectors of poor, acting under the Parish Council, from bringing the children to the prison door and handing them over to the father immediately on his release. This was then the conception of reinstating "parental responsibility." Possibly this variety of poor-law activity occurs from time to time still and no doubt, in the long course of handling worthless persons, the inspectors of poor have been driven to it as the sole method of "catching" the father and preventing his final desertion. But no one can regard this as a practical procedure. But in the four cases recorded above, it is difficult to know where to begin with a remedy, and with that difficulty the Scottish Society for the Prevention of Cruelty to Children is faced continually.

It is no wonder that the Society feels that the whole problem of the preservation of children should be be studied afresh, for police methods can deal only with the superficial aspects.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The German Surgical Congress.

THE first official subject of discussion at the German Surgical Congress, which has lately been held in Berlin, was the treatment of empyema. Prof. Sauerbruch (Berlin) said that experience in the influenza epidemic of 1918 and 1919 had modified our views on the advisability of rib-resection for this condition, the mortality after resection having been 90 per cent. For post-traumatic empyema he thinks that a wide opening with removal of part of the ribs still gives the best results, but for para-pneumonic empyema and in empyema after influenza this method has nowadays fallen into disuse, and puncture of the pleura is performed instead. Its object is to improve the general condition of the patient, and this is often effected by a single puncture though several may be necessary. Should exudation continue, Bülau's drainage is recommended; and if, in spite of this, resection becomes necessary, the operation is less dangerous after the improvement of the patient's general condition. Prof. Sauerbruch holds that rib-resection must be done in a pressure chamber. Of 63 patients operated on under these conditions, 57 healed without a fistula and six died, whereas of 32 patients operated on without a pressure chamber 17 died. Where the lung is adherent to the parietal pleura an extrapleural resection of the ribs must first be performed; two or three weeks afterwards the pleura may be opened and the adhesion reduced.

The second official subject was the treatment of ureteric calculi. Prof. Voelcker (Halle) spoke of the difficulty of distinguishing the symptoms of calculus, cholecystitis, appendicitis, and ileus, to which end radiography is not always reliable. By catheterisation of the ureter the calculus may sometimes be brought back to the pelvis of the kidney. To reduce the pain caused by a calculus spinal anæsthesia may be tried; if there is no improvement ureterotomy with primary suture is necessary. Should the colic and retention of urine improve without removal of the calculi a condition resembling chronic cholecystitis is set up and there is a danger of the kidney being damaged by infection. Treatment then consists of the administration of suitable mineral waters by the mouth, with injection of oil or glycerine into the ureter. Prof. Voelcker did not approve of dilatation of the ureter according to Burger's method or of permanent catheterisation, which increases the chance of infection. Some calculi, he pointed out, are primarily infected—especially phosphatic calculi with a rough surface. In such cases intravesical therapy is undesirable; ureterotomy is indicated and the kidney may have to be removed. In acute anuria where catherisation of the ureter has not succeeded the kidney must be made accessible. If its condition is still pretty fair a renal fistula may be made through which the calculus will usually be discharged. If stones are present in both kidneys, and neither radiography nor ureteral catheterisation shows which is most affected, both must be made accessible so that the worse can be removed.

The third official subject, the treatment of adhesions in the abdominal cavity, was opened by Prof. Clairmont (Zurich) who showed a large collection of anatomical specimens illustrating different kinds of adhesions.

A Serological Blood Test.

Prof. Zangemeister (Königsberg) not long ago reported to the Berlin Medical Society on his experiments on blood-serum. It is known that by mixing the serum of two persons, the albumin being precipitated, the mixture becomes opaque. The degree of opacity, however, is sometimes so slight that it cannot be ascertained in the ordinary way. Zangemeister has therefore used the Tyndall effect, with Zeiss's photometer, which allows a very accurate measurement of the intensity of light. A mixture of the sera of two unrelated persons and a mixture of the sera of a mother and her child are at first equally transparent. But whilst the transparency of a mixture of the serum of the two unrelated persons persists, that of mother and child by and by decreases. A second test is made by the ultramicroscope, with which the illuminated albuminous substances look like stars in the heavens. In the mixed serum of mother and child the stars gradually conglomerate into large spots. The test proved reliable in the cases tested by Zangemeister, not only for mother and child but also for father and child, and not only for new-born infants but also for persons up to the age of 30.

Nationalisation of the Profession.

Between the municipal authorities and the medical profession in Berlin a conflict has arisen, which is of fundamental importance apart from its local interest. According to the Act concerning the campaign against venereal diseases the municipal authorities are obliged to take measures for the care of persons suffering from, or suspected of suffering from, such diseases. This provision has been complied with in many cities by the establishment of municipal dispensaries. Throughout Germany these dispensaries abstained from treatment, the patient being sent with a note to his club doctor or private practitioner after he has been examined. In Berlin alone have the dispensaries from the first undertaken treatment as well as diagnosis. By an agreement made in 1928 it was stipulated that the existing dispensaries might continue on condition that no new dispensaries were established by the city, but the Berlin municipal authorities have now given notice that they do not propose to be bound any longer by this agreement, which expires on July 1st, and that they feel obliged to open new dispensaries. Negotiations between the Hartmann-Bund and the city having failed, the Hartmann-Bund has declared a boycott of these dispensaries so that no medical man belonging to the Bund may apply for or accept an appointment in them. The boycott has been extended to other dispensaries too—for instance, those for tuberculous patients, and for mothers. The Hartmann-Bund states that already no more than 10 per cent. of the patients calling at municipal dispensaries are sent to private practitioners, the remainder being cared for in the dispensaries. Obviously the Berlin municipal council, which is under the influence of the Socialist Party, aims at complete socialisation of the medical profession, as has been observed on other occasions. The Berlin profession will fight against this tendency, for it is calculated to destroy the small residue of private practice which still remains.

According to a report by the Berlin Municipal Health Office, 67 per cent. of the children examined by the municipal dentists needed dental treatment. Children with healthy teeth are rare in Berlin schools, the cause being inadequate feeding.

The Cleveland disaster has caused some anxiety as to the possibility of a similar happening in one of the German hospitals. The Government has stated in the press that long before the Cleveland disaster instructions were given to the hospitals about the storage of films and their separation from combustible material. According to this statement it is highly improbable such a thing could happen in this country.

STOKE NEWINGTON HOME HOSPITAL FOR WOMEN.—Recently Princess Helena Victoria, the Patron, unveiled a tablet to the memory of Miss Isabella Lister, who was long closely connected with this hospital, which, with the exception of the visiting doctor, is entirely staffed by women. The institution was founded in the present building in 1825 by an aunt of the late Lord Lister, whose grandfather resided at Stoke Newington; Miss Isabella Lister was another relation. The Princess named the ward containing the tablet the "Isabella Lister Ward."

MEDICINE AND THE LAW.

A Coroner on Vaccination.

AT the adjourned inquiry on June 13th into the death of a woman of 31 following vaccination (the case is reported on p. 1302 of this issue) the coroner, Mr. Ingleby Oddie, in summing up remarked that this death, as well as another into which he had just inquired, was due to post-vaccinal encephalitis after primary vaccination performed later than in infancy. People, he said, apparently acquired the unknown germ of encephalitis after infancy; in many cases it was lying dormant and was excited into activity by some such stimulus as vaccination. Since in infancy there was presumably no germ of encephalitis yet present in the child's body, it would be better for all children to be vaccinated in early infancy instead of waiting until a small-pox scare caused them to be vaccinated later in life. In that way they would evade this risk of post-vaccinal encephalitis. Further, inasmuch as secondary and tertiary vaccination did not apparently result in encephalitis, it was worth considering whether that was possibly due to the slight local and general reaction occurring in those cases. If so, might it not be wise, he suggested, to try vaccination in all cases with fewer insertions and therefore less reaction? Possibly a less active—i.e., more dilute lymph—might not give rise to post-vaccinal encephalitis in primary vaccinations. Mr. Oddie expressed regret that coroners were not supplied with important documents such as the Rolleston report, of which, it seems, he had never heard. This particular report contained recommendations which might save many lives. Such highly important records of current research work should, he said, be furnished to the officials who are always dealing with deaths. On account of their expensive nature coroners did not see, for example, the annual reports of the Medical Research Council.

Operation at Wembley Hospital: Successful Claim for Fees.

There may be a popular impression that treatment in any kind of hospital means free treatment. Another county court decision in connexion with the Wembley Hospital, has, however, illustrated the practitioner's right to charge a fee for professional services in a case where the ordinary elements of a contract can be inferred. It is a common legal principle that the acceptance of a performance which has been requested will generally support the inference of a promise to pay a reasonable reward. As the Watford county court judge pertinently asked in the case to be discussed below, "Why should a doctor be presumed to do everything gratuitously?" In such a case as the following the important evidence is that which proves or disproves the employment of the practitioner by the person against whom the claim for fees is made.

Dr. J. A. Mackinnon, of Park-drive, Wembley, claimed 30 guineas from Mr. Henry King, of Berkhampstead-avenue, Wembley, for professional services. Plaintiff, who is on the honorary staff of the Wembley Hospital, attended defendant's wife in July, 1928, having been called into consultation by Dr. Cowardin. He decided that an operation was necessary, but, as the patient suffered from a definite heart disease, the operation was postponed and medical treatment was relied upon. In August, in Dr. Cowardin's absence on holiday, Dr. Mackinnon again attended Mrs. King; in September he saw her again and came to the conclusion that immediate operation was necessary to save her life. Her husband was not then at home. Dr. Mackinnon explained to her son that he would not take the responsibility of postponement for a single day. The son was asked to get into touch with his father; he did so by telephone, returning with a message that it was all right and that the operation should proceed. It was decided to remove Mrs. King to a private ward at the Wembley Hospital and no objection was taken to that plan. Dr. Mackinnon stated that he saw the defendant at the hospital that evening and made it clear that operation was the only means of saving Mrs. King's life; Mr. King replied "I am glad you have decided to do it." The operation was entirely successful and the patient was placed in the public ward, the private ward being full. Dr. Mackinnon had further conversation with Mr. King that night. Next day he attended Mrs. King, who had collapsed in the ward, and he obtained another nurse for her. The following day there was a vacancy in the private ward (in which, it is understood, there are four adult beds) but the patient preferred to remain where she was. In answer to the judge, Dr. Mackinnon estimated that he had attended Mrs. King at least twice a day for the 12 days she was in the hospital. In cross-examination he agreed that doctors in attendance who were members of the honorary medical staff should not charge a fee; but he did not agree with that rule as regards patients who could afford to pay. He was not asked by the hospital authorities to perform the operation. Dr. Cowardin gave confirmatory evidence for the plaintiff, and another witness remembered hearing Mr. King (in discussing expense) say that he was prepared to pay in moderation. The defendant said he earned £400 a year. He received his son's telephone message and had no alternative but to agree; he was not aware that the doctors were at that moment in his house. He had agreed with the hospital authorities to pay three guineas a week for his wife; he was told he would not have to pay anything for the operation. After hearing other witnesses for the defence, including the secretary of the hospital, the judge gave judgment for Dr. Mackinnon with costs, adding that he had not heard an action with a defence of less merit. He found that there was, in fact, a contract of employment for the performance of this particular operation and that the charge was fair and reasonable. It was a very serious operation which was completely successful; moreover the plaintiff's services continued afterwards. There was nothing to suggest that the defendant should not pay the plaintiff's fee. A number of side-issues had been introduced by the defence; whatever bearing they might have on the hospital authorities of the organisation of the medical profession, they had—said the judge—no bearing on the action before the court.

One of these side-issues was a desperate attempt to discredit Dr. Mackinnon by an accusation of dichotomy. He had stated in cross-examination that Dr. Jenkins was the anæsthetist and that Dr. Cowardin also assisted at the operation; they would receive three guineas each. The objectionable element in fee-splitting is, of course, the danger that fees are unnecessarily inflated by transactions between practitioners of which the patient is kept in ignorance. In Mr. King's case the judge (after hearing evidence at what he evidently regarded as excessive length) was satisfied with the fairness of the plaintiff's charges. To know which patients can afford to pay a fee, and to know what fee they can afford, may be a difficulty, but it is a difficulty which hospitals will have to face increasingly in future. Hospitals presumably do not desire to antagonise the medical profession, nor would they feel justified in asking the public to subscribe for the treatment of those who do not need charity. In the case under discussion two witnesses who sought to establish the defendant's case were the secretary of the hospital and the chairman of its house and finance committee; the solicitors for the defendant, it is believed, are also the solicitors for the hospital. If so, there is nothing improper or sinister in the alliance—least of all if it means that the hospital will make itself responsible for Dr. Mackinnon's costs. But the recurrence of these incidents at Wembley raises a suspicion of unfriendliness towards the medical profession which tact is needed to avoid.

Workmen's Compensation: Suicide following Nystagmus.

A miner contracted nystagmus in 1926. Three years later, after visiting a doctor (accompanied by the branch secretary of the Miner's Federation) and after being told that he was still suffering from nystagmus, he disappeared and his body was recovered from a canal two miles away from his home. A claim was put forward by the widow in the St. Helen's County Court on June 12th. Evidence was given that, before he lost his health, the deceased was cheerful in temperament, but that, after contracting the disease, he grew morose and depressed. Some doubt was raised on behalf of the employers as to whether the deceased was actually suffering from nystagmus when he committed suicide. The Medical Referee held that the disease had turned his brain and caused him to take his own life. Suicide being thus regarded as a consequence of the nystagmus, the widow was awarded £400 compensation.

Merchandise Marks Act Prosecution: Coffee and Caffeine.

The magistrate at Bow-street on June 12th dismissed a summons against Wallace Pure Foods, Ltd., for having applied to certain tins of coffee, with intent to defraud, a false trade description. The tins were labelled "P. R." coffee, the initials standing for "Physical Regeneration." Labels stated that the coffee was "practically caffeine free, 100 ounces (representing 100 pints of liquid coffee) containing one-hundredth part of an ounce of caffeine." The prosecution's analysis indicated that caffeine from 3·37 to 3·7 grains per ounce was present, which was only a fraction less than the average amount contained in ordinary commercial coffee. For the defendants an analyst said that free caffeine might have been found in the coffee by analysis; but the analyst would have to obtain it from caffeine chlorogenate, a substance containing properties entirely different from those of ordinary caffeine salts. The magistrate accepted the defendant's contention that "caffeine" must mean "free caffeine" and not caffeine in conjunction with other substances. Experts for the prosecution had shown that, in order to obtain free caffeine, they had to break down the compound. This, said the magistrate, was a pale roasted caffeine (according to the label), and there was always more caffeine in dark roasted caffeine. On the dismissal of the summons an application for costs was refused. The prosecution mentioned the possibility of taking the matter to the High Court.

Tincture of Iodine.

An article which appeared in THE LANCET of Sept. 1st, 1928 (p. 443), was the subject of discussion before the Ealing magistrates on Thursday of last week, when Messrs. F. W. Woolworth and Co., Ltd., were fined £2 under the Food and Drugs (Adulteration) Act, and ordered to pay 10 guineas as costs for selling to an inspector of the Middlesex County Council "tincture of iodine" not compounded in accordance with the British Pharmacopœia, but consisting of a weak solution of iodine in isopropyl alcohol. For the defence it was stated that Messrs. Woolworths formerly sold tr. iodi mit., B.P., but last August were warned by the Excise authorities that the sale must be discontinued unless they had a spirit licence. The article by Dr. R. A. Macdonald and Mr. J. W. Peck, of the Great Ormond-street Children's Hospital, which appeared in THE LANCET soon afterwards, recommended a solution of iodine, 1·25 per cent., in isopropyl alcohol as an economical and satisfactory substitute for hospital use for skin antisepsis. This could be sold without a licence, and Messrs. Woolworths had been selling it labelled "iodine solution" since February. Among the witnesses for the defence was Dr. P. W. Boobbyer, of Ealing, who said that the solution was an excellently effective preparation which he would use himself without hesitation. Anyone other than a doctor who used iodine generally used 500 times as much as was required. The magistrates intimated that they thought that in selling the substitute when tincture of iodine was asked for, Messrs. Woolworths had been negligent, but not deliberately fraudulent.

Public Health Services.

REDUCTION OF TUBERCULOSIS IN LANCASHIRE.

THE Tuberculosis Committee of the Lancashire County Council has just presented a report showing the decrease in the number of deaths recorded from both pulmonary and non-pulmonary tuberculosis during 1928, as compared with previous years. The death-rate from *pulmonary* tuberculosis—namely, 0·58 per 1000 of the population—is the lowest on record in the administrative county for the sixth year in succession. For *non-pulmonary* tuberculosis the death-rate—namely, 0·15 per 1000—is also the lowest recorded for the county. Under the Public Health (Tuberculosis) Regulations, 1912, the total number of notifications of new cases of tuberculosis for the year 1928 in the administrative county is the lowest on record, as will be seen from the following table:—

Tuberculosis Notifications.

Year.	Pulm. tuberc.	Non-pulm. tuberc.	Total	Notifications.*	Year.	Pulm. tuberc.	Non-pulm. tuberc.	Total	Notifications.*
1913..	2700	1592	4292	1·54	1921..	2044	899	2943	1·16
1914..	2820	1140	3960	1·61	1922..	1863	956	2819	1·05
1915..	2872	1128	4000	1·64	1923..	1937	1188	3125	1·09
1916..	2689	1180	3869	1·52	1924..	1972	1120	3092	1·10
1917..	2375	1062	3437	1·35	1925..	1846	1027	2873	1·03
1918..	2534	885	3419	1·47	1926..	1828	953	2781	1·02
1919..	2105	847	2952	1·21	1927..	1794	1045	2839	0·99
1920..	2084	968	3052	1·20	*1928..*	*1660*	*956*	*2616*	*0·91*

* Number of notifications of pulmonary tuberculosis per 1000 of population.

The improvement, it is pointed out, is really greater than the figures show, as in the earlier years there is no doubt that a considerable number of cases escaped notification. This is proved by the fact that in 1918 there were 303 deaths from pulmonary tuberculosis in which the case had not been notified, whereas during 1928, with general greater efficiency in rendering notifications under the regulations, the figure dropped to 56.

The decline in the number of deaths recorded, and of new cases of tuberculosis notified in 1928, has taken place despite the serious amount of unemployment in the staple industries.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 8TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 272 (last week 242); scarlet fever, 1614; diphtheria, 929; enteric fever, 41; pneumonia, 1014; puerperal fever, 36; puerperal pyrexia, 110; cerebro-spinal fever, 14; acute poliomyelitis, 2; encephalitis lethargica, 22; dysentery, 6; ophthalmia neonatorum, 112. No case of cholera, plague, or typhus fever was notified during the week.

The largest incidence of small-pox at the moment is in London (Bethnal Green, 15; Shoreditch, 11; Stepney, 30); Blackwell R.D. (Derby), 15; South Shields, 11; West Ham, 28; Northampton, 16; Stoke-on-Trent, 24; Spenbury (Yorks), 6; Pontefract R.D., 8.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on June 11th–12th was as follows:—Small-pox, 301 under treatment, 14 under observation (last week 286 and 16 respectively); scarlet fever, 1348; diphtheria, 1525; enteric fever, 16; measles, 164; whooping-cough, 583; puerperal fever, 30 (plus 10 babies); encephalitis lethargica, 119; "other diseases," 51. At St. Margaret's Hospital there were 18 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (1) from enteric fever, 63 (3) from measles, 4 (1) from scarlet fever, 32 (6) from whooping-cough, 21 (6) from diphtheria, 48 (5) from diarrhœa and enteritis under two years, and 53 (6) from influenza. The figures in parentheses are those for London itself.

Liverpool reported 20 deaths from measles, Leeds 6, and Birmingham 5. Leeds stood highest with 3 deaths from whooping-cough. Diarrhœa accounted for 5 deaths in Liverpool, 4 in Nottingham, and 3 each in Birmingham, Leeds, and Sunderland. Birmingham reported 4 deaths from influenza.

The number of stillbirths reported during the week was 264 (corresponding to a rate of 35 per 1000 births), including 53 in London.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1928 statistics of two sea-port cities and a county:—

Name of district and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Plymouth .. (211,980)	17·0	12·0	0·90	1·52	2·1	1·3	69/34	38	6·0
Aberdeen (City).. (159,954)	20·7	14·0	1·05	1·55	1·8	—	94/38	43	7·5
Aberdeen (County).. (105,713)	21·9*	13·4	0·97†	1·29	1·6	—	63/—*	—	4·2*‡

* Amongst a population of 120,801, including 8 of the 10 burghs.

† Amongst a population of 143,191, including the 10 burghs.

‡ From puerperal sepsis only.

Plymouth.

Dr. A. T. Nankivell mentioned last year that extension of maternity and child welfare work would be not only desirable but also popular with the citizens. This increase has not yet been accomplished, but Dr. Nankivell hopes that before long it will be forthcoming. Some of the practitioners in Plymouth view with apprehension this extension and that of the school medical service, and Dr. Nankivell goes on to point out how very much better from a financial point of view it is for the panel doctors to have charge of patients whose health has been well supervised in their youth. An increase in the medical staff is needed not only for extensions but for meeting sickness absence, holidays, and emergencies. There were 28 cases of mild small-pox with no deaths, and Dr. Nankivell welcomes the provision of the new hospital at Lee Mill which is now nearing completion. Among other matters which indicate the progress in 1928 are: The completion of the central laundries for the corporation hospitals; the opening of a new block for boys at Didworthy sanatorium; the installation of an X ray plant at Beaumont House tuberculosis dispensary; the provision of a new motor-ambulance, and the sanction of the Ministry for the treatment of 40 cases of intermediate and advanced tuberculosis in women at Swilly Hospital.

Health education has received much attention. 132,000 copies of the magazine "Better Health" were distributed. As an example of the usefulness of the latter, a case is quoted where a woman consulted her doctor early as the result of listening to an article read by her son on cancer. The articles in "Better Health" are used for essays and lectures in the schools. The municipality own a number of cinematograph films, which were exhibited thousands of times at the theatres and cinemas. The "Runsyne" machine with its illuminated messages on health subjects has been operating in two positions during the year. Much educational work was carried out at the Health Exhibition in the Drill Hall during a week in July. Dr. Nankivell mentions that there have never been so few deaths from tuberculosis as in 1928, but that there is a marked increase in cancer mortality. He thinks the slow disappearance of tuberculosis is chiefly due to the facts that the disease is naturally dying out, that the standard of living is getting better, that the people are becoming more educated, and that the activity of tuberculosis schemes is increasing. Plymouth has much house property of so poor and decadent a nature that it is not reasonably fit for human habitation. The reconditioning work done during 1928 is described but, says Dr. Nankivell, only the fringe of the housing problem is touched as yet, and the fact that we are now suffering from the want of foresight of our great grandfathers is no excuse for inertia to-day. Dr. Nankivell looks forward to a great improvement in the hospital facilities of Plymouth when the poor-law is taken over next year.

The yield of oysters from the Tamar beds shows a reduction in recent years, and there is reason to believe that the beds have been overdredged and should be given a rest for several years. The oysters obtained, owing to the pollution of the Tamar, are replanted in the Yealm and Helford rivers until ready for sale. The purity of the Yealm is being threatened by crude sewage from the new houses springing up on its banks. The attempt to breed oysters in the Yealm has up to now been a failure.

The municipal slaughter-house ("an unseemly and inadequate place") is to be closed, and a new modern abattoir with proper cold storage in the neighbourhood of Prince Rock is strongly urged. This question has been discussed without result for a quarter of a century.

Aberdeen.

The acting medical officer of health, Dr. George S. Banks, states that the present report is mainly a statistical survey, the results of various experimental investigations of the health department having been incorporated in the 1927 report. The figures for 1928 bring out the greater relative fatality of measles and whooping-cough. Thus there were 728 notifications of scarlet fever with 5 deaths, a case-fatality of 0·7 per cent.; there were 458 notifications of diphtheria with 15 deaths, a case fatality of 3·3 per cent.; the cases of measles known to the health department numbered 1812 with 50 deaths, a case-mortality of 2·8 per cent.; while the cases of whooping-cough reported numbered 579 with 37 deaths, a case-mortality of 6·4 per cent. Out of 15 notified cases of paratyphoid B, 6 occurred in an institution as the result of infection by a carrier. The immunisation scheme makes progress and during the year 1704 children were immunised at the welfare centres and 2646 in the schools simultaneously against diphtheria and scarlet fever, while 665 out-patients were similarly dealt with. The case-notes are given of an unusual attack of continued fever caused by *B. alkalescens* (Andrewes). The illness ended in recovery after about six weeks in hospital. It is estimated that of the 168 deaths from tubercle, 92 per cent. were due to the human bacillus and 8 per cent. to the bovine. Of 90 samples of milk examined, 6, or 6·7 per cent., contained tubercle bacilli, while the average percentage for the years 1923–27 was 5·7.

In January an outbreak of septicæmia occurred in a maternity institution which had provision for 26 maternity beds and 8 antenatal cases. The wards were considered to be overcrowded and relief was given by the admission of patients to the municipal hospitals. Twelve mothers developed puerperal fever within a period of 5 weeks and 4 died. The outbreak was due to hæmolytic streptococcal infection. Concomitantly there was an outbreak of icterus neonatorum with 7 infant deaths, and the *S. hæmolyticus* was found post mortem. Examination of the "contact" mothers revealed the *S. hæmolyticus* in the uterus and throat of one, in the uterus of 4 others, and in the throat of 3 others. Out of 12 nurses, 5 gave positive results from throat cultures. Some of the findings of the report of the Scottish Board of Health on maternal mortality in Aberdeen 1918–27, published in 1928, are given. It is suggested, amongst other things, that the high incidence of puerperal sepsis in maternity institutions in Aberdeen is due to contagion, and that the higher incidence of puerperal sepsis in the practice of doctors as contrasted with that of midwives is due, partly, to a streptococcal carrier condition in doctors. Of 3423 live births, 652 were attended by midwives; 603 as in-patients and 194 as extern patients by the maternity hospital; 1972 by medical practitioners, and 2 were unattended. There were 25 deaths of women associated with pregnancy and childbirth, including all deaths within four weeks after childbirth or later if the illness originated in the puerperium. In 4 the confinement was attended by a midwife; in 9 by the maternity hospital; in 7 by medical practitioners; and in the remaining 5 by other institutions. In 12 of the cases the fatal confinement was the first.

The undertaking with the parish authorities to admit all the sick poor to Woodend Hospital was occasionally difficult to fulfil, but no pneumonias were refused admission to hospital. There were 110 lobar pneumonias treated in hospitals with 7 deaths, 76 broncho-pneumonias with 12 deaths, and 7 influenzal with no deaths. One butcher, who sold a carcass of a pig grossly affected with tuberculosis to another, was fined £20 and the recipient of the pig £5. The sunshine record was 1227 hours, as compared with an average of 1285 for the previous 30 years.

A table giving a comparison of the statistics of the six principal Scottish towns shows that the standardised death-rates from all causes were: Edinburgh, 13·9; Aberdeen, 14·1; Paisley, 14·4; Dundee, 15·1; Glasgow, 16·7; and Greenock, 17·1; and that the infant mortality-rates were Edinburgh, 75; Aberdeen, 94; Dundee, 102; Paisley, 105; Glasgow, 107; and Greenock, 120.

Aberdeen County.

Dr. Harry Rae (who has since been appointed M.O.H. for the city of Aberdeen) reports that the immunisation scheme against diphtheria and scarlet fever is being continued, but that this work in a rural area must be more or less sporadic unless a special medical staff is employed. In addition to the schools immunisation has been used for the employees of three dairy farms which supplied Certified Milk. Retesting is found to be very necessary, but during the year there were only three notifications of diphtheria among children who had been inoculated. In order to obtain a higher immunity against scarlet fever four injections are being used instead of three, the fourth being one of 5000 skin test doses. It has been found that immunity against scarlet fever is usually established 14 days after the last injection. This scarlet fever immunisation may prevent the occurrence of "return" cases, whilst the same cannot be said of diphtheria, in the case of which immunity takes from six weeks to six months to develop. In order to prevent "return" cases of diphtheria, passive immunisation by 2000 units of antitoxin is recommended. The dosage laid down for the treatment of diphtheria is 4000 units for the first day of illness, 6000 units for the second day, and 8000 for the third day.

A county institution had one fatal case of typhoid fever in April and contemporaneously, an outbreak of ten cases of paratyphoid B, which appeared to be associated with a carrier in the kitchen staff. At the end of August there was a sudden outbreak of infantile paralysis chiefly in the neighbourhood of Fyvie. There were 13 cases in all, with one death. Three of the cases occurred in areas distant from Fyvie. Of the ten Fyvie cases three occurred in one family and two in another. Social circumstances and milk-supply had no bearing on the outbreak. The diagnosis was confirmed by the examination of the cerebro-spinal fluid. One of the two cases in one family had a previous attack six years ago, on which occasion paralysis of the leg appeared five weeks after the initial illness. After the second attack there was paresis of the left arm. The particulars of this case were confirmed by the records of the county public health department and of the city hospital. A previous outbreak of this disease occurred in the city from April to September, 1916, when there were 79 cases and 4 deaths, and coincidently 16 cases in the county with no deaths. In the 1916 outbreaks there appeared to be no connexion between the cases except in two households where there was a second case, and the households affected were chiefly of good social status.

The housing position shows progress in the provision of new houses. Dr. Rae is enthusiastic as to the advantages of the Housing (Rural Workers) Act, 1926, and thinks it is the only Act which will stem the tide of rural depopulation. Under this Act there were only 50 applications in 1927, whereas in 1928 there were 126, 43 of which were dealt with by the Deer District Committee. Dr. Rae goes on to point out that the Act is not limited to the housing of agricultural workers, but applies to those with similar financial resources, and is also applicable to burghs. He urges every burgh to adopt the Act, and further emphasises the powers given by many housing Acts to local authorities to purchase and reconstruct dilapidated properties, which can then be let at rentals within the reach of the poor. In many of the burghs owners of houses are financially unable to put them in habitable repair according to present-day standards.

The county veterinary inspector points out that with the present staff it is only possible to visit the dairy farms in the widespread area of the county once a year, and that a more frequent inspection is necessary for the detection of tuberculosis. In Aberdeenshire many of the cows are bought newly calved and only retained in the herd for one lactation. It follows, therefore, that many cows enter and leave a herd during the course of a year without ever having been seen by the veterinary inspector. During 1928 the inspector discovered 21 cows with tuberculous mastitis, which were dealt with under the Order. In three notified cases of (human) non-pulmonary tuberculosis the evidence appeared to incriminate certain milk-supplies, and the veterinary inspector found that two of the patients had been supplied with milk over a prolonged period from farms where there were cows suffering from tuberculous mastitis.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The Neech prize offered annually for the best paper read before a branch or group of this Society has been awarded for the session 1927–28 to Dr. H. Stanley Banks, medical superintendent of the City Isolation Hospital, Leicester. Dr. Banks's paper was on the Intensive Serum Treatment of Severe Diphtheria, and was read before the Fever Hospital Medical Service Group of the Society. A paper on the same subject by Dr. Banks and Dr. George McCracken appeared in THE LANCET of July 7th, 1928 (p. 4).

The annual provincial meeting of this Society will be held at the Sedbury Park Hotel, near Chepstow, on Saturday, June 29th, at 10.30 A.M., when Dr. E. Colston Williams (county medical officer for Glamorgan) and Dr. R. M. F. Picken (medical officer of health for Cardiff) will open a discussion on the Medical Aspects of the Local Government Act, 1929. After lunch members will motor to Chepstow Castle, Tintern Abbey, and Raglan Castle, and thence to a garden party at Llanover Park, by invitation of Lord Treowen, Lord-Lieutenant of Monmouthshire, and Lady Treowen. The full programme may be found in the current issue of *Public Health.*

Corrigendum.—We regret an error which occurred in the obituary notice last week of Sir William Fairbank. Mr. H. A. T. Fairbank is the son of the late Dr. Thomas Fairbank, the elder brother of Sir William.

Obituary.

SIR WILLIAM THOMPSON, M.D. DUB.,

FORMERLY REGISTRAR-GENERAL FOR IRELAND.

THE sudden death of Sir William Thompson on the night of June 10th caused a sense of personal loss to the whole medical profession of Dublin, as well as to a large circle of friends. After a day of usual activity, and presenting no evidence of ill-health, he retired to bed, and was found dead next morning. He was 68 years of age.

Thompson was born in the north of Ireland, but spent his whole life from boyhood in Dublin. As a young man he entered the Civil Service, but shortly abandoned it for medicine, and qualified in 1888 with the double diploma of the Irish Royal Colleges. Six years later he proceeded to the degree of Bachelor of Medicine of Dublin University, took the M.D. degree in 1895, and became a Fellow of the Royal College of Physicians in 1902.

SIR WILLIAM THOMPSON.

Photo by Lafayette.

In his earlier professional life Thompson was engaged in general practice, but soon was elected physician to Jervis-street Hospital. He resigned medical practice in 1909 on his appointment as Registrar-General for Ireland, in which office he continued until his retirement under the age rule three years ago. During the second Vice-Royalty of Lord Aberdeen he was one of the physicians to the Lord Lieutenant, and during his tenure of this post he came prominently before the public eye. For Lady Aberdeen decided to organise a campaign for the improvement of health in Ireland, and, in particular, to fight against tuberculosis, and in this campaign Thompson was her chief adviser and right-hand worker. He showed an energy and power of organisation which had hitherto had little scope, and the success of the campaign in educating the public of Ireland, and in reducing the mortality from tuberculosis, is largely due to his energy and gifts. In work of this kind he remained indefatigable up to the day of his death.

In 1925, having filled various other offices, he was elected President of the Royal College of Physicians of Ireland, and the following year saw his retirement from public office, since when he devoted the whole of his time to voluntary philanthropic work. The Women's National Health Association, the Sanatorium for Tuberculosis at Peamount, Sir Patrick Dun's Hospital, the Royal Victoria Eye and Ear Hospital—these are only a few of the institutions where he expended his energy. He was a working member of innumerable committees, and everywhere that he worked his common sense, his business capacity, and his good humour made his help effective. He will long be missed on the executive of these and other philanthropic and humane undertakings in Dublin. For his gifts of adaptability, geniality, and good-heartedness made him the most pleasant of colleagues.

At his funeral, which was held at the Centenary Methodist Church, St. Stephen's Green, Dublin, on June 13th, all the numerous institutions and associations which he had served so well were prominently represented, among a large assembly of friends and the general public.

Correspondence.

"Audi alteram partem."

EXAMINATION OF TUBERCULOSIS CONTACTS.

To the Editor of THE LANCET.

SIR,—I have read with great pleasure your leading article of June 8th and the criticisms of it last week. If Sir Robert Philip and Dr. Fanning will pardon me I think they have taken the lighter parts of the article far too much to heart. At various periods I have had charge of a children's sanatorium and there is nothing I think sadder than the thought that probably 90 per cent. of the little patients had no tuberculosis at all and yet they had been notified and thus stigmatised for life. Every central tuberculosis dispensary ought to have a good X ray plant, but in many ways it would be dangerous as many more children would be sent to sanatoria simply on hilar shadows, if the tuberculosis officer has an idiosyncrasy in that direction. Obviously we do get pulmonary tuberculosis in school-children with tubercle bacilli in their sputum, but they are extremely rare. The omnibus expert and the pseudo-sanatorium are the two outstanding blots on all tuberculosis schemes. Abolish them and the "contact" and other questions will right themselves. There ought to be many more convalescent homes for debilitated contacts.

I am, Sir, yours faithfully,
JAMES D. MACFIE.

Winsley Sanatorium, near Bath, June 15th, 1929.

To the Editor of THE LANCET.

SIR,—It is perhaps natural that the first paragraph of your leading article of June 8th should have provoked indignant replies from those who practise and preach the doctrine of examination of contacts. Even those of us who are very sceptical about its value as a preventive measure would nevertheless hesitate to recommend that this practice should be dropped. The careful examination and following up of the families and contacts of tuberculous persons, while, in the experience of most tuberculosis officers, it fails to detect symptoms of tuberculosis which anyone with an ounce of scientific scepticism would regard as significant, is gathering for us over a long series of years just that information necessary to establish a sound knowledge of the natural history of the disease which at the present time tends to be theoretical and founded on analogy with the pathological course of the disease in animals. Here is a group of persons willing in their own interest to submit themselves to examination, some of whom are certain to present manifest signs of tuberculosis sooner or later. The opportunity of watching their progress should not lightly be thrown away.

It is a fact that the great majority of cases of pulmonary tuberculosis which come under the notice of a department for the first time are not associated by familial or other contact with any previous known case. Further, those cases which do come of tuberculous families are very frequently unrecognisable as cases of tuberculosis even of an incipient character during the period over which it is reasonably practicable to submit most of them to continuous examination and supervision. For the reason already given it is desirable to extend the period of observation indefinitely in as many cases as possible, but if the results are to be of practical value the selection of cases for such observation should not depend on the presence of some evidence that the individual so selected is already prone to develop the disease. The obstacles to such a line of study are, of course, obvious to all whose function is the detection and cure of disease.

Since ever measures specifically directed at the eradication of tuberculosis have been discussed, there has been difficulty in balancing the two arms of attack—viz., prevention of infection and stimulation of resistance to it. The pendulum has swung one way and then the other. The inevitable result of the enthusiasm of the sanatorium specialists in the first decade of this century naturally led to the inauguration of schemes for early detection of cases and their submission to open-air treatment. An essential part of such schemes was the examination of contacts, and, of course, if the signs and symptoms are sufficiently indefinite it is possible to get very good results by this means. But, as a result of the work of the very sound and able clinicians of whom the tuberculosis service is now composed, there appears to be a swing back to the importance of preventing the spread of infection by isolating the advanced and highly infectious forms of the disease. The facts presented by Dr. Lissant Cox as to the incidence of tuberculous meningitis in the *infants* of infected households are an illustration of the influences coming to bear on the problem.

Obviously, we must lose nothing which we have gained by the intensive study of sanatorium treatment since 1912, but one of its most important lessons seems to be that the boosting of resistance should be applied before symptoms of any kind have appeared, and should not merely be confined to the suspected contacts of known cases of tuberculosis. Indeed it is a question affecting the general health of the community and depends as much on the education in hygiene of the healthy as of the *suspected*, since the latter must suffer for the communal sins of the former—as witness the problems of ventilation even in the office of a medical officer of health.

I am, Sir, yours faithfully,
RALPH M. F. PICKEN,
June 17th, 1929. M.O.H. and School M.O., Cardiff.

To the Editor of THE LANCET.

SIR,—Your thoughtful and timely comments on the report of Dr. Lissant Cox and the Lancashire Group of Tuberculosis Officers include criticisms of contact examinations as carried out at dispensaries with which many, though not all, tuberculosis officers will agree. But the criticisms hardly apply to home visits and contact examination in the home. If the tuberculosis officer makes a routine visit to the home of every patient, notes the conditions of life there, writes down the names of all members of the family as well as others exposed to infection, and reviews, or inquires about, the health of each, the procedure is by no means futile ; for—

(1) He is enabled to suggest useful readjustments in the patient's mode of life and endeavour to prevent infection.

(2) He may discover delicate children and benefit them by preventorium treatment.

(3) An unsuspected source of infection is sometimes noted.

(4) Occasionally a case of active major tuberculosis is found and treatment initiated. It is true that a number of cases with a few physical signs and symptoms will be seen who do very well at home with no special treatment; but experience helps to indicate what line should be followed in such cases.

(5) He notices what is disclosed in this report—the frequency of non-pulmonary tuberculosis in the households of tuberculous patients.

Some of this work can be done by the health visitors, but their services are perhaps more useful in following up cases and assuring, as far as possible, that patients act, and continue to act, according to instructions. The best potential preventive agent is the general practitioner, but the tuberculosis officer can help him considerably, without friction and without causing the patient to lose confidence in his adviser.

I am, Sir, yours faithfully,
Paignton, June 14th, 1929. ERNEST WARD.

To the Editor of THE LANCET.

SIR,—I read with great interest the first paragraph of your leading article of June 8th, and congratulate you on your courage. We have, in the Administrative County of Lancaster during the last 14 or 15 years, found that the examination of contacts is a matter of the greatest importance. But the contacts require to be selected. Thus, in the Administrative County in the last three years we have examined 3047 contacts, of whom 253 (168 pulmonary and 85 non-pulmonary) cases were definitely diagnosed as tuberculous ; 33 per cent. of the pulmonary cases had a positive sputum. Clearly, as your writer pointed out, a large proportion of such contacts are above school age. Your paragraph concludes with the sentence : " The so-called ' tuberculous seedling ' is not the precursor of the consumptive adolescent who from diffidence or pressure of business is usually reluctant to attend the dispensary as a contact." Our experience entirely supports this view. Further, our administrative arrangements as to the proportion of beds for adults and children are based upon it. Thus, 91·6 per cent. of pulmonary beds are reserved for adults, and we save much money by having but few beds for children supposed to be suffering from tuberculosis. Out of part of this saving we are able to devote more money to provide the tuberculosis officer with up-to-date diagnostic facilities—e.g., X ray apparatus—and also to pay salaries which will attract highly skilled officers. In short, we lay the greatest stress on accurate diagnosis and isolation of adult infective cases.

I am, Sir, yours faithfully,
G. LISSANT COX,
June 17th, 1929. Central Tuberculosis Officer, Preston.

*** We print on p. 1326 an extract from Dr. Cox's report to the Lancashire County Council giving the results of the Tuberculosis Committee's scheme.—ED. L.

PAYING A PATIENT'S BILLS.

To the Editor of THE LANCET.

SIR,—As the defendant in the action, Maley *versus* Churcher, certain features of the case struck me forcibly. Never have I been so surprised at reluctance to pay an account. A young schoolmaster is found one evening lying on the floor of one of the school bathrooms with a large wad of cotton-wool soaked with ether over his face. The scholars are mostly foreigners, boys and girls, thoroughly scared at this development. At his own request, the patient is sent home by car in the charge of a nurse. Neither will the father, who has his son home safe and sound, nor will the principal, who has had the cause of the upset in her school removed, pay for the hire of the car. The only application for payment made to me was a curt solicitor's letter stating I was liable for the hire of the car, and that failing immediate payment proceedings would be started. This was the first definite information I received that the car had not been paid for.

This case illustrates once again the value of membership of one of the medical defence societies. The solicitors of the Medical Defence Union came down to Eastbourne, with counsel, to contest the case, and did their unavailing best. Two appeals have failed to reverse the decision. It would have been very simple to have paid the £5 when first demanded, but a principle appeared to be at stake. The case was well worth fighting, even if the result was defeat. I have to pay the car hire and the Medical Defence Union the costs of both sides throughout the case. As a profession we now know that no one need suppose that a doctor is acting as an agent for his patient, unless with one and every order an explicit statement of such agency is made.

It may be mentioned that the school was only a holiday one, not one of the Eastbourne resident schools, and that my account for professional attendance remains unpaid.

I am, Sir, yours faithfully,
D. G. CHURCHER, M.D., F.R.C.S.
Eastbourne, June 17th, 1929.

*** We protested vigorously last week against the continued operation of legal rules under which the decision against Dr. Churcher was possible.—ED. L.

WOMEN'S HOLIDAY FUND.

To the Editor of THE LANCET.

SIR,—At a time when discussion of holiday plans is heard in all directions, and the eye is met by posters urging one to travel abroad or to take one's holidays in June, may we be allowed to remind your readers of the many poor women in London who get little or no relief from the monotony and drudgery of their daily lives? Last year the Women's Holiday Fund sent away 1025 women and 377 children for a fortnight's holiday to the seaside. The committee hope to be able to assist at least as many this year, provided they receive the same generous support. £3 is the average cost of a fortnight's holiday, but a gift of £2 will ensure *one woman having a holiday*, as the applicants contribute about one-third of the cost. It is unnecessary to dwell on the value of a holiday to those coming from poor and in many cases sadly overcrowded homes, and particularly to the wives and mothers on whom the burden and strain of life rests most heavily. The experience is, as many of them express it, "like a bit of heaven," especially when it is the first holiday of their lives. Subscriptions, large or small, will be gratefully received and acknowledged, and should be sent to the Secretary, Women's Holiday Fund, 76, Denison House, 296, Vauxhall Bridge-road, London, S.W. 1.

We are, Sir, yours faithfully,
A. F. LONDON,
MANUEL J. BIDWELL,
J. SCOTT LIDGETT,
HELEN A. POWNALL
(Chairman of the Executive Committee of W.H.F.)
June 18th, 1929.

WANTED, A PHOTOGRAPH.

To the Editor of THE LANCET.

SIR,—I am forming a collection of photographs of the pioneers of tropical medicine in connexion with the museum of the new London School of Hygiene and Tropical Medicine. I am particularly anxious to secure a photograph of Dr. George Thin (1838–1903), who made notable contributions to our knowledge of tropical affections, especially in connexion with sprue. If any reader has such a portrait to spare, or would lend it to be copied it would be very much appreciated.

I am, Sir, yours faithfully,
H. B. NEWHAM, M.D.,
Curator, London School of Hygiene and Tropical Medicine.
37, Torrington-square, W.C., June 18th, 1929.

SURGICAL ILLUSTRATIONS.

To the Editor of THE LANCET.

SIR,—I cannot help feeling that your reviewer has somewhat missed the point in his note on "the Graphic Guide to Elementary Surgery," by Prof. Naegeli, an English translation of which has just appeared. (THE LANCET, May 25th, p. 1096.) Whatever its artistic merits or defects it is unquestionably the most complete attempt that has yet been made to enable the student to visualise the underlying principles of surgery. Every page of the volume is filled with thumb-nail sketches, and, although it is true that in many instances these are from the artistic standpoint extremely crude, yet in every instance they show precisely the point which the surgeon wishes to stress, so much so that it would be a perfectly simple matter for a student to revise his knowledge without ever reading a line of the text. The mere crudeness of the illustrations is in fact a guarantee that the attention of the student will be directed to the essential point and that it will not be distracted by "artistic" detail. Personally, from the point of view of a teacher, I regard the volume as a perfect gold mine of suggestions for the blackboard, for there is not a single drawing in it which cannot be reproduced in chalk in a few seconds.

In my appreciation of Prof. Naegeli's diagrams, I am speaking from experience, for in my own book, "The Art of Surgery," I have attempted to illustrate my meaning by thumb-nail sketches in a somewhat similar way, and the difficulty of doing so can only be appreciated by those who have attempted it. It has been a constant source of friendly rivalry between my artist and myself as to whether the picture should show what I want or be well drawn, and we have both realised the risk of losing the meaning of my own crude sketches in an effort after artistic perfection. It is quite obvious that Prof. Naegeli was "top dog" in the partnership, whilst I perhaps have given in too much, but I am by no means sure which of us is right. At any rate, there is no possible doubt in my mind as to the immense practical value of his book, both to the student and his teacher.

I am, Sir, yours faithfully,
Queen Anne-street, W., June 18th, 1929. H. S. SOUTTAR.

A DESERVING APPEAL.

To the Editor of THE LANCET.

SIR,—We are writing to appeal for funds on behalf of Dr. Charles Powell White, who, as the result of a severe cerebral hæmorrhage, is unable to maintain himself, his wife and family. This position is largely due to the fact that he has devoted his life to cancer research for the benefit of the general public and the world at large. By his writings and works he has obtained an international reputation as an authority on cancer problems.

For many years he has given all his time to cancer research in Manchester for the Christie Hospital for Cancer, the Pilkington Cancer Research Fund, the University of Manchester, and the Manchester Committee on Cancer. In each of these appointments he has received only a nominal salary for a man of his eminence, and not being on the teaching staff of a University, he is not eligible for any pension. Possessing the highest medical and surgical qualifications, he could have commanded a much more lucrative position in the active practice of his profession, but he preferred to use his wide knowledge of mathematics, chemistry, physics, and general natural sciences for the study of cancer, its treatment and prevention.

Dr. Powell White's work has a soundness of character and a breadth of application still only incompletely recognised. Thus it is to him that we owe the present classification of tumours—a classification which has been very widely adopted by pathologists. His other work is less generally known, since it is more mathematical and abstruse, but from it emerges the fact that certain analyses suggest that in persons suffering from malignant disease, changes occur which show that some fundamental metabolic disturbance is present in this condition and that these changes are greater than can be accounted for by the growth itself. He possesses a grip of the problem of malignant disease shared by few.

Dr. White has conducted long and tedious analyses on cancer problems which would have daunted many by their extent and difficulty, and it was in his laboratory that he was taken ill. He has a world-wide reputation as an authority on cancer, and has communicated an article on the subject to your columns. We hope that many of your readers to whom we cannot send the special letter of appeal will be able to contribute towards the fund.

Subscriptions should be sent to Mr. Wilson Hey, 16, St. John-street, Manchester.

We are, Sirs, yours faithfully,
WALTER H. MOBERLY,
Vice-Chancellor, The University of Manchester.
FREDERICK P. NATHAN,
Chairman, The Christie Pavilion and Home.
R. VEITCH CLARK,
Chairman, The Manchester Committee on Cancer.
June 18th, 1929.

LOCAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—The duration of anæsthesia after the injection of novocaine solution is a direct function of the concentration of the drug. It is immensely increased if adrenalin be added. This suffices to explain the long anæsthesia which Mr. C. Abbott-Brown obtains, for he uses a much stronger solution than is injected into the spinal canal and adds adrenalin which should not be used intradurally as the resulting prolonged anæmia has been thought to be harmful to the delicate nervous tissue of the spinal cord.

I am, Sir, yours faithfully,
CHARLES A. PANNETT.

Pensford-avenue, Kew Gardens, June 17th, 1929.

THE NATIONAL PHYSICAL LABORATORY.

ANNUAL INSPECTION BY THE GENERAL BOARD.

THE annual inspection of the National Physical Laboratory at Teddington by the General Board is a function to which invitations are accepted with enthusiasm. While the visitors make holiday the scientific staff are allowed to enjoy only that form of recreation which results from change of occupation, for the work of answering questions and explaining the exhibits is at least as strenuous as their ordinary labours. The problem for the visitors consisted in deciding which of over 200 exhibits they would inspect. Many of them were anxious to be towed along the William Froude national tank, and while waiting their turn found much to interest them in the moulding shop where model ships the size of small pleasure boats are cut to any desired shape by most ingenious mechanical devices. The material of which these models are made is hard wax (not, as one visitor guessed, soap) to which any desired superstructure can easily be attached.

Wind Resistance to Ships.

The tank, which is enclosed in a building, is 500 feet long, 30 feet broad, and 12 feet deep. It is used chiefly to measure the air resistance to a ship in motion by means of tests made in water. A model is made of a ship, with funnel, masts, captain's bridge, and all deck erections. This model is then inverted in the tank and so arranged that the same part of the ship is immersed as would be above the water line if the ship were floating the right way up. This model is then towed along at different angles to the direction of motion over a range of low speeds, and the resistance of the water at various points is measured by the lengthening springs on the float to which the boat is attached by wires. The object of the tests is to determine the wind resistance and centre of effort of ship superstructures, with a view to improvement in ship speed and steering.

Experiments in Acoustics.

Another direction in which experiments with water can be adapted to give useful information about air conditions is in the investigation of acoustics. The path of a ripple in water closely resembles that of a sound wave in any one plane, and a small ripple tank on the plan of a vertical section of a town or concert hall has been devised for investigating acoustic reflections. At a place corresponding to the position of a speaker in the hall a disturbance is made in the water and the wave caused and its reflections from the roof can be photographed or thrown on a screen. The hall represented has two balconies, one of which has a roof continuous with that of the main hall, and the other a roof separated from that of the main hall by a short partition extending downwards from the ceiling. One of the problems to be solved concerned the balconies. In which of them could the speaker be best heard? The answer is that unless the hall is very large the audience on the balcony with the continuous roof hear better; where, however, the total path of the sound wave after reflection is greater than the normal path by more than 75 feet, the reflection instead of intensifying the sound will cause an echo, and in a hall of these dimensions the partition is therefore desirable.

Skidding in Motor-cars.

In the engineering department the model motor-cars used in the study of skidding excited interest. They are propelled along a flat surface by a catapult; at a given distance the brakes come into operation and the deviation of the car from the straight path is recorded. Some revision of the current methods of adjusting four-wheel brakes can be anticipated as a practical outcome of these experiments. For example, the retarding force is now generally distributed by manufacturers as two-thirds on the rear wheels and one-third on the front wheels. Experiments suggest that the proportion on the front wheels should be increased. Moreover, though it is now usual for back brakes to be adjusted to lock before the front ones, the model cars are found to keep a straighter course if the front wheels lock first. The importance of keeping the centre of gravity low to avoid the risk of overturning has been shown; also the advantages of a long wheel base in preventing rotation.

The Centre of Gravity in Man.

A model figure wearing a lifebelt of the pattern officially approved was shown floating in a tank in a semi-horizontal position. A very slight adjustment, made through the hollow tube which represented his spinal column, to a small weight in this tube, served to lower this centre of gravity and he assumed the vertical posture. The efficacy of the official belt is confirmed by experiments on this model, which show, however, that the margin which may determine a fatal change of position is narrow. It is interesting to learn that the investigators found considerable difficulty in ascertaining from physiologists the normal centre of gravity of man. Eventually it was obtained from German army figures as 0·54 of his height from the feet upwards, the centre of buoyancy being very nearly the same.

The Equilibrium of Dental Amalgams.

An ambitious programme of work on dental amalgams is being pursued. The amalgams in general use are largely empirical, and are not free from disadvantages. Experiments are in progress in which amalgams of different proportions of metals—for example, silver 29 per cent., mercury 71 per cent., are heated under pressure, in order to determine the thermal critical points, and their associated dimensional changes. It is known that when the dentist has prepared his alloy and inserted it, the equilibrium of the two metals is not stable for a period still to be determined. It is important to ascertain under what conditions either contraction or expansion is to be anticipated in order that the dentist may choose the alloy most suitable to his purpose.

Colorimetric Apparatus.

The apparatus shown in connexion with the measurement of colour includes equipment arranged for determining the properties of the "normal" eye, based on measurements of the spectrum colours by a large number of observers. When this determination is completed it will form a connecting link between the various practical methods of colorimetry and the physical properties of colouring materials, and will establish an accurate standard means of recording a colour by three numbers corresponding to the amount of red, blue, and yellow of which it is composed.

Clinical Thermometers.

The department where clinical thermometers are tested has not made any important changes in technique elaborated in previous years. Since the repeal of the law making compulsory the testing of every thermometer sold to the public, the staff has diminished to about half the number employed during the war. The standard required is not exorbitantly high—an error of less than 0·2 of a degree (Fahr.) does not lead to rejection of any thermometer. The cost to manufacturers of the test is only 3*d.* a thermometer, and if the medical profession urged the public to refrain from buying any thermometer not stamped with the letters N.P.L. at least one source of error in taking temperatures would be avoided.

Medical News.

University of Oxford.—At a congregation on June 8th the following degrees were conferred :—

D.M.—G. I. Evans.
B.M.—R. M. J. Harper, D. C. Shields, M. V. Bhajekar, and H. G. Wells.

Royal College of Surgeons of England.—A meeting of the Council was held on June 13th, with Lord Moynihan, the President, in the chair. It was announced that the Lister Medal for 1930 for distinguished contributions to surgical science had been awarded to Dr. Harvey Cushing, of Boston, U.S.A., and that Dr. Cushing had undertaken to give an address in London on some day in 1930 to be arranged later. It was also announced that the Sir Gilbert Blane Medal for 1929 had been awarded to Surgeon Lieut.-Commander T. N. D'Arcy.

Diplomas of Fellowship were conferred upon the following :—

C. D. Shapland and N. L. White, Univ. Coll. ; J. C. Ainsworth-Davis, St. Bart.'s ; R. C. Taylor, Univ. Coll. ; E. S. Freshman, Manchester ; L. N. Pyrah, Leeds and Guy's ; J. V. O'Sullivan, London ; A. M. Lazarus, St. Bart.'s ; R. M. Bates, London ; A. Simpson-Smith, Guy's ; R. V. Cooke, Bristol and Guy's ; H. P. Nelson, St. Bart's. ; J. F. Simpson, St. Mary's ; N. Attygalle, Middlesex and King's Coll. ; H. J. Burrows, St. Bart.'s ; G. M. FitzGibbon, St. Thomas's ; Vairamuttu Kathirgamatamby, Madras, London, and King's Coll. ; A. K. Gupta, London ; R. W. Kenney, Dalhousie and London ; F. J. Milward, St. Thomas's ; N. M. Matheson, Otago and Middlesex ; R. L. Flett, Otago and Guy's ; S. Howard, London ; M. Axford and H. S. Billcliff, Otago and Guy's ; J. H. Cramsie, Sydney and St. Bart.'s ; D. D. McKenzie, New Zealand and Guy's ; F. E. Stabler, Durham.

Diplomas of Membership were conferred upon the following :—

Nancy M. Badeley, S. T. Crowther, Catherine Day, Margaret L. Hamburger, and L. Nallainathan.

Diplomas in Public Health were granted, jointly with the Royal College of Physicians, to the following :—

Allah Bakhsh and Y. P. Bedi, Royal Inst. of Public Health ; F. G. Brown and J. P. Chaudhuri, Univ. Coll. ; D. S. Chowdhary, Royal Inst. of Public Health ; Gordon Covell, Guy's and Univ Coll. ; S. D. De Vos, H. N. Dewan and D. P. Dutta, Royal Inst. of Public Health ; Nancy G. Howell, Univ. Coll. ; B. S. Kanga, Royal Inst. of Public Health ; G. R. Lynn, St. Bart.'s and R.A.M. College ; Elsie Lyon and D. G. Mobile, Univ. Coll. ; Samuel Mutty, Royal Inst. of Public Health ; C. C. Po, Univ. Coll. ; Marion Ravell, A. E. Schokman, Amarnath Sharma, Patricia H. S. Shaw, and K. A. Soutar, Royal Inst. of Public Health ; H. S. C. Starkey, St. Bart.'s ; G. G. Stewart, St. Bart.'s and Middlesex ; K. M. R. Swami, J. P. R. Tennekoon, and R. L. Tuli, Royal Inst. of Public Health.

At the primary examination for the Fellowship, held from June 4th to 14th, for which 164 candidates presented themselves, 47 were approved. The following are the names and schools of the successful candidates :—

A. H. Baker, M.B., Manchester ; D. S. M. Barlow, M.B., Middlesex and St. Mary's ; A. W. Bayley, M.B., Melbourne and Univ. Coll ; K. B. Bridge, M.B., Otago ; E. Carew-Shaw, M.R.C.S., King's Coll. ; D. O. Clark, St. Thomas's A. A. Davis, M.B., Manchester and Middlesex ; E. A. Devenish, Univ. Coll. ; K. J. Elliott, Edinburgh and Middlesex ; A. L. Eyre-Brook, Bristol ; L. Fatti, M.B., Univ. Coll. ; K. Fletcher-Barrett, M.B., Cambridge and St. George's ; R. J. Furlong, St. Thomas's ; J. Gabe, M.B., St. Mary's and Middlesex ; R. H. Hadley, M.B., Melbourne and Middlesex ; C. S. Hallpike, M.R.C.P., Guy's and King's Coll. ; J. Hardman, Birmingham ; E. A. H. Hindhaugh, M.R.C.S., Univ. Coll. ; O. Hooper, B.M., Oxford and London ; Ruby D. Johnson, Oxford and Univ. Coll. ; E. C. B. Jones, M.B., Melbourne and London ; H. Y. Khwaja, M.B., Bombay and London ; C. E. Kindersley, M.B., St. Bart.'s and St. Mary's ; S. Lal, M.B., Punjab and Middlesex ; M. Lee, M.B., Durham and Middlesex ; M. J. F. McArdle, Guy's ; D. J. MacMyn, M.B., Cambridge and King's Coll. ; D. H. Mitchell, M.B., Melbourne and King's Coll. ; E. W. T. Morris, M.R.C.S., Adelaide and St. Thomas's ; A. B. Pain, M.B., Leeds ; G. T. Partridge, Camb. and St. Bart.'s ; R. S. Pilcher, M.R.C.S., Univ. Coll. ; A. E. Porritt, M.B., Otago and St. Mary's ; C. A. M. Renou, M.B., Melbourne and Middlesex ; L. A. Riddell, M.B., Otago and St. Mary's ; T. O. Sayle, M.B., Melbourne and Middlesex ; H. H. Skeoch, M.B., Sydney and King's Coll. ; J. O. Smith, M.D., Melbourne and Middlesex ; S. B. Smith, Guy's ; F. R. Stansfield, M.B., Leeds ; S. C. Suggit, Univ. Coll. ; B. M. Sundaravadanan, M.B., Madras and London ; G. L. Talwar, Punjab and St. Thomas's ; K. H. Watkins, M.B., Manchester and Middlesex ; F. E. Webster, M.B., Otago ; Eileen M. Whapham, Lond. Sch. Medicine for Women ; H. L. C. Wood, M.B., King's Coll.

The following examiners were elected for the ensuing year :—

Dental Surgery.—(Surgical Section).—Mr. L. Bathe Rawling, Mr. H. S. Clogg, Mr. T. P. Legg, Mr. Russell J. Howard, Mr. Gwynne Williams, Mr. John Murray, Sir Cuthbert Wallace, and Mr. Clement E. Shattock.
Primary Fellowship.—(Anatomy).—Mr. C. P. G. Wakeley, Mr. P. N. Blake Odgers, Prof. William Wright, and Prof. J. E. Frazer ; (Physiology)—Prof. H. E. Roaf, Prof. C. Lovatt Evans, Prof. R. J. S. McDowall, and Prof. John Mellanby.
Conjoint Qualification.—(Elementary Biology).—Dr. T. W. Shore and Prof. J. P. Hill ; (Anatomy)—Mr. J. Basil Hume, Prof. William Wright, and Mr. R. Bramble Green ; (Physiology)—Prof. E. B. Verney and Prof. Hamilton Hartridge ; (Midwifery)—Mr. Clifford White, Mr. T. Berwyn Davies, Mr. Aleck W. Bourne, and Mr. Sidney Forsdike.
Diploma in Public Health.—Dr. C. W. Hutt.
Diploma in Tropical Medicine and Hygiene.—Colonel W. P. MacArthur and Dr. P. H. Manson-Bahr.
Diploma in Ophthalmic Medicine and Surgery.—Mr. C. B. Goulden, Mr. H. Willoughby Lyle, and Mr. R. Affleck Greeves.
Diploma in Psychological Medicine.—Dr. F. L. Golla.
Diploma in Laryngology and Otology.—Mr. W. M. Mollison, Mr. Norman Patterson, and Mr. Walter G. Howarth.

Mr. W. McAdam Eccles was appointed the representative of the College on the British Social Hygiene Council in place of the late Sir Anthony Bowlby.

University of Bristol.—At recent examinations the following candidates were successful :—

FINAL EXAMINATION FOR M.B., CH.B.

Part I. Forensic Medicine and Toxicology only.—A. J. B. Miall, H. M. Strover, and W. L. Sleight.
Part II. *R. A. S. Cory, *R. J. Krogh, Isabella J. Armstrong, A. O. Fisher, and April D. James.
Part II. (Group I.).—N. D. Gerrish and Mabel F. Potter.
Part II. (Group II.).—N. L. Price and †Eric Southam.
* With Second Class Honours. † Completing examination.

FINAL EXAMINATION FOR L.D.S.

C. R. H. Edwards and L. W. G. Jones.

The Parliamentary Secretary to the Ministry of Health, Miss Susan Lawrence, M.P., has appointed Mr. D. C. L. Ward to be her private secretary.

A Motorists' Hospital Badge.—A Motorists' Fund has been opened in aid of Nottingham General Hospital. In return for an annual payment of 10*s.* for a private car, 5*s.* for a commercial vehicle, and 2*s.* 6*d.* for a motor-cycle the owner receives a badge which can be fixed to the vehicle. There are nearly 14,000 motor drivers in the City of Nottingham, and last year 40 persons were killed and 987 injured in vehicular street accidents.

Post-graduate Course at Trinity College, Dublin.—The authorities of the School of Physic, Trinity College, Dublin, have issued the prospectus of their annual post-graduate course, which will begin on Sept. 16th, and last for three weeks. The lectures and demonstrations range over medicine, surgery, and midwifery, with the ancillary specialties, and the teachers include many of the leading specialists in Dublin, as well as the staff of the school. An attractive feature of the course is that members of the class can be housed and boarded in Trinity College on moderate terms, while women members can be accommodated at Trinity Hall.

Oxford Ophthalmological Congress.—As we have already announced, this Congress will be held at Keble College, Oxford, from Thursday, July 4th, to Saturday, the 6th. On Thursday, at 10 A.M., the proceedings will begin with an address by the Master, Mr. Bernard Cridland, after which a discussion on diseases of the lacrymal apparatus will be opened by Prof. Joseph Meller, of Vienna, and Dr. J. S. Fraser, of Edinburgh. After lunch there will be demonstrations in the Scientific and Commercial Museums, and in the evening the annual dinner of the Congress will be held at Keble College. On Friday, at 11 A.M., Miss Ida Mann will deliver the Doyne Memorial Lecture, entitled Some Observations on the Vascularisation of the Vertebrate Eye, and at 3 P.M. Mr. Hugh Cairns and Mr. Charles Goulden will open a discussion on the Ocular Manifestations found in Head Injuries. Saturday morning will be devoted to shorter addresses. Further particulars may be had from the hon. secretary of the Congress, Mr. C. G. Russ Wood, 12, St. John's Hill, Shrewsbury.

North-East Coast Exhibition.—The attention of medical men visiting this exhibition is drawn to the accommodation and facilities offered by the Medical Institute, 7, Windsor-terrace, Newcastle-upon-Tyne.

Extension of Acton Hospital.—Last week Lady Skinner opened an extension of Acton (Middlesex) Hospital. The enlargement comprises a nurses' home, private wards, and administrative offices.

South London Hospital for Women.—A house-to-house collection in Clapham has produced £1000 for the endowment of this hospital on Clapham Common, and recently Princess Helena Victoria, the President, unveiled a commemorative tablet at the head of the bed. The new out-patient's block has cost £65,000, and £28,000 is required to enable it to be opened free of debt.

University of Manchester.—The University Council have appointed Dr. Frank Edward Tylecote to be Professor of Systematic Medicine as from Sept. 29th.

Dr. Tylecote was a student in the Manchester Medical School and graduated as M.B. in 1902 and M.D. in 1904. He has been honorary physician to the Manchester Royal Infirmary since 1914, in which year he resigned his appointment as senior honorary physician to the Salford Royal Hospital. Last year he was the chairman of the Medical Board of the Manchester Royal Infirmary. From 1914–19 he held a commission in the Royal Army Medical Corps (T.F.), and attained the rank of major on the staff of the 57th General Hospital, British Expeditionary Force. He has been a lecturer in clinical medicine in the University of Manchester since 1916, and was elected Fellow of the Royal College of Physicians of London in 1923.

St. Thomas's Hospital.—Speaking at the annual distribution of Medical School prizes by the Duke of Connaught at St. Thomas's Hospital last week, Sir Arthur *Stanley, the treasurer, explained a change of plans respecting* the proposed new Medical School. Instead of building a new out-patients' department on the opposite side of Lambeth Palace-road, as originally intended, it had been decided, for reasons of convenience, to transfer the school to the new site and to transform the existing school into an enlarged out-patients' department. The present accommodation for these patients is totally insufficient. When the hospital was built in 1871 there were 60,000 attendances; last year there were 601,000. There is also urgent need for an enlarged nursing home for middle-class patients, and a site in Paris-street adjoining that of the new Medical School has been secured. The present St. Thomas's Home has 40 beds, always full, and 80 or 100 could be filled.

St. Thomas's Hospital Dinner.—The annual dinner of old students will be held at St. Thomas's House, Lambeth Palace-road, London, S.E., on Friday, Oct. 4th, with Dr. H. G. Turney in the chair.

Harveian Society of London.—The annual dinner of this Society which was held at the Connaught Rooms on June 13th was something of a red-letter day owing to the approach of a centenary celebration and the presence of Mr. G. Buckston Browne, the doyen of the Society. Guests had the opportunity of seeing and examining for themselves a new portrait of Harvey discovered by Dr. C. M. Wilson. Mr. Duncan Fitzwilliams, who occupied the chair, in recalling the aim of the Society to initiate discussion of clinical medicine in its broadest aspect, remarked that Harvey was as much a surgeon as a physician, and one who, like Hunter after him, dissected every imaginable kind of animal. His own particular ambition was to secure publication of the discussions in the form of transactions which could be circulated to the whole medical profession. Sir D'Arcy Power, in proposing "The Society," remarked *on its highly hereditary character, for he had himself been* its secretary 40 years ago, and was the son of a former President, while his neighbour, Sir John Broadbent, was the son of another. The toast of "The Visitors" was proposed by Dr. R. Cove-Smith in a cheerfully provocative vein. Besides those who were to respond, they welcomed at the dinner the Presidents of the other independent medical societies in London, as well as the medical heads of the Navy and of the Air Force. Response was made by Dr. J. Walter Carr, who offered the thrilling suggestion of a guest who had the audacity to refuse when asked to reply; by Lieut.-Colonel C. T. Samman, Master of the Society of Apothecaries; and by Mr. A. P. Herbert, who as a member of the staff of *Punch* described himself as the only Christian among a tribe of cannibals, and one of the few present with a real faith in the medical profession. It was, he said, the only department in public life that had a firm conviction it was making progress. During the evening Mr. Finlay Dunn rendered some amusing skits at the piano with acclamation. The officers of the Society could not be induced to speak for themselves, but due acknowledgment was made to Dr. G. de Bec Turtle, Dr. J. A. B. Hammond, and Dr. H. C. Bull of their share in a happy and well-arranged festivity.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Thursday.—Urology: Summer Meeting, 11 A.M. to 1 P.M. Exhibition of Urological Instruments. 2 P.M., Operations at St. Peter's Hospital, Henrietta-street, W.C. 8.30 P.M., Sir John Thomson-Walker Cinematographic demonstration showing a prostatectomy, litholapaxy and internal urethrotomy.

MEDICO-LEGAL SOCIETY.

Thursday, June 27th (at 11, Chandos-street, Cavendish-square, W.), At the conclusion of the Annual General Meeting a Paper will be read by Dr. Francis Temple Grey on The Medico-Legal Expert in France, followed by a discussion.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

Wednesday, June 26th.—4.15 P.M., (at St. John's Hospital, 49, Leicester-square, W.C.), Annual General Meeting followed by Clinical Cases.

TUBERCULOSIS ASSOCIATION.

Thursday, June 27th, to Saturday, the 29th.—Provincial Meeting at Medical School, Cambridge.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, June 24th to Saturday, June 29th.—Medical Society of London, 11, Chandos-street, Cavendish-square, W. M.R.C.P. Course of Lectures, on Tues. and Fris. at 8.30 P.M. Tues., Dr. Harold Pritchard: Diseases of the Pancreas. Fri., Dr. A. F. Tredgold: Mental Deficiency.—Hospital for Epilepsy and Paralysis, Maida Vale, W. Thurs. at 2.30 P.M., Lecture-demonstrations by Dr. W. G. Wyllie on Nervous Disease in Children. No fee.—Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C. Thurs. at 2 P.M., Mr. Harold Kisch: Clinical demonstration in the O.P. Department. No fee. St. Mark's Hospital, City-road, E.C. All-day Course in Proctology, lectures, demonstrations, operations. One week only.—Children's Clinic and other Hospitals. Special two weeks' course in Diseases of Children, occupying most afternoons and some mornings.—Prince of Wales's General Hospital, Tottenham, N. Special post-graduate course in medicine, surgery, and the special departments, for two weeks from 10.30 A.M. to 5.30 P.M. daily.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, June 24th.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

Friday.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE. Hammersmith, W.

Monday, June 24th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Ward Visit. 2 P.M., Mr. Donald Armour: Operations.

Tuesday.—10 A.M., Medical Registrar: Ward Visit. 2 P.M., Mr. Addison: Operations. 2 P.M., Mr. Sinclair: Surgical Out-patients.

Wednesday.—10 A.M., Dr. Owen: Children's Out-patient Department. 2 P.M., Mr. Tyrrell Gray: Operations. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. MacDonald: Genito-Urinary Out-patient Department.

Friday.—10 A.M., Dr. Pritchard: Medical Ward Visit. 12 noon, Dr. Shaw: Clinical Demonstration. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

Saturday.—9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Children's Medical Out-patient Department. 10 A.M., Resident Assistant Surgeon: Ward Visit. Medical and Surgical Out-patients at 2 P.M., daily. Operations. Special Departments daily, 10 A.M. to 5 P.M., Saturdays 10 A.M. to 1 P.M. Special Classes in Anæsthetics and Operative Surgery.

NATIONAL HOSPITAL, Queen-square, Bloomsbury, W.C.

Monday, June 24th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Collier: Poliomyelitis.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Post-traumatic Neuroses (2).

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Just: Demonstration of Methods of Testing the Eighth Nerve.

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Spastic Paralysis.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

Thursday, June 27th.—4.30 P.M., Mr. W. K. Irwin: The Diagnosis and Treatment of Some Important Bladder Conditions.

NATIONAL CAMPAIGN AGAINST RHEUMATIC DISEASES.

Wednesday, June 26th.—5 P.M. (at the Royal Society of Medicine, 1, Wimpole-street, W.). Meeting of supporters. (Chairman: Sir Thomas Horder.)

Appointments.

Alexander, B., M.D., C.M., has been appointed Resident Surgical Officer at the Manchester Royal Eye Hospital.

Brookfield, R. W., M.D., Ch.B. Liverp., D.P.H., Hon. M.O., Royal Southern Hospital, Liverpool.

Little, R. C., M.B., Ch.B. Edin., Certifying Surgeon under the Factory and Workshop Acts for Witham, Essex.

Rae, Harry J., D.S.O., M.B. Aberd., D.P.H., Medical Officer of Health for City of Aberdeen.

Manchester Royal Infirmary: Melland, C. H., M.D., F.R.C.P. Lond., Hon. Physician; and Ferguson, F. R., M.D. Manch., D.P.H., Hon. Asst. Physician.

New Sussex Hospital for Women and Children, Brighton: Neate, Dorothy L., M.B., B.S. Lond., House Physician; Bisset, Susan, M.B., Ch.B., House Surgeon.

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital.—Asst. H.S. At rate of £100.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—Asst. P. 50 gns.

Birmingham, Dudley-road Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham General Hospital.—Res. Surg. Reg., &c. £100–£140. Two Res. Anæsthetists. Each £120. Also three H.P.'s. Each £70.

Bolton Infirmary and Dispensary.—H.S. At rate of £150.

Bootle Borough Hospital, Derby-road.—Sen. M.O. Also Two Jun. M.O.'s. At rate of £150 and £125 respectively.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £120.

Brighton, Royal Sussex County Hospital.—Two Cas. H.S.'s. Each £120.

Bristol City Mental Hospital.—Third Asst. M.O. £350.

Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Asst. S. Two Chief Clin. Assts. Also Res. H.S. At rate of £75.

Chester Royal Infirmary.—H.S. to Ear, Nose and Throat Dept. and Cas. O. £120. Also H.S. £120.

Derby, Guardian's Institution and Infirmary.—Second Res. M.O. £250.

Dublin, Dr. Steevens Hospital.—Resident Surgeon. £150.

Dudley, Guest Hospital.—Hon. Orthopædic Surgeon. Also H.S. and Asst. H.S. £175 and £150 respectively.

Durham County Council.—Asst. Welfare M.O. £600.

East Suffolk Administrative County.—Asst. County M.O. £625.

East Suffolk, Administrative County of.—Asst. County M.O.H. £600.

Essex, Administrative County of.—Asst. County M.O.H. £600.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

Exeter, Devon Mental Hosp., Exminster.—Jun. Asst. M.O. £300.

Exeter, Royal Devon and Exeter Hospital.—Asst. H.S. At rate of £100.

Farringdon General Dispensary, Holborn-circus, E.C.—Hon. Surgeon to Dental Department.

Gateshead County Borough, Mental Hospital, Stannington.—Asst. M.O. £400.

General Lying-in Hospital, York-road, Lambeth, S.E.—Hon. Asst. P.

Gloucester, Gloucestershire Royal Infirmary.—H.P. At rate of £150.

Golden-square, Throat, Nose and Ear Hospital, W.—Hon. Asst. S.

Grange-over-Sands, Westmorland Sanatorium, Meathop.—Med. Supt. £800.

Great Yarmouth General Hospital.—Jun. H.S. £100.

Hellingley, East Sussex County Mental Hospital.—Res. Locum Tenens M.O. 7 guineas per week.

Hosp. for Sick Children, Great Ormond-st., W.C.—Part-time Jun. Cas. O. At rate of £150. Also Res. M.O. for Country Branch Hospital, Tadworth Court, Tadworth, Surrey. At rate of £250.

Hull Royal Infirmary.—2nd Res. H.S., Res. H.S. to Ophth Dept., &c. Each at rate of £150. Also Res. Cas. H.O. At rate of £130.

Ilford Emergency Hospital.—Jun. H.S. £100.

Indian Medical Service.—Recruitment of European Officers.

Ipswich County Borough Sanatorium.—Asst. M.O. At rate of £250.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. At rate of £120.

Leeds, St. James' Hospital.—H.P. and S. £200.

Leicester Royal Infirmary.—M.O. for V.D. Dept. £4 10s. per week.

Liverpool, David Lewis Northern Hospital.—Surgical Tutor. £145.

Liverpool Eye and Ear Infirmary, Myrtle-street.—H.S. to Ophthalmic Dept. £100.

Liverpool Heart Hospital.—Maurice Stern Research Fellowship. £150.

Liverpool University.—Jun. Lecturer. £300.

London, Administrative County of.—Principal M.O.H. to Pub. Health Department. £2000.

London Temperance Hospital, Hampstead-road, N.W.—Cas. O. At rate of £120.

Lowestoft and North Suffolk Hospital.—H.S. £120.

Macclesfield General Infirmary.—Res. H.S. £180.

Manchester University.—Amy Henrietta Worswick Fellowship. £150.

M.A.B. Mental Hospitals Service.—Jun. Asst. M.O. £500.

M.A.B. Tuberculosis Service.—Consulting Laryngologist. At rate of 200 guineas.

Miller General Hospital, Greenwich-road, S.E.—H.P., H.S. Each at rate of £125. Also Pathologist. £600.

Nottingham General Hospital.—Res. Surgeon. £250.

Palestine, Hebron Medical Mission.—Medical Missionary.

Poplar Hospital for Accidents, East India Dock-road, Poplar, E. 2nd Res. O. At rate of £175.

Preston Union.—Jun. Res. M.O. At rate of £104.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Asst. S. to Ear, Nose and Throat Dept.

Princess Louise Kensington Hospital for Children, N. Kensington.—H.S. At rate of £75–£100.

Queen Mary's Hospital for the East End, E.—Hon. M.O. for Electro-Therapeutic Dept. Hon. S. for Orthopædic Dept. Hon. P. for Skin Dept. Anæsthetist. 50 guineas. Also Cas. O. £150.

Queen's Hospital for Children, Hackney-road, E.—Surgeon to Ear, Nose and Throat Dept.

Rochester, St. Bartholomew's Hospital.—Third Res. M.O. At rate of £175.

St. Bartholomew's Hospital.—Asst. Physician and Asst. Director of the Medical Professorial Clinic.

Sheffield City Hospitals.—Res. M.O. £350.

Sheffield, Jessop Hospital for Women.—Three Asst. H.S.'s. Each at rate of £100.

Shrewsbury, Royal Salop Infirmary.—Res. Surg. O. £200.

Stafford, Staffordshire General Infirmary.—H.S. Also H.P. At rate of £200 and £150 respectively.

Stockport Infirmary.—Asst. Aural Surgeon for Ear, Nose and Throat Dept.

Surrey County Council.—Asst. M.O. £600.

Swansea County Borough.—Asst. M.O. £600.

Swansea Hospital.—Res. H.P. £150 to £200. Also Res. H.S. £150.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Tunbridge Wells, Eye and Ear Hospital.—H.S. £150.

University of London.—External Examinerships.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.S. At rate of £100.

Walsall and West Bromwich Union, Great Barr Park Institution. Asst. M.O. £200.

Watford, Herts, Peace Memorial Hospital.—Res. M.O. At rate of £150.

West London Hospital, Hammersmith, W.—Director to Venereal Dis. Dept. £700.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Non.-Res. H.S. At rate of £150.

Weston-Super-Mare Urban District.—Part-time M.O.H. £600.

Willesden General Hospital, N.W.—Res. H.S. At rate of £100.

Wolverhampton Royal Hospital.—Two Surgeons to Ear, Throat and Nose Dept.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

York County Hosp.—H.S. Also Res. Anæsthetist. Each £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Chapel-en-le-Firth (Derbyshire).

Births, Marriages, and Deaths.

BIRTHS.

Byworth.—On June 4th, at Savernake, Stanmore, the wife of Dr. Harold A. Byworth, of a daughter

Gillespie.—On June 10th, at a nursing home, Headingley, the widow of Dr. R. K. H. Gillespie, of Headingley, Leeds, of a daughter.

Pridham.—On June 7th, at Hillfield, Broadway, Weymouth, the wife of Dr. J. A. Pridham, of a daughter.

Spackman.—On June 4th, at Coventry-road, Market Harborough, the wife of Dr. E. D. Spackman, of a son.

Thomson.—On June 9th, at Overstrand Mansions, S.W., the wife of Ian S. Thomson, M.D., of a son.

Traill.—On June 7th, at Ottery St. Mary, the wife of R. R. Traill, M.B., B.Ch., of a daughter.

Whitehead.—On June 16th, at Woodfield, Cheadle Hulme, to the wife of Gordon Whitehead, M.B., Ch.B.—a son.

Wilshere.—On June 6th, the wife of Roger G. Wilshere, L.D.S., Sunrise, Grovelands-road, Purley, of a daughter.

MARRIAGES.

Morgan—Thomas.—On June 12th, at Tredergarville Church, Cardiff, T. W. Morgan, M.R.C.S., L.R.C.P., to Dorothy, elder daughter of Mr. and Mrs. Edward Thomas, 7, Winchester Avenue, Cardiff.

DEATHS.

Brand.—On June 11th, at Bellfield, Banchory, William Henry Eden Brand, F.R.C.S.E., D.P.H.

Fawssett.—On June 17th, at High-street, Lewes, Frank Fawssett, M.B., B.S. Lond., M.B.E., aged 64.

Frazer.—On June 13th, at Upton Lodge, Eastbourne, Kenneth Frazer, M.D., aged 71.

Jollye.—On June 3rd, at Brooklands, Hemel Hempstead, Herts, Arthur Dixon Jollye, M.D., aged 57 years.

Tresidder.—On June 13th, at The Waldrons, Croydon, the residence of his sister, William Elliott Tresidder, M.B., B.S. Lond., aged 65.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

HEALTH OF BECHUANALAND.

IN the annual report on the affairs of this Protectorate, signed by Mr. C. L. O'B. Dutton, Government Secretary, it is stated that health conditions during the year ended March 31st, 1928, have been, as regards widespread prevalence of disease, the worst for the past ten years. During the winter of 1927, which ushered in a series of severe outbreaks of fever, following upon cold snaps, the incidence of disease was little less favourable than what is usual at that date. But with the opening and advance of summer there was a sudden rise in the prevalence of fever, which continued to increase until during January, February, and March it had assumed epidemic form and prostrated thousands of the native population. The epidemic was chiefly confined to the southern portions of the Protectorate—especially the alluvial levels—the valleys and low-lying granitic areas, abutting on the main watersheds—Molepolole, Mochudi, Gaberones, Ramoutsa, and Gopane.

Associated with this extensive prevalence of malaria were the invariable complications of influenza and bronchial catarrhs—bronchitis, acute pneumonia, rheumatic affections, enteritis, and the common sequelæ. The total returns of disease, which are the heaviest on record (close upon 20,000 cases), have been swelled to these unusual proportions by the record of many ailments, concurrent and otherwise, which the increased medical activities in connexion with the epidemic brought under observation.

Free Government supplies of quinine were issued to the areas most severely affected. And this, together with measures of supervision of distribution and energetic medical attention, helped to mitigate the effects of this disease. A fortunate and remarkable feature of the epidemic was the low rate of mortality. At Mochudi, where over a thousand cases of malaria were seen, there were only two deaths, and these of indirect or remote connexion. At Gaberones, Molepolole, Ramoutsa, and Gopane, where the numbers were still greater, the death-rate was equally low in proportion. The epidemic outbreaks were largely determined by the conditions prevailing over the southern Protectorate throughout the summer—that is, heavy rains at long intervals, over the impervious, low-lying, and easily water-logged areas; the constitutional lack of stamina of the people on the low-lying lands as against those on the higher levels—which is a long observed and constant factor—invariably shows up under unusual meteorological conditions, such as heavy rains or severe cold snaps.

Of other epidemic and infectious diseases the returns for the year show: anthrax 15 cases (1 death); dysentery, infantile or undefined diarrhœas, 627 cases; influenza, 257 cases; tuberculosis, 142 cases; puerperal fever, 2 cases; leprosy, 16 cases; enteric fever, 8 cases (1 death); tetanus, 2 cases (1 death); cerebro-spinal meningitis, 5 cases; scarlet fever, 1 case; measles, 13 cases; and a few cases of whooping-cough, mumps, and chicken-pox. The tuberculous cases generally gave a history connecting the origin of the disease with working on the Rand mines, whilst the unusual outbreaks of enteric fever were clearly traced to the Lichlenburg diamond diggings. There has been an increase in the number of syphilitics treated, the returns for the various districts showing an aggregate of 4782 attendances.

During the month of November water was struck on the site selected for the Serowe Hospital. Subsequent tests have proved the supply to be ample, and as the bedrock is pure sandstone, the supply is not likely to vary or be affected by drought. The work of clearing the site and fixing the position of the hospital and accessory buildings has since been put in hand, the hospital plans reviewed and adopted in final form, and it is intended that the new hospital shall be finished, equipped, and staffed during the next financial year.

The position with regard to the extension of plague and the proximity to the Protectorate borders of suspected and proved infection gave cause for increased vigilance, and at the end of the financial year measures were under consideration for taking practical steps, during the coming summer, towards conducting a rodent-infected survey of the Protectorate along the boundaries of possible approach.

The territory of the Bechuanaland Protectorate is bounded on the south and east by the Union of South Africa, on the north-east by Southern Rhodesia, on the north and on west by the territory of South-west Africa. It has not been surveyed as a whole, but its area is estimated at 275,000 square miles. Its mean altitude is about 3300 ft.

A CASE OF ENURESIS.

To the Editor of THE LANCET.

SIR.—In reply to "Puzzled," when I meet such a case as this I give a suitable gland compound; if the patient is cured, I am right, if not, no harm is done. Generally some good results. Using thyroid gland alone, I have had at times to stop it, as unpleasant symptoms arose, but this has never occurred with a gland *compound* tablet, such as Dynotabs Thygon-Spermin. 106 (to be obtained from Hormones and Chalones, 27, Cavendish-square, W.1). I offer the suggestion that if the system needs a gland extract it absorbs it; if it is not required it is simply passed out by some safety valve.

I am, Sir, yours faithfully,

C. G. S. BARONSFEATHER, M.D.

Bournemouth, June 15th, 1929.

CARE AND TREATMENT OF THE PATIENT.

Dr. Emerson has brought together here nine essays[1] by well-known American authorities, the origin of the work being the establishment of a set of lectures in the Harvard Medical School dealing with the personal care of the patient by the physician. The following well-known teachers have contributed to the volume: Dr. David L. Edsall, Dr. C. F. Martin, Dr. W. S. Thayer, Dr. Austen Fox Riggs, Dr. Franklin G. Balch, Dr. Lawrence K. Lunt, and Dr. Alfred Worcester. One of the most useful essays is entitled "The Medical Education of Jones by Smith," and purports to be introduced by Dr. Thayer. The characters may be imaginary but the precepts have the ring of being founded upon reality. Whether "Smith" is "Jones," whether either is Prof. Thayer, and who was "Fowler" are questions the answers to which could probably be provided at Harvard, but the personalities have no significance, which is exactly what the teaching possesses. It is interesting to read Dr. Alfred Worcester's chapter on the care of the aged alongside the section in Dr. David Tindal's book on the treatment of the aged (see below) for the obviously learned American and the delightfully simple Englishman provide sensible teaching between them, each supplying notes that are lacking in the pages of the other.

Dr Tindal[2] has set down in his "Gleanings from General Practice" the results of long experience as an urban practitioner, in the hope that they may prove of service to young members of the profession. We may say at once that his gleanings are useful while his advice is sound. Wise remarks on professional conduct, some of which are so obvious that they are perhaps needless, lead to chapters on treatment generally, treatment of children and of the aged, and where, as not infrequently happens, part of the treatment is connected with diet, reference is given to a useful section of the book containing notes on cookery and the serving of meals in the sick-room. The last 50 pages of the book are taken up with formulæ, the prescriptions being directed generally or specially towards the relief of common conditions. Certain preliminary reflections of the author, which point to the absence of instruction given to-day to students in regard to the conduct of practice, justify the issue of this unpretentious work.

PHARMACEUTICAL LATIN.

A COMPACT little book,[3] measuring only 6½ by 4 inches, provides the pharmaceutical and medical student with a concise Latin grammar and a list of phrases and abbreviations used in prescriptions, a few exercises and examples of prescriptions, and a Latin-English vocabulary. After absorbing its contents the student should be well primed. He will note that O.o.o. stands for the best olive oil (oleum olivæ optimum) and that S.o.S. to a pharmacist is a call for help only if there is need (si opus sit). M.d. means as directed (more dicto) and M.p. is a pill mass. The reaction of a grocer to the precious student who asks for pastille as "coni odorati" or for a packet of isinglass as "colla piscium" might be alarming. Incidentally, for isinglass most dictionaries prefer the Greek "ichthyocolla." "Cascara sagrada," which is included in the Latin-English vocabulary and explained as cascara, bark, sagrada, adj. sacred, is really pure Spanish, except that the first a has an accent in that language. The word cortex, bark, is included in its proper place. Vehiculum is described as vehicle. The explanation might have been extended by adding "excipient or medium." Ne tr. s. num. (ne tradas sine nummo) seems to be the druggist's way of saying what other tradesmen more simply call "C.o.d.", but then the druggist keeps a "taberna" and not a shop. The book will be useful especially to students near qualification whose powers of writing prescriptions are too often limited to a quotation of the name of the mixture in the Hospital Pharmacopœia deemed most nearly appropriate to the patient's condition.

An Address

ON THE

NATURAL ACQUIREMENT OF IMMUNITY.

Delivered at the Institute of Pathology and Research, St. Mary's Hospital, on May 23rd, 1929,

BY W. W. C. TOPLEY, M.D. CAMB., M.Sc. MANCH., F.R.C.P. LOND.,

PROFESSOR OF BACTERIOLOGY AND IMMUNOLOGY IN THE UNIVERSITY OF LONDON, AT THE LONDON SCHOOL OF TROPICAL MEDICINE AND HYGIENE.

THE natural acquirement of immunity is a well-worn theme; but current bacteriological literature displays a curious diversity of opinion with regard to the relative importance of the various factors which are, or may be, involved. There is general agreement as to the essential mechanism of antitoxic immunity; but widely divergent views are held about the relative significance of heredity and individual experience in determining the antitoxin production on which such immunity depends. Far less agreement has been reached upon the nature of acquired resistance to those tissue-invading bacteria which do not produce powerful exotoxins. There is an orthodox view, which was slowly evolved during the controversies between the cellular and humoral schools, and emerged in its present form from the synthesis which followed the demonstration that efficient phagocytosis depends on the direct action of antibodies on the bacterial cell. There are less orthodox views. Some would jettison the cellulo-humoral hypothesis in favour of a local tissue immunity in which antibodies play no part. Others would relegate it to a position of quite minor importance, assigning the dominant rôle to some other intrinsic or extrinsic factor. This particular problem of specific antibacterial immunity merits, as it seems to me, reconsideration in the light of recent advances in our knowledge of antigen-antibody reactions in general; since the observations in question lend strong support to our established conceptions, help to explain many anomalies which have encouraged the grosser forms of heresy, and suggest hopeful avenues for future research.

SOME TENTATIVE CONCLUSIONS.

Most of us, I suspect, have formed the habit of reading the conclusions of a paper first, and then turning to the paper itself to see whether we agree with the judgment on the evidence. This method has certain advantages in presentation as well as in reading; and it may simplify matters to set out the conclusions which seem to me to be supported, more or less strongly, by the available data, and then to attempt to justify these conclusions by a brief reference to the evidence on which they are based. They may be stated as follows:—

1. The acquirement of specific antibacterial immunity depends, in the main, on the production of specific antibodies which sensitise the bacterial cell. The sensitised bacteria are more readily ingested by the phagocytic cells of the tissues, and are, in some cases at least, acted upon by other non-cellular agents, which destroy them, or inhibit their invasive activity. These specific antibodies are themselves produced, or increased significantly in amount, in response to the entry into the tissues of bacteria which contain the corresponding antigens.

2. These antibodies are of one kind only, in the sense that for each antigen there is one, and only one, corresponding antibody.

3. In any pathogenic bacterium, on the other hand, there are several antigens; and these antigens are of unequal importance in immunity reactions in vivo. The presence of the antibody corresponding to one particular antigenic component may profoundly modify the course of events in favour of the host. The presence of the antibody corresponding to another antigenic component may be without effect. This difference in the immunological significance of different antigens probably depends on their position in the bacterial cell. The acquirement of specific antibacterial immunity depends on the production of antibodies acting on the effective bacterial antigens.

4. The condition of an animal which has acquired immunity differs from that of a normal animal not only in the presence of the effective specific antibody in its blood and body fluids, but in the readiness with which this antibody is produced in response to further stimuli, and perhaps in the presence of fixed antibody in certain cells and tissues.

5. During the process of natural immunisation foci of infection are established in the tissues, and these may persist over long periods of time. The animal is, however, relatively immune to fresh infections from without, and to the spread of infection beyond the localised foci. This specific immunity depends on the maintenance, at a high level, of the clearing mechanism of the tissues, which ensures the prompt removal of any bacteria which gain access to the lymphatics or blood-vessels. It may be overcome, either by massive infection from without or by the action of various non-specific factors, which cause a spread of infection from the latent foci.

6. The available evidence does not suggest that the bacteria in such latent foci become avirulent. In some cases, at least, they may retain their full virulence over long periods of time.

SPECIFIC PROTECTIVE ANTIBODIES.

Taking these points in order, it may first be noted that the critical experiment of passive protection with the serum of an immunised animal has been so frequently repeated from the days of Pfeiffer onwards that no reasonable doubt remains that active immunity is associated, in many cases, with the presence of protective antibodies in the blood. These protective antibodies are, moreover, specific; as has been shown by Pfeiffer[1] and his colleagues for the cholera vibrio, by Neufeld and Handel[2] for the pneumococcus, and by a host of other workers. The objections to the view that active antibacterial immunity is always associated with this type of reaction may be classed under two headings: (1) there are cases on record in which an animal has been actively immunised without the appearance of protective antibodies in its blood; (2) there have been repeated failures to correlate the protective power of a serum with its antibody content, as estimated by some in vitro test. Both these objections can be considered more conveniently at a later stage; meanwhile it may be noted that the second objection does not suggest doubts as to the presence of protective antibodies, but merely as to the identification of these antibodies with those which are measured by the particular in vitro test employed. That protective sera commonly contain antibodies which promote phagocytosis, in vitro and in vivo, and in some cases give rise to the phenomena of bacteriolysis, has been demonstrated by innumerable experiments. Recent studies on the bactericidal power of the whole blood, or of serum-leucocyte mixtures, have demonstrated the action of this mechanism in cases in which it had not been revealed by the methods previously employed. It is, of course, possible that the sensitisation of bacteria by the serum antibodies may have other secondary effects, of which we have as yet no knowledge.

THE UNITARIAN CONCEPTION OF ANTIBODIES.

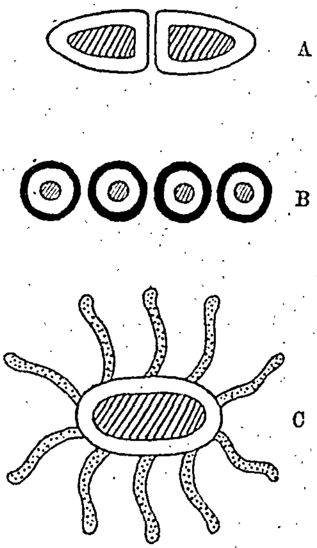
Secondly, the antibodies are of one kind only. It is, perhaps, premature to suggest that agreement has been reached on this point; but I do not think there is any doubt that the views sponsored by Dean[3] in this country, by Zinsser[4] in America, and by Nicolle and Césari[5] in France, are steadily gaining adherents. The most convincing experimental evidence in favour of this unitarian conception is probably that provided by Dean's[6] well-known studies on the relation between precipitation and the fixation of complement. His earlier results have been elaborated and extended by his more recent studies with Webb[7] on the importance of the quantitative relations between antigen and antibody in the precipitin reaction, and by the work of his colleague Goldsworthy.[8] It is now fairly clear that complement-fixation is an adsorption process which occurs during a particular stage of the flocculation of the serum-globulins, and that it is possible, by adjusting the time relations and the antigen-antibody ratio, to demonstrate either phenomenon, or both, in the case of any soluble antigen and the corresponding antiserum. The unitarian hypothesis, in its generalised form, would deny the existence of agglutinins, lysins, precipitins, opsonins, &c., as separate entities; in the moribund terminology of the side-chain theory it would deny the existence of ergophore groups with different functions, and would regard each antibody as a sensitising substance in Bordet's sense. This sensitising substance, by combining with its corresponding antigen, renders it sensitive to various environmental conditions to which it was before indifferent. The exact happenings in a test-tube, or in the animal body, will, according to this view, depend on various secondary factors. If electrolytes are present, a sensitised bacterium will be agglutinated, or the colloidal compound formed by a soluble antigen and its corresponding antibody will be precipitated. If the antigen is incorporated in a cell, and complement is present, the cell may be lysed. If phagocytes are present, the sensitised cells will be ingested. This hypothesis does not, of course, suggest that one antibody, and one only, is produced when a complex antigenic material, such as a bacterial suspension, is injected into an animal. It suggests that, for each antigenic component, there is one, and only one, corresponding antibody. We may, in the light of the data to be discussed in the next section, take this argument a step further, and suggest that the functional specificity which was formerly attributed to the antibody, belongs, in the case of organised cells, to the antigen.

THE IMMUNOLOGICAL SIGNIFICANCE OF DIFFERENT ANTIGENS.

Thirdly, the antigenic structure of all those bacterial species which have been adequately examined has been shown to be complex; and evidence is rapidly accumulating which suggests that the different antigenic components, contained in any bacterial cell, vary widely in their immunological significance. It is impossible, in a brief sketch of this kind, to give an adequate review of the available data. The recent studies of Arkwright,[9] Andrewes,[10] Weil and Felix,[11] Orcutt,[12] White,[13] and others on the antigenic components of bacteria of the coli-typhoid group, combined with the earlier observations of Smith and Reagh[14] on somatic and flagellar antigens; the work of Avery, Heidelberger[15] and their colleagues on the antigens of the pneumococcus; and the studies of Lancefield[16] and of Todd[17] on the serological behaviour of the hæmolytic streptococci, have together provided a framework on which we may construct a model of the antigenic structure of the bacterial cell.

In Fig. 1 the picture which emerges from these various studies is represented in diagrammatic form, taking as illustrative instances the pneumococcus, a hæmolytic streptococcus, and a motile bacillus of the coli-typhoid group. In each case the fully virulent type of organism has been depicted, and no indication has been given of possible antigenic variations, since these do not concern the question immediately at issue. It should, however, be noted that, in the pneumococcus, and in the bacilli of the colon-typhoid group, rough variants may be obtained which have lost the somatic polysaccharide antigen which is characteristic of the normal smooth forms. The occurrence of these variants has rendered possible the separate study of the immunological significance of the two somatic antigens. At A is represented a pneumococcus, possessing a type-specific polysaccharide antigen, and a nucleoprotein antigen. In this particular case the spatial relations of these two components is clearly evidenced by the collection of the polysaccharide at the surface in the form of a capsule, covering the nucleoprotein antigen within the cell. At B is depicted a virulent hæmolytic streptococcus, with three antigenic components: a nucleoprotein antigen within the cell, a polysaccharide antigen represented as lying in an intermediate zone, and a third antigen, which is regarded by Lancefield[16] as an acid-soluble protein, shown as a surface layer. In this case we are arguing from analogy in placing the third antigenic component, which determines type-specificity, at the surface of the cell; but the analogy, which is afforded by the observations of Todd and of Lancefield on virulence and immunological behaviour, is sufficiently strong to render it highly probable that this spatial relation holds true. The distribution, within the streptococcal cell, of the polysaccharide and nucleoprotein components is, in this case, more doubtful. At C is represented a flagellated bacillus, possessing three major antigenic components, one limited to the flagella; a second, probably polysaccharide in nature, forming part of the bacterial body and represented at its surface; and a third, probably nucleo-protein in nature, situated within the bacterial body and covered by the polysaccharide component.

FIG. 1.



In constructing this diagram I have adopted the tentative suggestion, contained in a recent paper by White, that the smooth virulent forms of bacteria of the salmonella group contain the nucleo-protein component of the rough variant, masked by the specific polysaccharide somatic antigen.

The Significant Antigens in Various Infections.

In each of these three cases there is evidence that one particular antigenic component—and that the one which is probably distributed at the surface of the bacterial cell—is mainly concerned in the *in vivo* reactions which determine resistance to infection. The case of the pneumococcus is too well known to require any detailed reference. Whether we take the example of passive protection in the mouse, of serum-therapy in man or the monkey, of active immunisation against experimental infection in animals, or of prophylactic vaccination in human herds, the answer is the same: immunity is type-specific. The antibodies corresponding to the polysaccharide antigens play a dominant rôle. The antibody corresponding to the nucleo-protein antigen has little if any protective power. In this connexion two related problems may be briefly referred to. As noted above, there have been numerous failures to demonstrate a correlation between antibody-content and protective power in comparing different samples of antibacterial sera. In the particular case of the pneumococcus it seems possible that this discrepancy has arisen through the unsatisfactory methods employed in titration. It is altogether doubtful whether any valid comparison can be drawn between the agglutinin titre of different sera and the number of bacteria against which a fixed amount of each of those sera will protect. It is of interest to note that recent studies by Friedlander, Sobotka, and Banzhaf[18] in which the protective power of the various sera has been titrated by the dilution method, and the antibody-content by determining the antigen-antibody ratio in precipitating mixtures of serum and purified polysaccharide antigen, show a close relation between the content in type-specific antibody and the power to protect. Again, in this particular case there is little evidence of any protective antibody other than that corresponding to the type-specific antigen; since, if such other antibodies played an important part in active or passive antipneumococcal immunity, we should have to suppose that the corresponding bacterial constituents differed in each serological type, and that they were in each case firmly linked to the polysaccharide antigen, an assumption for which there seems little warrant.

In the case of the hæmolytic streptococcus, the recent studies of Lancefield and Todd[17] indicate that the significant antigenic component is the acid-soluble protein. Antisera acting on this component are protective; antisera acting on the polysaccharide or nucleoprotein components are not.

In the case of the flagellated bacilli of the colon-typhoid group, Felix[19] has suggested that the somatic antigen of the normal smooth form is the significant component in immunity reactions in vivo. Arkwright's[20] studies on typhoid and paratyphoid infection in the guinea-pig supported this view. Observations by Springut[21] on *B. aertrycke* infection in the mouse suggested that the flagellar antigens played a larger part than Felix or Arkwright had supposed. A more recent study of the same infection by Ibrahim and Schütze[22] yielded results which, while differing in certain details from Springut's findings, were in general conformity with the conclusion that the flagellar antigens played some part in the immunising reaction; though, as the authors are careful to point out, the procedure employed to inactivate these antigens may have weakened the antigenic value of the somatic component.

The Importance of the Somatic Antigen.

In connexion with the study of epidemic infections in mice, Prof. Major Greenwood and I have investigated the immunising value of various bacterial vaccines, so selected and prepared as to allow us to differentiate the effect of the various components in question. In order to obtain the somatic (O) antigen without the flagellar (H) component we resorted to a vaccine consisting of a suspension of *B. paratyphosus* B. This species, as White[23] has shown, shares with *B. aertrycke* a common O antigen. As regards its flagellar antigen it is, as Andrewes has demonstrated, diphasic, possessing, in the group phase, an antigen which is identical with that of the group phase of *B. aertrycke*; but the type phases of the flagellar antigens of these two species are entirely distinct. It seemed unlikely, a priori, that the group flagellar antigen would exert any significant effect; since, as we have shown elsewhere, the type phase appears to be dominant in all epidemics of mouse typhoid. It was, however, a simple matter to obtain direct evidence on this point by preparing two vaccines of *B. paratyphosus* B, one in the group, the other in the type phase. As a further precaution against the presence of traces of group antigen in the latter, the flagellar antigen was removed by alcoholic extraction. The actual vaccines employed in this series of tests, and their antigenic components, are sufficiently indicated in Table I. The rough somatic antigen is not included among the factors tabulated, since its actual distribution is, at the moment, uncertain. The point is not of great moment. There is general agreement that this antigen has no immunising value, a conclusion which is fully borne out by our experience with the rough aertrycke and rough typhoid vaccines. In order to obtain a measure of any purely non-specific immunising effect, which might arise from the intraperitoneal injection of a killed bacterial suspension, we included in our series a staphylococcal vaccine, which, of course, bears no antigenic relationship to the causative organism of the epidemic.

TABLE I.

Group.	Vaccine.	Antigen.	Average daily specific death-rate.	Average daily specific death-rate as per cent. of normal mice.

H	No vaccine—Normals added with A—G.	—	0·0315	100·0

(S.s.; H.+F.) = Saline suspension; heat + formalin.

The test of immunity, in this particular experiment, was provided by exposure to risk of infection in a cage in which an epidemic was spreading. The epidemic was initiated in the usual way; three normal immigrants were added to the cage each day; and, every seventh day, an additional 80 mice were added—ten normals and seven groups of ten vaccinated mice. The latter had received two inoculations, each of 500,000,000 bacteria, of the seven vaccines under test. The two doses were given intraperitoneally, with a week's interval between them, and the mice were added to the cage one week after the second dose. The experience is as yet incomplete, and the figures recorded in the table refer only to the earlier phases of the epidemic. The number of mice in each group—200 in the case of groups A to H, and some 400 in group N—are, however, sufficiently large to make the differences observed statistically significant. It will be noted that the measure of resistance adopted here has been the daily specific death-rate—i.e., the death-rate calculated from the deaths in which *B. aertrycke* was isolated post mortem, *together with those deaths in which* cannibalism prevented a post-mortem examination. The death-rate is expressed in the usual life-table form, and, in the last column, the death-rate for each group is expressed as a percentage of the death-rate among the normal mice added to the cage on the same day as the vaccinated animals.

The results are fairly clear-cut. The death-rate among the normals added daily (group N) serves as a check on that among the H group—there is no significant difference. Groups A, B, and D show no significant difference inter se. It would appear that the intraperitoneal injection of any bacterial suspension confers a minor degree of temporarily increased resistance (group A), but that nothing further is gained by the presence of the rough somatic antigen (groups B and D), or of the flagellar antigen in its type phase (group D). The figures for groups C, F, G, and E are again fairly homogeneous inter se; they show a decided advantage as compared with the normal mice, or with the three vaccinated groups A, B, and D. The mice of each of these more resistant groups had received the O somatic antigen. It appeared to be immaterial whether this compound was administered alone (group G), in association with flagellar antigen in the group phase (group F), or with both group and type phases (groups C and E).

In Table II. the figures are combined in such a way as to show the effect of each component over the period in question, the group phase of the flagellar antigen and the rough somatic antigen being omitted from consideration. The results are of exactly the same order; and it seems clear that, under these

TABLE II.

conditions, the O antigen is the single significant factor in producing specific immunity against *B. aertrycke.*

In Vitro Reactions.

To these studies of experimental infection in vivo we must add the results recorded by various observers who have studied antigen antibody reactions in vitro. We know that the type-specific antibodies determine opsonification as well as agglutination of the pneumococcus. Recent studies have indicated that, in the motile bacilli of the paratyphoid group, the antibodies acting on the somatic O antigen are responsible for the phenomena of bacteriolysis (Felix,[19] Felix and Robertson[23]) and of opsonification (Braun and Nodake[24]), while the H antibodies play little part in those reactions. To complete the picture we may include, as supporting evidence, some of the facts which have emerged during recent studies on bacterial variation. The loss of the polysaccharide antigen by the pneumococcus, leaving the nucleoprotein component exposed, leads to the appearance of the rough avirulent variant. The loss of the polysaccharide O antigen by virulent smooth strains of bacilli of the colon-typhoid group, has a similar effect (Arkwright,[9] White,[18] Topley and Ayrton[25]); while there is ample evidence that the non-motile O forms, which have lost their flagella but retain the polysaccharide somatic antigen, are fully virulent. In the case of hæmolytic streptococci loss of virulence is associated with loss of the acid-soluble protein component, which determines type-specificity (Todd and Lancefield[26]).

If we survey this picture as a whole, its outlines, though sketchy and incomplete, seem highly suggestive. The reactions between an invading bacterium and the cells and tissue-fluids of the host must occur in the first place at the bacterial surface, and on the nature of that surface the virulence of the bacterium would appear mainly to depend. If the surface is of such a kind as to endow the bacterium with the property of virulence, when it gains access to the tissues of a susceptible animal, that animal may develop resistance by producing antibodies which attach themselves to that surface, and so alter its physical or chemical properties. Antibodies which react with antigenic components situated in bacterial appendages, such as flagella, or deeply within the bacterial cell, are ineffective from this point of view. Such a tentative hypothesis is, I think, in conformity with the known facts. It has, for instance, long been recognised that the titration of one particular serum antibody, such as an agglutinin, does not of necessity provide a measure of the resistance of the animal whose serum is examined, nor of the power of that serum to confer passive protection; and this apparent anomaly is clearly due, in some cases, to the fact that a flagellar antibody agglutinates but does not protect. It is of some interest to note that the findings of Wright[27] and his colleagues, that the antibody effects which provide the best measure of resistance are opsonification and bacteriolysis, are in entire conformity with the more recent observations referred to above.

IMMUNITY WITHOUT DETECTABLE ANTIBODIES.

Fourthly, while the mechanism with which we are here concerned depends on the presence in the animal tissues of an antibody acting on a particular bacterial antigen, or on the capacity of the tissue cells to produce such an antibody promptly in response to the stimulus provided by bacterial invasion, a significant degree of immunity may be acquired without the appearance of the antibody in question in the circulating blood, in concentrations detectable by the in vitro tests commonly employed. The recent studies of H. D. Wright[28] on antipneumococcal immunity in the rabbit provide an excellent example of this phenomenon. The point is an important one, because the conclusion that the O antibodies are the significant factor in antibacterial immunity has led in one particular instance to a further conclusion, which appears to me to be unfortunate and unjustifiable. Felix[19] and his colleagues have found that persons who have been inoculated with typhoid and paratyphoid vaccines do not develop O agglutinins to a titre of 1 in 100 or over; though, as is well known, they develop H agglutinins to a high titre. From this it has been concluded: (*a*) that antityphoid vaccination does not stimulate the production of O antibodies; (*b*) that antityphoid vaccination is therefore incapable of increasing resistance to infection. I would suggest that this is an example of a conclusion which carries its own refutation. There may be differences of opinion as to the degree of effective immunity which antityphoid inoculation confers; but the existence of a significant difference in the morbidity rates among inoculated and uninoculated samples of the population is attested by extensive data, which fulfil all the ordinary statistical criteria. In fact, as Gardner[29] has recently shown, the conclusion is not valid because the premises are false. Inoculation with typhoid vaccine does stimulate the production of O antibodies, though the titre attained is far lower than that reached by the H agglutinins. The study of the prophylactic value of various vaccines in an epidemic of mouse typhoid, to which I have referred above, enabled us to obtain further light on this particular problem. In order to ensure a constant number of mice in each vaccinated group, it was necessary to inoculate 12 to 15 mice, instead of the ten which would be required for addition to the cage; thus, on the day when the additions were made, we were left with a few superfluous mice in each inoculated group. These were anæsthetised, and as much blood as possible was collected. The serum was tested against three suspensions of *B. aertrycke*, so selected and prepared as to respond to flagellar agglutinins corresponding to the type or group phase, or to the O agglutinin. Each serum was tested against each suspension, in dilutions varying between 1:20 and 1:640. Table III. shows the number of mice so examined in each group, and the number of these which agglutinated each of the bacterial suspensions at a titre of 1:20 or over. It will be noted that the four vaccines, C, E, F, and G, which were known to contain O antigen, and which induced a significant degree of immunity, did in fact possess some power of stimulating the formation of O antibodies; but it will also be noted that this response, as revealed by our agglutination tests, was minimal. Only one of 66 mice inoculated with vaccine E showed O agglutinins at a serum dilution of 1:20, while the best response, obtained with vaccine F, produced agglutinins active at this titre in only 10 of 52 mice. It may be added that more extensive experience has amply confirmed these findings. Table III., when compared with Table I., affords clear evidence of the uselessness of H agglutinins. The mice of group D, which had produced H agglutinins in plenty, showed no evidence of specific immunity. The mice of group G, possessing O agglutinins only, showed the same increase in specific resistance as those of groups C and E, which possessed flagellar agglutinins active against each phase. We may conclude that, in the case of mice and men, the injection of O antigen in the usual form of a killed bacillary suspension, leads to the production of O antibodies in minimal amount; and that this minimal response, even

TABLE III.

Group.	Vaccine.	Number of mice.	Number agglutinating.		
			H (type).	H (group).	O

B	R. Typhoid.	72	0	0	0

though it does not result in the appearance of circulating antibodies in a detectable concentration, is associated with a significant increase in the resistance of the inoculated animal. It does not, of course, follow that a vaccine so prepared as to possess a greater power of stimulating O agglutinins would not induce a more effective increase in resistance. It seems possible that work along these lines would yield valuable results.

THE PERSISTENCE OF FOCI OF INFECTION DURING THE PROCESS OF NATURAL IMMUNISATION.

Fifthly, the type of immunity so acquired is not of such a kind as to ensure the sterilisation of the tissues. If the immunity is artificially induced, as by the inoculation of an appropriate vaccine, the animal may withstand a subsequent inoculation of virulent bacteria, yet these bacteria may in many cases be recovered from the spleen several weeks later. When the immunity is naturally acquired, as by the experience of a mild or latent infection during the course of an epidemic, the bacteria which provided the stimulus to antibody production may apparently remain latent within the tissues over long periods of time. So far as the particular example of mouse typhoid is concerned, each of these propositions has been established by numerous experiments. The figures set out in Table IV. illustrate sufficiently the type of immunity established by the inoculation of two doses of vaccine containing the O antigen. One week after the second inoculation the vaccinated mice, and a similar number of controls, were inoculated intraperitoneally with 1000 *B. aertrycke.* It will be noticed that the increased resistance of the vaccinated mice is evidenced in two ways: (*a*) those that succumbed to the infection lived, on the average, about three times as long as the controls; and (*b*) about 40 per cent. of the vaccinated mice survived in apparent health throughout the period of observation. When, however, the survivors were killed and examined on the 28th day, about half of them were found to be harbouring *B. aertrycke* in their spleen tissue.

TABLE IV.

Exp.	Mice.	No.	Died within 28 days	Average time to death in days.	Survived 28 days.	Survivors with positive spleen cultures.
A	Vaccinated.	50	29	18·3	21	12
	Control.	50	50	5·0	0	—
B	Vaccinated	50 50	27 30	15·6 15·8	23 20	7 12
	Control.	50	49	6.7	1	1

With regard to the natural acquirement of immunity during the course of an epidemic, the results already recorded in a considerable series of experiments have shown quite clearly (*a*) that mice which have survived for 30 days or more during an epidemic prevalence of mouse typhoid are more resistant to infection than unexposed controls; and (*b*) that survivors from an *epidemic have seldom escaped infection,* and are frequently harbouring the causative organism in their tissues; many, but not all of these survivors, show *the presence of agglutinins in their blood.*

The time relations of these reactions to infection may be illustrated by the results obtained in a small series of tests carried out in collaboration with Prof. Greenwood and others, during a particular epidemic of mouse typhoid. At intervals of four weeks a sample of 20 mice was withdrawn from the cage, so selected as to represent as closely as possible the cage-age constitution of the whole cage population on the day of withdrawal. The cage-age groups into which the population was divided were as follows: 0–5 days, 5–9 days, 10–19 days, 20–29 days, 30–59 days, 60–99 days, 100–199 days, and 200 days or over. In all, 10 samples of 20 mice were withdrawn. These mice were anæsthetised, and bled to the maximum extent. After death their spleens were removed and dropped into tubes of broth. Their serum was tested against three suspensions of *B. aertrycke* for the presence of *agglutinins. In recording the results we may regard* agglutination of any of these suspensions as evidence of an immunising response. As we have already noted mice do not readily form O agglutinins, and our present experience suggests that this holds in infection as well as in artificial immunisation, though we should not wish to dogmatise on this point on the basis of our present scanty data. We have seen, however, that mice which have been inoculated with vaccines containing both flagellar and somatic antigens respond much more readily to the former than to the latter, although their behaviour when exposed to risk of infection indicates that they have made an effective response to the somatic component. Those mice, in an infected herd, which have developed H agglutinins, have certainly received doses of the O antigen; and we may reasonably regard the presence of H antibodies as indicating that some response has been made to the double stimulus.

TABLE V.

Cage-age group in days.	No. in group.	Spleen cultural. Positive.		Agglutinins in serum.		Spleen + Aggl. +	Spleen + Aggl. —	Spleen — Aggl. +
		No.	Per cent.	No.	Per cent.			
0– 4	23	2	8·7	0	0	0	2	0

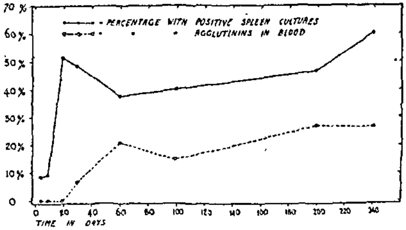
60– 99	20	8	40·0	3	15·0	3	5	0
100–199	26	12	46·2	7	26·9	4	8	3
200 +	15	9	60·0	4	26·7	3	6	1

The relevant figures are set out in Table V. and Chart 1, and their implications are sufficiently obvious, though the number of mice in any one age-group is small, and the percentages must, therefore, be regarded only as rough approximations. During the first 10 days of life in the cage some 9 per cent. of the mice are found to be infected. This probably measures the risk of infection to which newcomers were exposed *in the particular epidemic in question. Whether these* mice had acquired a fatal infection or were in process of natural immunisation we cannot tell. From the 10th to the 19th day the proportion of infected mice rises sharply to just over 50 per cent. As yet there is no evidence of any immunising response, as evidenced by the production of agglutinins. It is probable, from the statistical results obtained in a large series of mouse typhoid epidemics, that the majority of these mice were fatally infected and would have died in the course of the next few days. From the 20th to the 200th day and beyond the proportion of infected mice does not vary widely. Such fluctuations as occur are well within the

CHART 1.



sampling errors inherent in such small groups. Between the 20th and 29th days, however, agglutinins begin to appear, and there is a general upward trend in the proportion of mice showing evidence of antibody production, though it is doubtful whether any real significance can be attached to the variations which occur after the age-group 30–59 days. If these figures are compared with the results which have been recorded in earlier papers by Greenwood, myself, and our colleagues, it will be noted that the appearance of agglutinins about the 30th day corresponds closely with the period at which surviving mice begin to show a significant advantage over new entrants to the cage. It seems clear that, after this length of experience, a proportion of the survivors have acquired a resistance, which is characterised by the persistence of *B. aertrycke* in the tissues, associated with the presence of specific antibodies in the blood.

It will be noted that, even among the mice which have survived for 60 days or more, the majority of the infected animals do not show the presence of antibodies in the circulating blood; of 51 survivors beyond this period 29 yielded positive spleen cultures, but only 10 of these agglutinated *B. aertrycke* at dilutions of 1:20 or over. Any suggestion as to the probable condition of the remaining 10 mice must be merely speculative; but our knowledge as to the general behaviour of mice at this period of residence in the cage renders it unlikely that they were all in the throes of a fatal infection. It must be remembered that these mice, along with all their companions, were exposed to the risk of repeated infection; and it is possible that they had already acquired some degree of resistance as the result of earlier minute doses of bacilli, but had not yet received a stimulus of adequate intensity to produce circulating antibodies in detectable amount. It will be noted, also, that the presence of agglutinins, without the presence of *B. aertrycke* in the spleen, is a relatively rare finding; in only seven of the 200 mice examined was this condition of affairs revealed post mortem. It would appear that complete recovery from infection is a rare event, or, alternatively, that recovery with acquirement of immunity does not prevent reinfection of a type which leads to the fresh deposition of bacteria in the splenic tissues.

The Process of Bacterial Infection.

In may be of interest in this connexion to summarise the probable course of events during an infection with a bacterium of the tissue-invading type. The data on which such a description must be based have been accumulated by many workers during the study of experimental infection with the pneumococcus, the typhoid bacillus, and other organisms, and during the investigation of naturally occurring infections in man. It happens that the particular example of mouse typhoid has recently been submitted to detailed study by Ørskov[30] and his colleagues, with results which are in entire conformity with the picture which emerges from the more general observations. In Fig. 2 I have endeavoured to represent diagrammatically the progress of an infection of this type. At A is represented the initial phase, during which the invading bacteria gain access through a mucous surface, and pass to a regional lymphatic gland. At B the bacteria are proliferating in the gland, and there is an intermittent escape of some of them into the blood stream. At C these are shown as collecting in the liver and spleen, these organs being taken as examples of tissues rich in reticulo-endothelial cells, and hence concerned in the normal clearing mechanism of the blood. At D the bacteria are proliferating in those situations in which they have collected during the initial phases of infection, which correspond to the incubation period of a clinical attack of disease. At E there is a re-invasion of the blood stream from these foci of bacterial proliferation, a well-marked bacteriæmia, and a transport of bacteria to other tissues, not previously infected. This corresponds to the phase of clinical illness, and, in a fatal case, terminates in death. Up to this stage no antibodies have appeared in the circulating blood; but at this point they usually make their appearance in cases which recover. At F is represented the phase of clinical recovery. The improved clearing mechanism, consequent on an efficient antibody-producing response, has terminated the bacteriæmic stage; and we are left with a few scattered foci of infection, in the spleen, liver, and lymph nodes, and perhaps in other tissues. As we have seen, there is reason to believe that the persistence of this state of affairs over prolonged periods is consistent with the maintenance of apparent health. At G is represented the final stage of complete restitution, with the disappearance of all infecting bacteria, and the persistence, in the tissues or body fluids, of protective antibodies. It is, of course, possible, if not probable, that a proportion of infections may be terminated at one of the initial stages, A, B, C or D, without ever passing to E, the stage of clinical illness; and it seems reasonable to suppose that such abortive infections, especially if repeated, may lead to the acquirement of a significant degree of immunity to reinfection. That the immunity so produced is only relative is evidenced by the fact that no period of survival in an epidemic cage ensures a mouse against death from mouse typhoid. Under the conditions obtaining in these cages, almost all mice succumb, in the long run, to the prevalent disease. This fatal infection of partially immunised mice may be due in some cases to the reception of an overwhelming dose of bacteria from without. The fact that mice, which have been artificially immunised with dead bacilli, or have withstood an infection with living organisms, may die after a subsequent intraperitoneal inoculation of a moderate dose of the same

bacterial strain, shows that such a defence-rupture may readily be accomplished under experimental conditions. It is possible that, in other cases, the survivors succumb, not to fresh infection from without, but to a spread of infection from latent foci, determined by some temporary variation in physiological conditions. The demonstration, by Boycott and Price-Jones,[31] of the effect of fatigue in increasing the mortality-rate among rats infected with *B. enteritidis*, affords one example of the action of such a non-specific factor.

THE VIRULENCE OF BACTERIA IN LATENT FOCI.

Finally, the evidence does not suggest that the bacilli which remain latent in the tissues suffer any loss of virulence. In a series of experiments recently recorded we started several epidemics by inoculating 25 mice with a culture of *B. aertrycke* of known virulence, and adding to these infected mice 100 normal animals. When these epidemics had subsided two to three months later we were left in each case with a certain number of survivors; and from the majority of these *B. aertrycke* was recovered by spleen culture. Several of these recovered strains were tested for virulence by inoculating 30 mice intraperitoneally with 1000 bacilli; in each case the strain so tested was as virulent as that with which the epidemic was commenced. We have recently obtained evidence pointing in the same direction, by testing the virulence of strains recovered from some of the mice included in the samples withdrawn from the epidemic cage. In all, 16 of these strains have been tested, and the results are set out in Table VI., together with the number of days residence in the cage of the mouse from which each strain was recovered. It is obvious that all strains are fully virulent, the small differences in average time to death, and the occasional survival of a single mouse, being well within the limits of error of such a test as this.

H	29	30	29	7·6	Q	4	30	30	5·9

We have also tested the virulence of seven strains recovered from mice which had been vaccinated, and had subsequently survived the inoculation of 1000 virulent bacilli. The results of these tests are set out in Table VII. Clearly, residence within the spleen of an actively immunised mouse for a period of a few weeks does not result in any loss of virulence.

G	30	30	5·0

CONCLUSION.

I do not think that there can be any reasonable doubt that the defence mechanism which we have been considering plays an important part in the natural acquirement of immunity; and recent studies on diseases due to filtrable viruses suggest rather strongly, that the same general type of reaction is concerned in acquired resistance to these infections. It is, of course, possible that other factors, of which as yet we know nothing, may be concerned in specifically increasing the resistance of the host to invasive bacteria; but I think a protest may reasonably be entered against the readiness, noticeable in some of the recent contributions to immunological literature, to discard the conception of antigen-antibody reactions as an important factor in the defence mechanism of the host. This mechanism is, I think, as well authenticated as many of those which the physiologist would regard as fundamental to his conception of the working of the animal body; and any attempt to dismiss it as a chimera is to suggest a degree of instability and lack of form in this branch of pathology which does not in fact exist. No one doubts that many other factors, quite different in their action, are involved in resistance to bacterial infection, and some of these may well be of primary importance; but the present indications would suggest that these will be found to be non-specific in their action, or, at least, less narrowly specific than the antigen-antibody reactions which we have been considering.

ANCOATS HOSPITAL.—The recent centenary appeal for this hospital was for £100,000, but only £32,000 has been collected, and of this £20,000 was promised before the appeal was made. As a consequence only about half of the scheme can be carried out, and at most 50 beds will be added to the hospital, and even to achieve this the hospital will have to withdraw £18,000 from investments, which, with the £32,000 collected, will make £50,000, only one-half of the sum so urgently required.

HEALTH LECTURES IN PRISONS.—The People's League of Health is inaugurating a fresh series of health lectures in prisons and Borstal institutions in London and many parts of the country. Among those already arranged is a series entitled the Laws of Health as Applied to the Person. These are being given in Bedford Prison by Dr. Eric Holmes, Mrs. S. V. T. Adams, and Mr. Leslie Harris, D.Sc. Sir John Collie, M.D., will visit Wormwood Scrubs, taking as his subject the Human Body and Its Functions, and a series is also going on at Pentonville, including addresses by Dr. Tom Jays, Mr. George Thomson, L.D.S., and Dr. G. Orissa Taylor.

NOTES ON THE
X RAY DIAGNOSIS OF MITRAL STENOSIS.

BY HAROLD COOKSON, M.D., B.Sc. BIRM.,
M.R.C.P. LOND.,
CLINICAL ASSISTANT, NATIONAL HOSPITAL FOR DISEASES OF THE HEART; LATE MEDICAL REGISTRAR, MIDDLESEX HOSPITAL.

WHEN the diagnosis of so important a lesion as mitral stenosis is in doubt every method of investigation which has been shown to be of value should be used to lessen that doubt, or, better, to convert it into a certainty. The statistics given below indicate the part that X ray examination may play in attaining this object.

Clinical Criteria.

Differences of opinion are not infrequent at the bedside and in the out-patient clinic as to whether or not mitral stenosis is present in a given case. The reasons for this are manifold. The most certain clinical sign of mitral stenosis is a low-pitched rumbling diastolic murmur heard at or near the apex; in most cases, when normal rhythm is present, the end or presystolic part of this murmur, which coincides with systole of the auricle, is heard as a crescendo which terminates abruptly in the first sound. The impression gained of an increasing volume or crescendo of sound has been shown by phono-electrocardiograms [1] [2] to be an auditory illusion. These records show that the vibrations of the presystolic murmur and of the longer diastolic murmurs are fairly uniform in amplitude and do not show a progressive increase in size. The impression of a crescendo is probably given by the termination of the murmur in a loud sharp first sound. This explanation is supported by the change in character that occurs when the murmur is separated from the first sound as a result of delayed auriculo-ventricular conduction. The murmur under these conditions loses its crescendo quality; this change is noted by Cowan and Ritchie,[3] who, however, explain it in a different way. The mitral diastolic murmur with its intensity and its crescendo (though illusory) is often most conspicuous to the ear, but it has long been recognised as a most fugitive murmur. Present one day, it may have disappeared the next, or have become so faint as to be audible only to those specially skilled in its detection. If the precaution is taken of listening for the murmur in the left lateral position after the patient has undergone some exertion, it may be heard when it would otherwise be missed. But even when the conditions of examination are standardised and the greatest care is used in trying to elicit the murmur, it is found to come and go in a curious way which is not understood, and which is not correlated with any apparent changes in the circulation. This evanescent quality of the mitral diastolic murmur, when there is normal rhythm and no heart failure, constitutes the first difficulty in diagnosing mitral stenosis.

When a coördinated systole of the auricle is absent the diastolic murmur will terminate, unless the heart-rate be rapid and diastole therefore short, before the first sound—that is to say, presystole will be free of murmur. This is the case in auricular fibrillation, and the murmur is then more difficult to recognise. It will be even more elusive if the auricular fibrillation is accompanied by a rapid ventricle, for then diastole and with it the murmur is shortened. If the stenosis is mild it gives rise only to a short murmur in presystole, which coincides with systole of the auricle. As Mackenzie discovered in 1897, if auricular fibrillation has its onset under these conditions, the short murmur disappears and diastole is entirely silent. Considerable left auricular dilatation with thinning of its wall may, however, occur with the persistence of normal rhythm, and under these circumstances the auricular contraction is so weak that it fails to produce the presystolic part of the diastolic murmur. Failing a diastolic apical murmur of the kind described, there are certain equivocal signs on which a diagnosis of mitral stenosis may be based; of these the most important are a slapping apex-beat, a short, sharp first sound, a reduplicated second sound, a reduplicated first sound, and a blowing systolic murmur heard at the apex. Temporary replacement of the presystolic murmur by a reduplicated first sound is sometimes observed in mitral stenosis, and in some cases it may be difficult to distinguish a coarse reduplication from a very short presystolic murmur. It is particularly in nervous individuals and in patients with effort syndrome that the above signs may be met with and lead to a suspicion of mitral stenosis. Cabot's statistics,[4] which show that of 107 necropsied cases of "pure" mitral stenosis the diagnosis was made in life in 48·5 per cent., illustrate the difficulties which have been described.

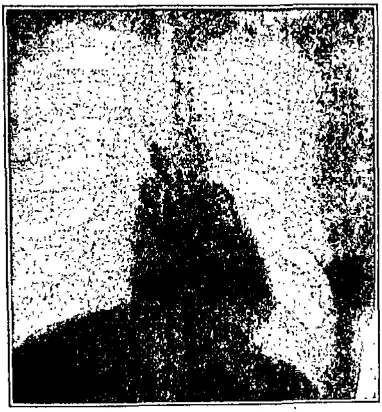
It has been stated above that a low-pitched apical diastolic murmur is the most certain sign of mitral stenosis, but that it is not an absolutely certain sign. Reported cases prove that such a murmur may be heard in the absence of this valvular lesion; it is recorded, for example, in aortic incompetence,[5] with adherent pericardium,[7] and in uræmia.[7] In hyperthyroidism, in addition to a slapping apex and short, sharp first sound, a rumbling bruit may be heard which closely simulates a presystolic murmur.

The X Ray Appearances in Mitral Stenosis.

That the shape of the heart as seen by X rays is often altered in a definite way is now well known. Figs. 1 and 2 show the X ray appearances of a normal heart in the anteroposterior and right anterior oblique (R.A.O.) positions respectively. The R.A.O. position is assumed when the patient faces the X ray screen, and then turns 45° to his left. Comparison with plates taken in corresponding positions in cases of mitral stenosis shows certain differences. Fig. 3, an anteroposterior picture of such a case, shows a prominent slightly convex left middle arc. This is due chiefly to prominence of the pulmonary artery, but partly to an increase in the size of the conus arteriosus and the left auricular appendix; rarely the two structures, pulmonary artery and left auricular appendix, can be discerned as separate prominences, the latter situated just below the former. The projection of the pulmonary artery is brought about by hypertrophy of the right ventricle; this causes the conus and pulmonary artery to be pushed upwards and to the left, and secondly causes a rotation of the whole heart in such a way as to carry the left ventricle posteriorly. Both these changes have the effect of making the pulmonary artery appear more prominently on the left profile of the heart. Frequently there is also an exaggerated convexity of the right border of the heart, due to right auricular and ventricular enlargement; this is shown in Fig. 3. Fig. 4 is an anteroposterior view from a case of mitral stenosis with aortic incompetence. Here the left ventricle is considerably enlarged and this, together with an enlarged left middle arc, results in a straight left border. An inconspicuous aortic knob has been stated to be another result of the rotation of the heart which occurs with right ventricular hypertrophy [6]; this, however, is of small importance, since considerable variation in the size of the knob occurs apart from mitral stenosis.

The right anterior oblique position normally shows a clear area, known as the retrocardiac space, which is bounded in front by the posterior border of the heart and behind by the anterior margin of the vertebral column (Fig. 2). This space is encroached on in mitral stenosis to a greater or lesser extent by the backward dilatation of the left auricle. Fig. 5 illustrates this condition; it shows the retrocardiac space almost entirely filled in. The abnormal shadow is not entirely produced by the left auricle, however; in this case there is, in addition, dilatation of the right auricle. The left auricle is above and the right below; where the two chambers are superimposed, in the middle third of the retrocardiac space, the resulting shadow is much denser. Fig. 6 is taken from another case of mitral stenosis, in the right lateral position, so as to define clearly the posterior border of the bulging auricle. In this position the auricular shadow does not extend as far as the vertebral column. The displacement of the œsophagus, which has been filled with bismuth, as it curves round the posterior surface of the auricle can be clearly seen. The flow of the bismuth has been impeded, as can be seen from the local dilatation of the lumen just above the auricular convexity; the slight constriction of the lumen just above the dilated part corresponds to that portion of the œsophagus crossed by the left bronchus. In a relatively small proportion of cases the enlargement of the left auricle is so great that it forms a part or the whole of the right profile of the heart; several cases of extreme dilatation in which the left auricle almost touches the right chest wall have been published since the first case was recorded in 1901 by Owen and Fenton.

FIG. 1.



Radiogram of normal heart, taken in the anteroposterior position.

Table of X Ray Findings.

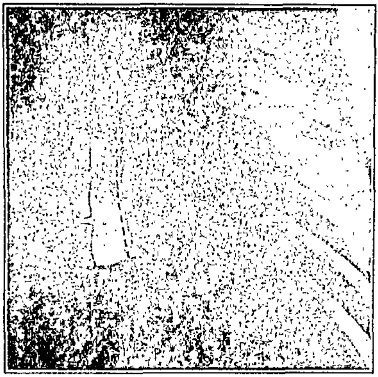
Group.		No. of cases.	Pulmonary artery—		
			Prominent and left auricle enlarged.	Prominent only.	Not prominent and left auricle not enlarged
I.	Cases with apical "mitral" diastolic murmur only.	25	18	3	4
II.	Cases with apical "mitral" diastolic murmur, and basal aortic diastolic murmur.	15	11	4	0
III.	Cases of rheumatic carditis and equivocal signs of mitral stenosis, but no mitral diastolic murmur.	10	6	4	0

Results of Investigation in 50 Cases.

In attempting to assess the diagnostic value of X rays in mitral stenosis the following method was adopted. At first cases in which the diagnosis was practically certain by clinical methods were examined by the X rays, with the object of finding the proportion in which the typical X ray picture occurred. Then a control group of cases of non-rheumatic heart disease was investigated to discover if this typical X ray picture ever occurred, and, if so, with what frequency.

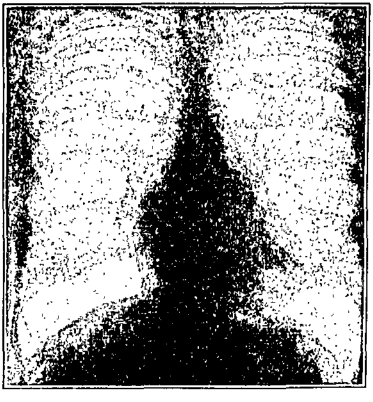
Finally, a group in which the clinical diagnosis of mitral stenosis was probable but not certain was examined in a similar way. The orthodiagraph was used in all cases; it gives an accurate picture of the shape, and, to a lesser extent, of the size of the heart, and is at the same time convenient to use and economical in time and materials. In saying that the clinical diagnosis was practically certain, I mean that at some time, but not necessarily at every time of examination, a rumbling or low-pitched diastolic murmur had been heard at the apex—that is, a diastolic murmur of "mitral" type. These cases have been divided into two groups—those in which there was a "mitral" apical diastolic murmur only (Group I. in Table), and those in which there was in addition the high-pitched murmur of aortic incompetence at the base of the heart (Group II. in Table).

FIG. 2.



Radiogram of normal heart, taken in the right anterior oblique position, showing a clear retrocardiac space.

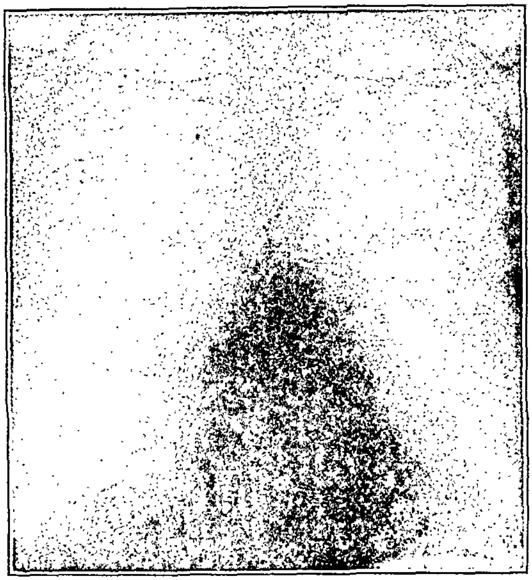
FIG. 3.



Radiogram from a case of mitral stenosis (anteroposterior position).

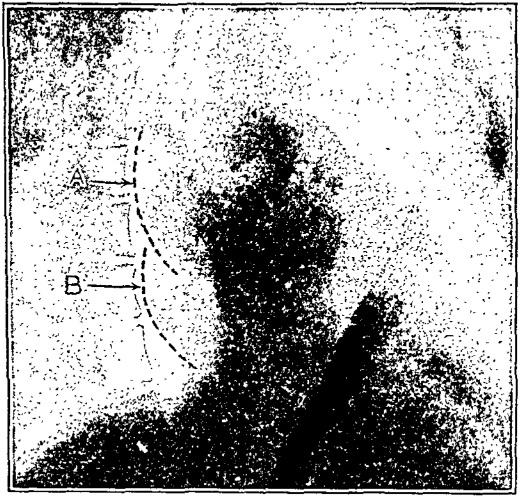
Since there are recorded cases of aortic incompetence in which a presystolic murmur has been heard and in which the mitral valve has been demonstrated to be normal post mortem, there is a possibility that the "mitral" diastolic murmur was of aortic origin in the cases in Group II. The possibility is, however, remote as such a demonstration has been very rarely made. There was no case of adherent pericardium—another condition in which the presystolic murmur has been heard, and yet the mitral valve subsequently shown to be normal. It may be taken, then, as almost certain that mitral stenosis was present in Groups I. and II. It will be seen that out of 40 cases in these two groups 29 (72·5 per cent.) showed a prominent pulmonary artery and an enlarged left auricle; four (10 per cent.) showed neither of these changes; and three (7·5 per cent.) showed a prominent pulmonary artery only. An obvious projection on the left middle arc or a straight left border when the left ventricle is enlarged has been taken as indicating a prominent pulmonary artery. A backward extension of the upper two-thirds of the posterior profile of the heart, so as to touch the anterior margin of the vertebral column at some point, has been used as the criterion of an enlarged left auricle. In two instances two convexities were present on the left middle arc; the upper of these is produced by the pulmonary artery, and the lower by a hypertrophied conus arteriosus, around which an enlarged left auricular appendix may be wrapped. This last condition has been seen recently in two autopsies. In three cases—i.e., 7·5 per cent.—the left auricle projected to the right so far as to form part of the right profile of the heart; auricular fibrillation was present in all three.

FIG. 4.



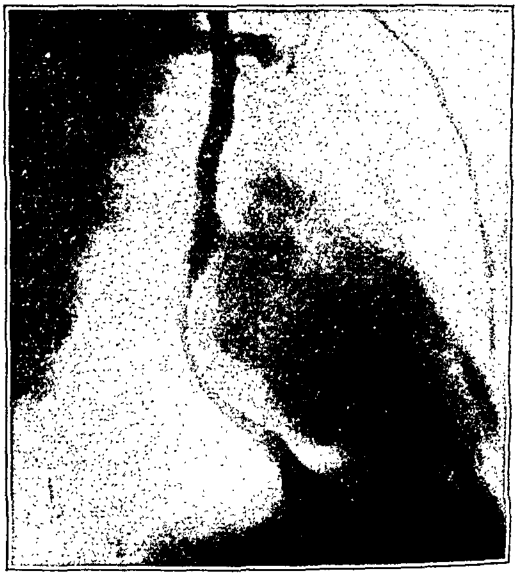
Radiogram of heart with mitral stenosis and aortic incompetence. Note the straight left border produced by exaggeration of the left middle arc together with enlargement of the left ventricle.

FIG. 5.



Radiogram of heart with mitral stenosis, taken in the right anterior oblique position. The retrocardiac space is almost entirely obscured by the shadows of the right and left auricles. (Compare Fig. 2.)

FIG. 6.



Radiogram taken in right anterior oblique position in a case of mitral stenosis. The œsophagus, outlined with barium, curves round the posterior border of the dilated left auricle.

Certain other structures may simulate a prominent pulmonary artery in the anteroposterior position and a dilated left auricle in the oblique position. A visible descending aorta, whether dilated or not, and an enlarged root-shadow may be mistaken for the first, and a rounded mass of glands in the posterior mediastinum for the second. With careful examination, however, it is easy to discriminate between these conditions; the shape, position, and regularity or otherwise of the contour of the shadows are distinctive. The X ray findings are vitiated if there is chest deformity, such as a funnel chest, or any abnormal curvature of the vertebral column. Vaquez and Bordet [8] state that increase in the size of the left auricle can be seen earliest and best in the left anterior oblique and right posterior oblique positions. I have found, however, that the outline of the auricle is shown more clearly in the right anterior oblique position, especially when the left ventricle is enlarged.

The next step was to determine with what frequency this picture, which has been shown to be very common in mitral stenosis, occurred in other conditions, for a prominent pulmonary artery will be met with in any condition which leads to right ventricular hypertrophy; it is very common in congenital heart disease and in Ayerza's syndrome, but these are rare. Enlargement of the left auricle is also known to occur apart from mitral stenosis, a few examples of extreme dilatation having been recorded in association with rheumatic heart disease and mitral incompetence.[9 10 11] It is, however, very rare apart from rheumatic heart disease, and mitral incompetence in chronic rheumatic heart disease is rare apart from stenosis. Thirty unselected control cases of non-rheumatic heart disease, made up of syphilitic cardiovascular disease, hypertension, cardiac enlargement of doubtful origin, atheroma of the aorta, and thyrotoxic heart disease, were X rayed. In one case (3 per cent.) the pulmonary artery was slightly prominent, and in one other there was enlargement of the left auricle only; in no one case was there prominence of the pulmonary artery as well as dilatation of the left auricle. The last group consisted of ten cases of rheumatic heart disease in which a "mitral" diastolic murmur had at no time been heard but in which the equivocal signs of mitral stenosis were present. In every case the pulmonary artery was prominent, and in six the left auricle was dilated (Group III. in Table).

Summary and Conclusions.

In 40 cases of rheumatic heart disease in which mitral stenosis was almost certain from clinical examination the orthodiagraph showed a combination of changes which occur in such a large proportion that it may be termed typical. This combination, consisting of prominence of the pulmonary artery and dilatation of the left auricle, was present in 72·5 per cent. of cases. In a further 7·5 per cent. there was a prominent pulmonary artery only. In 10 per cent. the picture was not typical, as neither of the two usual changes was present. Enlargement of the left auricle without any change in the left middle arc was never seen, although a specimen which I have lately examined would probably have given this picture; the mitral valve was stenosed and the left auricle was much enlarged, extending well to the right behind the right auricle, yet there was no appreciable change in the right ventricle. A control group of 30 cases, which were unselected except that rheumatic heart disease (and with it mitral stenosis) was, as far as possible, excluded, showed the typical picture in no instance, although in one the pulmonary artery was prominent, and in one other the left auricle was dilated. Of ten cases with rheumatic heart disease in which mitral stenosis was considered probable on clinical grounds, the typical picture was present in six and in the remaining four the pulmonary artery was prominent.

The conclusion seems justified that the X ray picture, though not infallible, is of great value in the diagnosis of mitral stenosis. It fails in 10 per cent. of cases where the disease is present, and in a much smaller proportion of cases without mitral stenosis it will show a partially characteristic change in the shape of the heart, but never, so these observations suggest, the typical picture

I am indebted to Dr. G. E. Beaumont and Dr. T. F. Cotton for permission to use their cases; and to Dr. F. G. Nicholas for taking the X ray pictures and some of the orthodiagrams.

BELFAST HOSPITAL FOR SICK CHILDREN.—The foundation-stone of the new building was laid recently by Mrs. Harold Barbour. The building will contain 60 beds, but the administrative block and offices are designed for a hospital of 100 beds, and there will be an enlargement so soon as means permit.

THE MEDICAL MANAGEMENT OF A CASE OF GASTRIC OR DUODENAL ULCERATION.

BY JOHN H. ANDERSON, C.M.G., C.B.E.,
M.D. MELB.,
PHYSICIAN TO RUTHIN CASTLE, NORTH WALES.

IN days gone by medical measures were employed exclusively in the treatment of gastric ulcer, and though gastric surgery has advanced greatly in recent years, medical treatment has lost nothing of its importance whether or not it is combined with surgery.

Medical treatment can be divided into: (*a*) feeding entirely by the bowel, or (*b*) a graduated diet, with alkalis, by the mouth. The latter practice is the routine adopted at Ruthin Castle. Essentials for medical treatment are: (1) coöperation of the patient, (2) removal of septic foci, (3) rest, (4) diet, (5) alkalis.

Coöperation of the Patient.

When the diagnosis is established the patient is told that his disease may be treated medically or surgically, and unless there is some feature calling for surgery medical measures are advised. It is stipulated that a reasonable time be given for treatment, otherwise it is feared that the result will not be satisfactory to patient or physician. Three months is suggested as the minimum time required, of which the first month is spent in bed, about a month getting up and about, and a third month for a gradual return to active life. For the first two months institutional treatment is to be preferred; for it has been our experience that treatment undertaken at home is not so successful as that carried out under the constant supervision which is possible in a hospital. The diet also calls for a care and precision which it is difficult to organise in a private house.

For example, a man of 37 preferred to carry out treatment at home when he could attend to his work with the help of a telephone by the bedside and daily visits from a stenographer and his works manager. All symptoms ceased, but the anæmia did not improve and X rays two months later showed no change in the gastric lesion, a small prepyloric ulcer.

During his time in bed an attempt is made by daily talks to get the patient to understand the reason for the various points in his routine, with a view to shaping his life after he leaves hospital. Lawrence has ably described the "diabetic life," and we attempt to lay down in these cases what may be called the "ulcer life," pointing out where dangers lie and emphasising the need of careful supervision by his medical attendant, and of a permanent routine after leaving hospital.

Removal of Septic Foci.

If not already done, the body is searched for sources of infection. In this quest mouth, throat, tonsils, nasal sinuses, teeth, bowel, gall-bladder, kidneys, and urinary bladder are systematically gone over and any lesion dealt with as far as possible. The importance of this procedure cannot be stressed too highly. If in this connexion laparotomy is required, the opportunity is, of course, taken to examine the ulcer and carry out any further surgical procedure that seems desirable. We have seen the removal of a septic focus, such as a chronic appendicitis, lead, with medical treatment, to a permanent healing of a gastric ulcer without any deforming or crippling operation on the stomach. Even when the collaboration of a surgeon has been sought, and the case dealt with in the first instance by him, it is felt that when the surgical condition has been relieved, the medical after-treatment should be in the hands of a physician.

Rest.

The whole body is rested by at least four weeks in bed, lying on the back, shoulders flat on the bed, and head raised by one or two small pillows. Daily massage helps to keep up the muscular nutrition and to avoid the cramps and aches which otherwise so often occur, particularly in the first two or three days in bed, and later about the end of the second week. The stomach is rested by frequent small meals as indicated under "diet." Aperients are avoided, and at first an enema is given on alternate days. At a later stage liquid paraffin is added and, as a rule, before the patient is getting up the bowels are acting naturally.

Diet.

In former days fasting or rectal feeding was the routine method. E. I. Spriggs published, in 1907, the first series of cases treated in this country by immediate mouth feeding,[1] and in the following year W. Langdon Brown described 11 cases similarly treated.[2] The present method is a combination of the diet of Lenhartz, and the olive oil of Cohnheim and Walko modified by Dr. Spriggs in the course of 21 years' experience. The régime cannot be applied as it is set forth to every, probably not to any, patient. Each case requires individual care and inquiry with resulting modification of the instructions.

The diet is graduated in 26 steps, starting with olive oil and alkaline water and working up gradually to a light diet. The best idea of it may be given by setting out three or four stages.

Diet on First Day.

(30 c.cm. = one ounce.)

	c.cm.		c.cm.
8 A.M. ..	15 of olive oil.	5 P.M. ..	15 of olive oil.
9 ,, ..	60 of alk. water.	6 ,, ..	60 of alk. water.
11 ,, ..	15 of olive oil.	8 ,, ..	15 of olive oil.
12 noon..	60 of alk.water.	9 ,, ..	60 of alk. water.
2 P.M. ..	15 of olive oil.	10 ,, ..	15 of olive oil.
3 ,, ..	60 of alk. water.		

Food value, 770 cal. approximately. Alk. = alkaline.

A few patients cannot take olive oil at all, and in this case a milk cream mixture is substituted for the oil. This is made by mixing 180 c.cm. of milk, 60 c.cm. of lime water, and 60 c.cm. of cream. The alkaline water is made up of 15 grammes of bicarbonate of soda in one pint of water, and an extra 30 c.cm. is allowed between the olive oil feeds if the patient desires. It has been found possible to start gradually a diet of this nature three or four days after a hæmorrhage.

Diet on Third Day.

This consists of egg and milk mixture three-hourly with a dose of olive oil an hour before each feed.

	c.cm.		c.cm.
8 A.M. ..	30 of olive oil.	5 P.M. ..	30 of olive oil.
9 ,, ..	50 of e.m. mixt.	6 ,, ..	50 c.m. mixt.
11 ,, ..	30 of olive oil.	8 ,, ..	30 of olive oil.
12 noon..	50 of e.m. mixt.	9 ,, ..	50 of e.m. mixt.
2 P.M. ..	30 of olive oil.	10 ,, ..	30 of olive oil.
3 ,, ..	50 of e.m. mixt.		

Food value = 1790 cal. approximately. E.m. mixt. = egg and milk mixture.

The egg and milk mixture consists of one egg in 100 c.cm. of milk, is taken in sips, and if possible is made to last from one dose of olive oil to the next. Alkaline water is provided and sips are taken when required for thirst at intervals of not less than 15 minutes. The olive oil is gradually reduced and the egg and milk mixture increased. On the seventh day boiled rice is added, and on the eighth day minced or pounded chicken.

Diet on Twelfth Day.

Here four meals are given, olive oil before the two chief ones, and extra feeds of egg and milk at 2 P.M. and 9 P.M. 30 g. = one ounce.

Breakfast, 8.30 A.M.—One egg; dry toast (25 g.); butter (10 g.); milk and water (100 c.cm.).
11.30 A.M.—30 c.cm. of olive oil.
Lunch, 12 noon.—Minced or pounded beef (56 g.); dry toast (20 g.); butter (5 g.).
2 P.M.—Egg and milk mixture (150 c.cm.).
Tea, 4 P.M.—Thin bread and butter (20 g.); milk and water (170 c.cm.).
6.30 P.M.—30 c.cm. of olive oil.
Dinner, 7 P.M.—Boiled rice (30 g.); milk and water (100 c.cm.) dry toast (20 g.); butter (5 g.).
9 P.M.—Egg and milk mixture (150 c.cm.).

Food value = 1930 calories approximately.

The alkaline water is still allowed for thirst. The milk and water mixture consists of 55 c.cm. of milk and 35 c.cm. of water. The allowances are increased gradually, as is shown by the diet on the twentieth day.

Diet on Twentieth Day.

Much the same as the preceding, but with more variety.

Breakfast.—Egg or fish; dry toast; butter; milk and water.
11.30 A.M.—30 c.cm. of olive oil.
Lunch.—Chicken; mashed potatoes; dry toast; butter; rice pudding; milk and water.
2 P.M.—Egg and milk mixture.
Tea, 4 P.M.—Dry toast or dried bread and butter; sponge cake; milk.
6.30 P.M.—30 c.cm. of olive oil.
Dinner, 7 P.M.—Steamed fish; toast and butter; macaroni or vermicelli; milk pudding or custard; water or soda water;
10 P.M.—Milk and rusk or Bengers' food.

Food value = 3000 calories approximately.

If pain or discomfort recurs the diet is kept the same for a day or two or is taken back to an early stage, and increased again later.

As the patient gets up, more foods are added, and the diet on leaving is made up as follows:—

Diet on Leaving.

A light ordinary bland diet.

Breakfast.—Porridge, fish, cold fat ham, egg; toast; butter; cream; flavoured milk or weak China tea.
Lunch.—Chicken, mutton, or lamb; potato; sieved greens; milk or light steamed pudding; cream; sieved fruit.
Tea.—Bread and butter; sponge cake; milk and water or weak tea.
Dinner.—Fish, chicken or sweetbread; potato; sieved greens; macaroni or vermicelli, milk pudding, cold sweet, sieved or puréed fruit; toast; butter; cream.

It must be intoned that in all cases variations are necessary to meet personal likes and dislikes and ingenuity is often severely taxed. It is surprising, however, how few failures there are in keeping fairly close to the desired diet if patience, tact, and humanity are displayed in the dealings between doctor and patient. Visiting at meal times is often a great help.

Alkalis.

Various alkalis are used, such as sodium bicarbonate, sodium citrate, cremor magnesiæ, magnesium carbonate or hydroxide, and calcium carbonate. Bismuth oxychloride is generally given three times a day in water as a routine; sodium bicarbonate is in the alkaline water which the patient takes steadily throughout his time in bed, and the other drugs are used from time to time as required. The magnesium compounds are especially useful if constipation is a feature, and the cremor magnesiæ if gastric flatulence is a leading symptom. The well-known combination of the carbonates of bismuth and magnesium and the bicarbonate of soda should be specially recalled. Another useful powder is one made up of equal parts of bismuth oxychloride, sodium citrate, and mag. carb. lev., one teaspoonful as a dose three times a day after meals in water. If there is any looseness of the stools calcium carbonate is substituted for the magnesium carbonate. No case of alkalosis has been seen.

General.

While in bed the mouth is cleaned after each feed, and sleeping helped when required with small doses of medinal or dial ciba. If wakefulness is complained of, a small feed through the night is often more useful than a hypnotic. Smoking is discouraged.

Progress.

Progress, as a rule, is uneventful and is checked by: (*a*) disappearance of symptoms; (*b*) examination of stools for blood, visible and occult; (*c*) radiography of the stomach. The pain gradually eases and, as a rule, is gone by the sixth to seventh day, though intermittent discomfort may be present for a few days longer. If pain is still prominent by the end of the second week, the case is reconsidered in all its bearings with a view to deciding whether medical treatment should be continued or surgery advised. At this time of alleviation of symptoms it is advisable to point out to the patient that his improvement does not mean a cure, but is merely an indication that cure would appear to be possible and even probable. He is told that the "ulcer is skinning over," but that time must be given for the new covering to become several cells thick. Histological work has shown that this process takes a long time; and it cannot be hastened. A useful analogy can be drawn between the healing of the internal ulcer and the gradual scarring of a deep abrasion of the skin. Blood disappears from the fæces at an early stage of healing, and the later progress can be judged from an X ray photograph of the ulcer site. The diet is steadily increased as has been shown, and more latitude of movement in bed allowed, and finally the patient is allowed to get up in a chair and out of doors as weather permits. Walking is carefully graduated, and violent exercise prohibited. He is cautioned that absence of symptoms does not mean that liberties may be taken. Lord Moynihan has stated the position in his aphorism that "clinical silence does not mean pathological inactivity," and this point is emphasised to the patient as clearly and as forcibly as possible. A normal life, with certain limitations, is resumed gradually, and on leaving hospital some simple instructions are given, in addition to the suggested diet as already described.

---

[1] Trans. Med.-Chir. Soc., 1907, xc., 283.
[2] Clin. Jour., 1908, 1908-9, xxxiii., 109.

Example of Instructions.

The diet should consist of simple foods, avoiding beef, pork, pastry, vinegar, pickles, twice-cooked foods, and foods containing shreds and hard pieces. Hot fats and raw fruit should be taken sparingly, and all fruit and greens should be passed through a sieve.

For the present rest a full hour in the middle of the day and in the evening. Bed not later than 10 P.M.

Exercise daily in the open air, increasing the time gradually, but not to the point of fatigue.

The return to work should be gradual; at first not more than two hours a day, gradually increasing as strength is regained. Work should be so planned as to avoid long-continued effort or hurry. Enough time must be allowed for meals.

Alcohol is not advised. Smoking is not advised for the present, and when resumed should be limited to the half-hour immediately after a meal.

Continue the liquid paraffin, dose modified as required, and the olive oil before meals. Half a teaspoonful of bicarbonate of soda or of the prescribed powder, in water, should be taken an hour after meals.

The return to full strength will be gradual and no alteration in the régime must be made without medical advice.

Results.

At the outset the problem arises as to what is a cure. For example :—

A man of 20 had a gastro-enterostomy for duodenal ulceration and was free from symptoms till the age of 30. Abdominal trouble returned, and at the age of 48 radiographic examination showed an inflamed area near the pylorus and what was regarded as a small ulcer near by. After medical treatment he was well and worked hard for nearly two years. Gross indiscretions in eating and drinking were then followed by two small hæmorrhages, and he now has an ulcer just beyond the pylorus. In this case it can be said that both surgical and medical treatment have been successful or unsuccessful, according to the view taken of what success in these cases really is. I feel that both were successful with the balance against surgery as the stoma has almost closed. The lack of success lay with the patient in that he did not realise and remain within his limitations, thus returning to his vomit, literally and metaphorically.

The method of treatment here described has been used at Duff House and Ruthin Castle for 15 years, and has yielded good results in cases of gastric and duodenal ulceration in which there is no direct call for surgery.

In cases with much pyloric or duodenal deformity, those in which symptoms persist after a fair trial of medical measures and, above all, those with any suspicion of malignancy, operation is advised, not as a different method, but as an incident in the course of the treatment. In our experience this occurs in about one case in five of gastric ulcer, the other four do well under medical treatment and, as far as can be ascertained, most of them go on well if a reasonable life is followed. In the last 30 cases of gastric ulcer four were advised operation. One died as a result of the operation, one refused operation and died later from a perforation, and the other two benefited from the operation. The exact figures in a series of over 200 cases of duodenal ulcer are not yet available.

The experiences of other workers have been deliberately omitted, but reference may be made to an article by Prof. Charles Pannett.[3] His opinion is that "No ulcer patient should be subjected to operation until medical treatment has proved a failure," and the same view has been expressed by many other leading surgeons. It is our duty as physicians to make the number of medical failures as few as possible.

I am indebted to my senior physician, Dr. E. I. Spriggs, for helpful criticism in preparing this article, and to Dr. Mary Watson for collecting and summarising the cases quoted.

NOTES ON FRACTURED PATELLA.

BY A. P. BERTWISTLE, M.B. LEEDS,
F.R.C.S. EDIN.

FRACTURES of the patella may be classified in two main groups according to their causation and treatment—viz., those due to direct violence, and those caused by muscular action. Whilst all are in agreement about the treatment of the former, that of the latter is by no means standardised. This is all the more surprising, as the patella was the second of all bones to be wired, and this procedure gives as good results as any other of its class. The olecranon was the first bone to be wired, and to Lister, who performed this operation, is also due the credit of wiring the patella, though Cameron preceded him by a year in 1876. In the eyes of his rivals it was Lister's boldest surgical effrontery. P. Turner recently reported a case operated upon by Howse 38 years ago; he probably used the carbolic spray and kept the limb on a back splint for six weeks.[1] At that time Malgaigne's hooks were considered effective, but the pain and irritation they caused led to their abandonment.[2]

Fracture from Direct Violence.

Fractured patella may occur in several members of the same family and re-fracture at the same or a different place is not uncommon. Both these facts suggest a congenital weakness. Bilateral fracture, of which I have seen an example, is not uncommon. Direct violence usually causes a starred fracture by crushing the patella against the femur, though transverse and longitudinal breaks are not unknown. The front of the joint becomes extremely swollen, partly from bruising, and partly from distension of the prepatellar bursa. It is only later that the joint itself becomes distended. Some movement is possible immediately after the accident; effusion prevents it later. The aponeurosis and lateral expansions are not divided, and hold the fragments in position. The fracture may be simple or compound. Lateral plaques are usually found at the upper and outer angle of the bone and are often bilateral, a point of considerable diagnostic importance. I have seen one, and Scudder depicts several.[3] The discovery of these plaques after an accident may present considerable confusion, and the symptoms may be due to injury to them.

(a) Simple Fracture.—All are agreed that it is inadvisable to operate on the starred fracture. The first essential is to reduce or at least arrest the swelling by an elastic bandage or firm bandaging over wool; evaporating lotions are of some service. A moulded back splint or a calliper is applied so that the limb can be elevated to an angle of 45°, to relax the rectus femoris, which is more or less taut when the limb is in line with the body. Massage is applied

---

[3] Brit. Med. Jour., 1928, i., 623.

daily to the quadriceps, which otherwise wastes rapidly. No active movement is permitted for three weeks, but passive movement should be recommended, or the clots and effusion organise into strong bands which may require open operation. The patient walks with a calliper which permits slowly increasing range of movement after the third week.

(b) *Compound Fracture.*—Fracture from direct violence may result in a compound fracture with a lacerated or punctured wound; the latter is liable to be overlooked, suppuration being the first indication of it. All compound fractures should be explored under anæsthesia and the wound carefully excised.

The immediate *prognosis* is good, bony union being the rule. There is, however, a liability to arthritic changes, since the joint may have been injured as well as the patella.

Fracture from Muscular Action.

By far the commonest accident is for the patient to have imagined a non-existent step while walking upstairs; he jerks his leg forward and collapses, so that the break occurs with the limb flexed. Lister's cases all occurred whilst the patient was in the act of extending the limb to prevent a fall. Immediately after the accident inspection reveals between the fragments a gap which is well seen in the silhouette-radiogram. Power to extend the leg is almost if not completely lost, though it may be possible to walk by swinging the leg forward and hyper-extending (Cotton). Effusion of blood and synovial fluid cause the joint to be distended earlier and to a greater extent than in the other variety of fracture.

The fracture is usually a clean, transverse one associated with a variable amount of laceration of the lateral expansions; the greater the laceration the wider the separation. A very important feature is that the aponeurosis over the patella tears at a different level from that of the fracture and comes to dip down over one fractured surface; crepitus, if felt, is therefore soft. The gap may be anything from ½ in. to 3 in. The lower fragment is usually tilted, so that its fractured surface is directed anteriorly.

The *differential diagnosis* is from: (1) dislocation; a radiogram clears up any doubt. (2) Ruptured ligamentum patellæ; the ligament is rarely ruptured, but usually evulses a flake of the tibial tuberosity, which is well seen in the radiogram, together with the wide separation of patella from tibia. (3) Torn quadriceps; a rare condition differentiated radiographically.

Treatment.

The knee-joint has the largest area of synovial membrane and the greatest number of vitally important ligaments of any joint in the body. It possesses the largest amount of avascular tissue in the form of cartilage. Its poor bony architecture and its exposed position favour synovitis, which may go on to arthritis; in fact, it is the commonest joint to suffer from these conditions. Draining the joint is fraught with danger to itself if not to life. An ankylosed knee is a most crippling deformity.

Two methods of treatment are in use, the conservative and the operative. Most surgeons would now operate unless the gap is very small, as only after operation can bony union occur. The aseptic surgeon of to-day does not consider that the behaviour of the patella differs from that of any other bone after operation. Pre-Listerian results of operation, especially on long-standing cases, surrounded the patella with an evil reputation which is not yet dissipated.

(a) *Conservative Method.*—From the start the limb is put up in the same position as has been described for the starred fracture. Means are taken to reduce the swelling. Some authorities use two loops of bandage, applied above and below the fracture, to maintain apposition, but these are not satisfactory and may cut the skin. Skudder's figures are probably as good as any, and yet he only secured 66·5 per cent. serviceable limbs in six patients not treated surgically, whereas he had good results in 84·5 per cent. of operations; he does not say why some were operated upon and others not.[4] Sir William de Courcy Wheeler records a perfect result with wide separation.[5] Possibly the poor results are due to failure to elevate the limb during treatment.

(b) *Operative Treatment.*—The after-treatment is very much simpler and saves a considerable amount of time but—what is still more important—operation ensures in bony union in most cases and, even if there is a gap, it is of little functional disadvantage. The objections were the fatalities and complications of pre-aseptic days. The former have almost disappeared; the latter are still with us and may be attributed to:—

1. Faulty preparation of the skin. The whole limb from buttock to toes should be prepared with spirit soap and antiseptics for three days. Fomentations are useful for the rugæ around the knee. At the time of operation there should be no eczema or blisters, since the latter teem with micro-organisms. To operate immediately is risky.

2. Unnecessary trauma. It is frequently observed that a surgeon who cuts and is gentle, yet not overfastidious as regards asepsis, gets results which compare favourably with those of one who tears and is rough, but who is scrupulously aseptic. One of the advantages of operation is the possibility of removing clots, but this must be done with the greatest gentleness with forceps and isotonic saline irrigations and not with gauze, since this tends to damage the cartilage and may cause the entrance of bacteria. A joint is well able to remove clot, as is seen in hæmophiliac effusions. Trauma is very important in dealing with long-standing fractures.

3. Devitalisation of the patella. Erichsen[6] describes some dissections performed by Manning which demonstrated that the vascular arch supplying the patella was torn across the internal condyle. This cutting-off of the blood-supply explains the formation of sequestra in unopened fractures, of which Erichsen cites a case.[7] Still more important is its bearing on cases where these form after operation. This devascularisation makes the patella an easy prey to sepsis.

Steps in the Operation.

1. *Time of operation.*—Probably the fourth is the ideal day; the first should be devoted to reduction of swelling.

2. Application of a *tourniquet.*—This useful measure is sometimes omitted. If any vessels are seen they can be ligatured; a firm dressing suffices to arrest capillary and venous hæmorrhage.

3. *Flaps.*—These are horse-shoe shaped; if they are turned up their vitality may be better secured, but if they are turned down the resulting scar is outside the pressure-bearing area of the knee.

4. After raising the flaps it is imperative to *change gloves* or, better, to remove the outer of two pairs worn at the start.

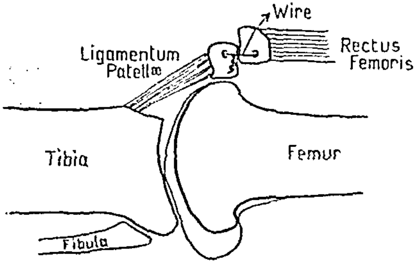
5. *Tetra-cloths* must be arranged to prevent skin contamination.

6. The field must be cleared of *blood-clot* and as much as possible removed from the joint with forceps and saline irrigation. Tags of tissue which are of no use for suture are removed.

7. *Wiring.*—The number of methods in use is legion, suggesting that the ideal is yet to be sought, but Hey Groves's original method fulfils all that is necessary. Two wires are passed transversely and the ends twisted. If trouble arises later, all that is required is an incision over each twist, cutting the twist on one side and removing the rest of the wire. Surgeons generally advise that, if the lower fragment is too small, the wire should be passed through the ligamentum patellæ, and this was actually found necessary in one of Lister's cases. It is in any case much better to introduce one wire through the ligament or rectus expansion, for this makes it much easier to correct any angulation without re-drilling. This tissue, moreover, resents a foreign body far less than such a vital structure as bone. (See figure.) A suture passing into the joint was once used, but no joint will stand such an insult.

8. *Elevation of the limb.*—This is a most useful manœuvre at the time of twisting the wire and one which, in a recent case at the Wembley Hospital, obliterated a gap of 1 in. with ease.

9. *Suture of periosteum* over the patella.—Some surgeons, including Sir Robert Jones, rely entirely on suture of the periosteum and lateral expansions, but the omission of wiring precludes early movement.



10. *Suture of the lateral expansions and tear in the capsule.*—This is of the greatest importance.

11. *Suture of the skin.*

12. A firm, bulky *dressing* arrests hæmorrhage and effusion and restrains movement. Some surgeons use a back-splint until the patient is round from the anæsthetic.

13. *Removal of the tourniquet.*

After-treatment.

On the third day a less bulky dressing is applied and massage to the quadriceps is commenced. All dressings are removed between the seventh and tenth days, when the wound should be healed. The patella may with advantage be moved on the femur to prevent adhesions. The patient is allowed to walk with a stick after two or three weeks and should be able to resume his former occupation in three months.

It was observed during the late war that fractures united more quickly in the south of France, where it was warm, than in the north. Recently I have tried radiant heat for fractures; the patients were pleased and one case, where union had been delayed, united rapidly under heat.

Wire v. *absorbable suture.*—This is a very controversial subject. Wire permits early movement, which most surgeons consider advisable, though some, including Sir Robert Jones, keep a fractured patella six weeks on a back splint. Against the advantage of strength is the fact that wire is not well tolerated by some patients and may have to be removed or it may break months after insertion. Kangaroo tendon is good but scarce. Autogenous grafts, first used by Golding Bird, are awkward to use and lengthen the time of operation. Stout catgut possesses little tensile strength after a week.

Old Fractures.

To quote Lord Lister, "the ununited case is in every respect worse as a subject for treatment than the recent one." [8] It is these cases which account for many of the failures of operative treatment. It is imperative to freshen the ends by sawing off a flake of bone, so introducing the all-important element of trauma. In addition to lengthening of the ligaments, there is often marked wasting and contracture of the quadriceps. The contracture may be so marked that the operation has to be performed in two stages, the first aiming at reducing the separation as much as possible with the limb elevated, subsequently allowing it to be lowered for a week or so. The second consists of making apposition. In severe cases the rectus femoris or even the quadriceps may need incisions to lengthen them.[9] Extreme old age, debility, and infective conditions are the only strong contra-indications. Spinal or regional anæsthesia can be used where necessary. The outlook for diabetics has been completely changed since the advent of insulin and a properly controlled diet.

Summary.

1. Starred fractures should be treated on conservative lines, elevating the limb to an angle of 45°.

2. Transverse fractures with separation are best treated by operation.

3. Complications and deaths after operation are due to sepsis caused by (*a*) faulty preparation of the skin, and (*b*) unnecessary trauma. They are predisposed to by devascularisation of the patella.

4. Hey Groves's method of using two transverse wires is the ideal one.

5. Elevation of the limb at the time of securing the twist is most helpful.

6. Old fractures account for most of the poor results.

THE LÆVULOSE TOLERANCE TEST
FOR HEPATIC EFFICIENCY IN PATIENTS WITH EPILEPSY.

BY MINNIE GOSDEN, M.B. LOND.,
ASSISTANT MEDICAL OFFICER, LINGFIELD EPILEPTIC COLONY, SURREY;

AND

J. TYLOR FOX, M.D. CAMB., D.P.M.
MEDICAL SUPERINTENDENT OF THE COLONY.

IN 1916 Thom [1] pointed out that the ratio of brain to liver weight in patients who had had epileptic fits was greater than in normal persons. It is well known that degenerative changes are found in the liver in patients dying in status epilepticus. Lennox and Cobb,[2] in an extensive review of the literature on epilepsy up to 1927, state that although the liver has been thought to be at fault in these patients, they had not found any results of tests for hepatic function published.

In view of these findings the following results of the lævulose tolerance test in 16 patients with epilepsy and in three medical cases with no history of fits are thought to be worth recording.

The technique used has been to take a sample of blood, usually in the morning, with the patient fasting from the previous evening in order to estimate the fasting level of sugar in the blood, then to administer 45 g. of lævulose dissolved in 100 c.cm. of water by mouth, and collect samples of blood at half-hourly intervals for two hours, and estimate the blood-sugar in each of the samples. The method of blood-sugar estimation used has been that of Folin and Wu [3] using 1 c.cm. of blood obtained by venepuncture for each estimation.

The result of administering lævulose by mouth in normal people has been found to be a very slight rise in the amount of sugar in the blood. In cases where the function of the liver is deficient a higher and more prolonged rise occurs. This result has been found by several different workers, who, using different methods of blood-sugar estimation, have obtained very consistent results. In 1913 Schirokauer [4] found that administration of lævulose by mouth caused little or no rise in the blood-sugar level in a normal person, but that a definite rise occurred in cases of hepatic disease. This was confirmed by MacLean and de Wesselow [5] in their work on tolerance to various carbohydrates. They found that lævulose was the only carbohydrate which caused only a slight rise, averaging about 8 mg. per 100 c.cm. in the level of sugar in the blood. Spence and Brett,[6] in 1921, found it a useful test for hepatic efficiency. Working on cases of salvarsan poisoning, they found that the amount of the rise and the delay in return to the fasting blood-sugar level were proportional to the amount of liver damage present. (In normal subjects the fasting level is reached within two hours.) In five normal cases they found a maximum rise of 12 mg. and a minimum of 2 mg. per 100 c.cm. of blood. Covell[7] confirmed these results in cases of hepatic disease of many kinds, and it is interesting to note that in his series of medical cases without known liver disease was one case with a history of epilepsy who gave a result indicating some degree of liver deficiency. Tallerman,[8] Finkelstein and Dannenberg,[9] and King[10] have all found similar results both in normal people and in cases of hepatic disease.

TABLE OF RESULTS.

No.	Age and sex.	Fasting % blood-sugar.	Blood-sugar after 45 g. of lævulose.				Rise in mg. per 100 c.cm.	Result.
			½ hr. after.	1 hr. after.	1½ hrs. after.	2 hrs. after.		
1	13 M.	0·094	0·123	0·148	0·142	0·117	54	Marked rise and delayed return to fasting level.
2	36 M.	0·063	0·106	0·126	0·091	0·063	63	High rise.
3	15 F.	0·095	0·128	0·157	0·123	0·119	62	Very marked rise and delayed return.
4	15 F.	0·084	0·094	0·101	0·097	0·092	17	Normal rise, some delay in return.

From the finding of all these workers it appears that in the normal individual the result of administering a dose of lævulose by mouth is to cause a temporary rise in the blood-sugar level of at most 18 mg. in 100 c.cm. of blood. The average rise is much lower, being about 8 mg., and the fasting level is regained by the end of two hours. In cases of hepatic disease, whether toxic, inflammatory, neoplastic, or degenerative, the rise is considerably higher and more prolonged, so that the fasting level is not regained in two hours.

It has been found that the test is simple and safe, but there are some difficulties in applying it to epileptics, the chief being that it is only possible to administer the lævulose when the patient is sufficiently conscious to drink, so that, although results have been obtained in cases of severe serial epilepsy, it has not been possible to apply it while status epilepticus was in progress. There was a tendency in several of the patients to vomit after fits and in some cases the lævulose was wasted in this way. The epileptic patients investigated were all living an outdoor life at Lingfield Colony at school or work, and clinically had no abnormalities except those associated with their epilepsy.

The results obtained are expressed in tabular form.

CASE 1.—Male, aged 13. During a severe series of major fits. Two occurred during two hours of test, 29 during previous 24 hours. (Series ended three hours after completion of test.) General history: Physically hypotonic. Tremors. Some stigmata. Intelligence nearly normal, but conduct very abnormal, especially when fit-incidence is high. First fit aged 8. Large number of attacks, mostly major in type, occurring very irregularly.

CASE 2.—Male, aged 36. During frequent series myoclonic attacks occurring every 3–4 seconds, commencing two and a half hours before and ending in a major fit half an hour after commencement of test. General history: Family history unknown; mentally dull. Temperament difficult. Physical condition fairly good. Some stigmata of degeneration. First fit date unknown. Liable to major fits at the rate of three a year and to periods of myoclonus about twice a month. The myoclonus is generalised and very severe, and recurs at intervals for a few hours, occasionally culminating in a major fit.

CASE 3.—Female, aged 15. Following eight major fits in preceding 12 hours. Mentally confused during this morning. General history: Physically poorly developed; frail. Low grade, feeble-minded, and very abnormal mentally. First fit aged 12 months. Frequent major attacks often recurring in groups of eight or ten, accompanied by grave mental confusion.

CASE 4.—Female, aged 15. Following period of freedom from fits. Last fit three weeks earlier, next one hour after end of test. General history: Same as Case 3.

CASE 5.—Male, aged 12. Following five major fits during previous 12 hours. One fit during test, next fit one month later. General history: Physically and mentally normal in spite of frequent fits. First fit aged 11 months, ascribed to fall on the head two months previously. Major attacks occur in groups from one to eight about once a month.

CASE 6.—Male, aged 16. Following one major fit three hours previously. General history: Mentally retarded and deteriorating. Physically poor circulation, and some stigmata of degeneration. First fit aged 4, ascribed to encephalitis following measles. Major fits in large numbers, often in series.

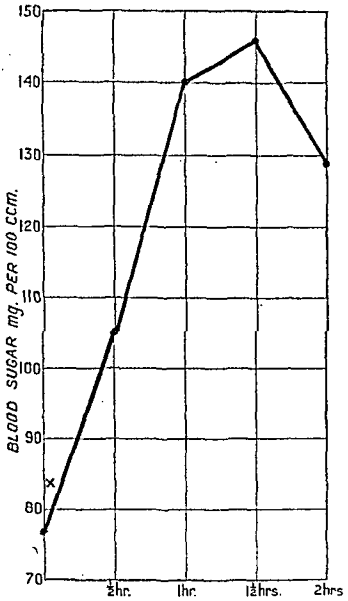
CASE 7.—Male, aged 16. During momentary attacks of slight petit mal, repeated every few seconds. General history: Father had convulsions during teething and mother's mother died of asthma. Mentally and physically normal. First fit, aged 7, ascribed to measles. Major attacks average two a month. Also very large numbers of slight attacks, consisting of jerking head and eyes to right and lasting two to three seconds. (They were diagnosed at one time as a right sterno-mastoid tic.) Luminal partly controls the majors, but neither it nor any other drug influences the minor attacks. Occasionally free from attacks for a day or two, but more often they occur almost continuously for some hours.

CASE 8.—Male, aged 14. During momentary attacks of petit mal, occurring every few seconds, and ending after first hour of test. General history: Family history clear. Physically and mentally normal (many scars due to falling in attacks). First fit aged 7. Very frequent short attacks with loss of consciousness, often falls, rapid return to consciousness. May have a day or two free from attacks; on other days attacks are practically continuous. Bromide and luminal medication useless. ? A case of pyknolepsy.

CASE 9.—Female, aged 14. During long attack of serial epilepsy commencing six weeks earlier. Fits occurring at an average rate of one every 30 minutes by day and night. General condition little affected. General history: Physical condition good. Mentally a little subnormal. First fit aged 12 months. Second attack a few years later. During 1928 isolated major fits every two or three weeks, gradually becoming more frequent until the beginning of December, when they averaged 20 a day and are still (Feb. 1st, 1929) continuing at about the same rate.

CASE 9A.—Female, aged 14. Another morning during this series (Case 9). Patient vomited at intervals during this test, and it is doubtful if much lævulose was absorbed. The estimates were continued for three hours, but fasting level had not been regained. General history: Same as Case 9.

FIG. 1.



CASE 10.—Very marked rise and no return to fasting level. At × 45 g. of lævulose was given by mouth.

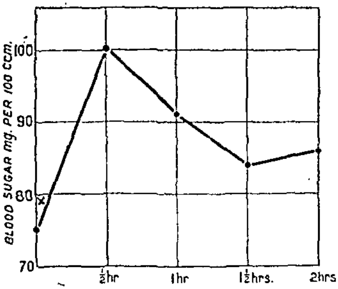
CASE 10.—Male, aged 12. During severe and serious series of fits commencing seven hours previously. Fits occurred every three minutes during test with sufficient return of consciousness to drink lævulose. At commencement of test temperature was 101·4° F., pulse 136, and condition becoming serious. General history: Father's mother insane. High grade, feeble-minded. Difficult temperament. Deteriorating mentally and physically. Poor circulation. First fit aged 4. Since admission to Lingfield two years ago has twice had a clear period lasting four months, and twice had prolonged and very severe series of attacks, one in March–May, 1928, and once in December, 1928. A third such series is likely to prove fatal.

CASE 11.—Male, aged 12. Following two major fits during previous 12 hours, last being five hours previously. No fit during test, none during next month. General history: Brother epileptic imbecile. Mentally feeble-minded and deteriorating. Physical condition fair. First fit aged 9. Liable to series of about a dozen major fits once a month and occasional isolated attacks.

CASE 12.—Male, aged 24. During interval between fits. Last fit 48 hours previously, none for five days later. General history: Physically frail and deteriorating. Mentally feeble-minded and deteriorating. Difficult temperament. First fit aged 4 months. Subject to very frequent major and "automatic" fits, and to occasional attacks of status epilepticus. A very severe case of epilepsy.

CASE 13.—Male, aged 25. Last fit one year previously. Fits have ceased without any drug treatment. General history: Severe head moulding at birth. Some asymmetry of chest. Left-handed. Mentally normal, physically frail. First fit aged 14. Frequent major fits persisted for six years. Recurred a year later in smaller numbers. Last fit recorded September, 1927.

FIG. 2.



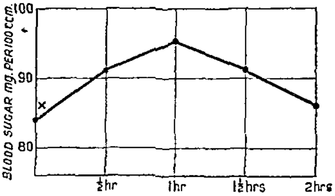
CASE 6.—Slightly abnormal rise and delayed return.

CASE 14.—Male, aged 28. During interval between fits. Last fit three weeks previously. Few myoclonic attacks five days previously. General history: Physically and mentally normal. First fit aged 15, following a fractured skull (large irregular depression of bone in right fronto-parietal region). Now has about one major fit a month.

CASE 15.—Male, aged 31. During interval between fits. One during preceding 12 hours, next two days later. General history: Father committed suicide. Feeble-minded and deteriorating. Physically frail and deteriorating. First fit aged 12. Now major fits at the rate of eight a month. Occasional petit mal.

CASE 16.—Male, aged 42. During interval between fits. Last fit seven days previously. Two slight myoclonic attacks during first half hour of test. General history. Physically frail and deteriorating. Mentally low grade, feeble-minded, and deteriorating. First fit aged 5. Slight myoclonic attacks every morning. A major fit every year or two.

FIG. 3.



CASE 7.—Normal curve.

CASE 17.—Male, aged 20. During interval between fits. General history: Sister died from convulsions. Physically robust. Some stigmata of degeneration. Mentally a little below normal. First fit aged 11. Major fits two or three times a month. Petit mal irregularly

Control Cases.

CASE 18.—Male, aged 26. Case of bronchitis and asthma. No history of epilepsy.

CASE 19.—Male, aged 66. Case of amyotrophic lateral sclerosis. No history of epilepsy. A wasted and ill man.

CASE 20.—Female, aged 20. Abdominal pain, with nil found wrong. Probably a normal person.

In considering these results it will be seen that the cases fall into three groups.

1. Cases with a response typical of severe liver derangement (Nos. 1, 2, 3, and 10)—viz., a very marked rise in blood-sugar and a delayed return to the fasting level, of which an example is given in Fig. 1. These were all patients with severe epilepsy on whom the test was performed during or immediately after numerous fits.

2. Cases with a rise higher than the usual maximum normal (*i.e.*, 18 mg.), but not such a marked rise as group 1, indicating a slight degree of liver deficiency of which an example is given in Fig. 2. Of these cases one (No. 5) was a boy who had a single major fit during the test, and who has little ill-effects from his fits. Another (No. 9) was a girl having repeated fits whose condition remained good in spite of the number of fits occurring. The other result from this patient (No. 9A) was obtained when she was more affected by the fits, and shows a slow gradual rise in level. Vomiting on this morning probably prevented the absorption of much lævulose. The other patients in this group were investigated when they were having intervals free from fits. They were all cases of long-standing epilepsy with some degree of resulting deterioration.

3. Cases giving normal results (Nos. 7, 8, 13, 14, and 16), of which an example is given in Fig. 3. These include two cases of petit mal (Nos. 7 and 8), one man who had been free from any fit for more than a year, one case of traumatic epilepsy, and one old-standing and deteriorating epileptic. Of the three non-epileptic patients (Nos. 18, 19, and 20) two gave normal results and one a result indicating some liver deficiency the cause for which is obscure.

These results appear to indicate that there is a definite liver deficiency in epilepsy, which during severe fits is very marked, and which in old-standing cases persists in a slighter degree in the interval between fits. This agrees with post-mortem findings in cases of epilepsy.

It is realised that this investigation is far from complete and that it needs controlling by other tests for hepatic functions in epilepsy and by more control tests on non-epileptic patients, but in view of the fact that the test for lævulose tolerance has given very constant results with many workers, and as one of the authors has gone abroad and cannot continue the investigation, it has been thought worth recording these findings as showing a defect in liver function in epilepsy which needs further study.

These results form part of an investigation on epilepsy at Lingfield Epileptic Colony, the expenses of which have been met by a grant from research funds of the London Hospital, and the writers wish to express their thanks to the Trustees of the Epilepsy Research Fund and to Dr. Russell Brain and Mr. H. D. Kay, Ph.D., for their help and suggestions, and to Dr. Brain for permission to investigate the three non-epileptic patients at the London Hospital.

Clinical and Laboratory Notes.

"IDIOPATHIC" HYPERTROPHY OF THE HEART IN A YOUNG MAN.

BY C. H. WHITTLE, M.D. CAMB., M.R.C.P. LOND.,
CLINICAL PATHOLOGIST TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

THE number of cases of sudden death to which no cause can be assigned must be greater than is generally suspected. How incomplete is our knowledge of pathology the following account bears witness:—

A student, aged 20, apparently in good health, was seen in the act of falling off his bicycle when cycling home from a lecture, and was picked up in a dazed condition, breathless and blue. He died before he could be got to hospital, five minutes' journey away.

Post-mortem Examination.

He was broad-shouldered, normally developed for his years, with dark hair, pale complexion, and height about 5 ft. 9 in. Hypostatic lividity was marked. The external genitalia were normal.

The thorax contained an enormous heart, weighing 28 oz. The organ was excessively hypertrophied, especially the left ventricle, and the right ventricle was greatly dilated and distended with dark blood. The great veins were similarly engorged. The tricuspid valve ring admitted four fingers easily, and the mitral three. The aortic ring was dilated, but apart from the dilatation the cusps of all four valves appeared normal. Nothing abnormal was found in the coronary arteries or their openings, and the heart muscle though pale was firm. The endocardium was normal.

The aorta was of rather small calibre and the wall thinner and more delicate than usual. At the commencement of the descending part it measured 16 mm. diameter; at the diaphragm 13 mm.; at the bifurcation 8 mm. (The normal measurements at the first two planes are given in Cunningham's *text-book of anatomy* as 23 mm. and 21 mm. respectively.) There were flecks of what appeared to be early atheroma near its origin. There was no congenital abnormality of the cardiac septa or the great vessels.

The trachea and upper part of the bronchi were acutely inflamed, with muco-pus on the mucosa. The tracheal and bronchial lymphatic glands were enlarged and dark purple in colour. The lungs were deeply congested and weighed 16 oz. and 14 oz., right and left respectively.

The thymus was readily found. It weighed 30 grammes. The abdomen and abdominal viscera appeared normal except for venous congestion. The liver weighed 67 oz., the spleen 7½ oz., the right kidney 5 oz., the left kidney 5 oz. The renal capsules were stripped easily and a clean, smooth surface was left. There was no gross abnormality in the suprarenal capsules.

The cranial cavity and brain were normal in appearance; and all visible arteries were good.

The cause of the cardiac dilatation and failure therefore remained obscure, nor was there any reason apparent for the enormous size of the heart.

Morbid Histology.

Microscopic sections of the heart muscle (left ventricle), however, showed considerable swelling and loss of regular striation of the fibres, indicating cloudy swelling. There was no sign of fatty degeneration or infiltration, nor were there any foci of necrosis or inflammation found. The aorta showed small areas of fatty deposits along Henle's membrane, both in the media and in the intima. There was also occasional slight thickening of the intima. Apart from these the wall, though a little thinner than usual, appeared healthy.

The thymus presented a well-nourished cortex and medulla, without sign of atrophy. Hassall's corpuscles were prominent and were calcareous. The liver was a little congested and its sublobular veins distended. There was some finely divided fat in the cells at the centre of the lobule and the Kupfer cells were frequently filled with fat in coarse droplets. Otherwise the liver was normal in appearance. The kidney showed some venous congestion, but was otherwise normal in all respects. There was no sign of vascular changes. The arteries of all sizes in the various viscera appeared perfectly healthy.

Discussion.

The history of the patient revealed little. He had been healthy and normal all his life as far as could be ascertained, and there was no evidence of any illness or indisposition preceding death. He had done much cycling over fairly long distances but no racing.

Apart from the enormous heart, the small, delicate aorta, and the large thymus, the only noteworthy feature of the case was the acute tracheitis, of which unfortunately no cultures were taken. I am indebted to Dr. J. F. Gaskell for the suggestion that tracheitis is most commonly due to influenzal or post-influenzal infection (also see Horder [1]), and that an attack of influenza occurring a few days before death might have been responsible both for the inflammation in the trachea and for the cloudy swelling of the myocardium. There is some evidence that influenza exerts a toxic action on the heart muscle (Horder [2]), and such an explanation would account for the sudden cardiac dilatation. A slight attack might easily be disregarded by a young man, and in the absence of severe muscular exertion it affords the most likely clue to the immediate cause of death.

Some hesitation is felt in stressing the size of the thymus because of the recent tendency to recognise greater variations than heretofore in the normal limits in size of this organ—e.g., Greenwood and Woods.[3] Nevertheless the finding of a thymus weighing 30 g. in a man of 20 years is, I believe, comparatively uncommon.

The great size of the heart remains entirely without explanation. There was no evidence of renal and very little evidence of arterial disease. Several cases of "idiopathic" hypertrophy of the heart have been recorded—e.g., by Howland [4] in 1919—but no light is shed thereby on the pathology of the condition. Unexplained cases of congenital hypoplasia of the aorta have also been noted by Abbott[5] and others. The case under review was carefully searched for any evidence of the changes in small arterioles described by Jores and Prym,[6] Aschoff, Gaskell,[7] and others, but such changes were conspicuous by their absence. The literature affords no indication of the true nature of the condition.

I think, however, that this case is instructive in so far as it bears witness to the fact, recognised by Allbutt,[8] that great enlargement of the heart, possibly accompanied by high blood pressure, may be attained in the entire absence of renal disease, either vascular or parenchymatous. I suggest that the prolonged muscular exertion of cycling may have been an important factor in the case in inducing the remarkable cardiac hypertrophy described.[9]

I wish to thank Dr. J. F. Gaskell for help in the histology of the case.

THE TREATMENT OF BLACKWATER FEVER BY ORAL SODIUM BICARBONATE.

By CLEMENT C. CHESTERMAN, O.B.E., M.D., M.R.C.P. LOND.,

HOSPITAL OF THE BAPTIST MISSIONARY SOCIETY, YAKUSU, HAUT CONGO BELGE.

IN view of the successful treatment of blackwater fever by intravenous sodium bicarbonate recently reported,[1] the following case is of interest in that the patient's second attack of blackwater fever, and a relapse following it, both yielded within 24 hours to large oral doses of sodium bicarbonate, whereas his first attack 13 months previously, treated by other methods, was of a very serious and prolonged nature.

The patient, a man aged 23, was employed on a rubber and coffee plantation. In June, 1927, he arrived in the Congo. He was very irregular in taking quinine and had occasional malarial fever. In February, 1928, he had his first attack of blackwater fever, being admitted to hospital on the second day with oliguria and exhaustion. Hæmoglobinuria continued for a week, and the treatment was by intravenous glucose, rectal salines, cupping to loins, hot baths, &c.

The present attack began on March 17th, 1929, when he was feverish and bilious and took two doses of 0·5 g. quinine hydrochloride in capsules. On the following day, in spite of fever, he went to work at dawn until he noticed that his urine was dark red. He was transported on an improvised stretcher to the river side and reached hospital in a steamer five hours later. On admission his temperature was 39·7° C. and his pulse-rate 98. He twice vomited brownish bile-stained gastric juice and had one dark liquid motion. The spleen was just palpable.

Treatment was confined to the administration of as much natural lemonade, Vichy water, and tea without milk, as could be taken, 1 to 3 g. of sodium bicarbonate and as much powdered glucose being added to most of the feeds. The course of the illness was as follows:—

1st day: 11 A.M. to 6 P.M. Sod. bic. 10 g., glucose 10 g. in 1000 c.cm. fluids. Urine: 320 c.cm., acid, very dark red with thick brown deposit. Hæmoglobin + + +. Night: Sod. bic. 5 g. in 750 c.cm. fluids. Urine: 700 c.cm., acid, not so dark. Hb + +.

2nd day: 6 A.M. to noon. Sod. bic. 6 g., glucose 10 g. in 750 c.cm. fluids. Urine: 510 c.cm., alkaline, brown colour. Hb + +. Noon to 6 P.M. Sod. bic. 6 g. in 750 c.cm. fluids. Urine: 250 c.cm., alkaline, light brown. Hb trace.

3rd day: Copious clear yellow urine, no albumin. No drugs.

4th day: Two 0·07 g. doses quinine, sod. bic. 10 g. Urine alkaline.

5th day: Two 0·15 g. doses quinine, sod. bic. 10 g. Urine alkaline.

6th day: Four 0·15 g. doses quinine, no sod. bic. Urine alkaline and Tanret's reaction for quinine positive.

7th day: Four 0·30 g. doses quinine. Temp. 38·8° C. No parasites detected in blood.

8th day: Four 0·30 g. doses quinine. Urine acid.

9th day: Four 0·30 g. doses quinine. Temp. normal.

10th day: Two 0·60 g. doses quinine. Felt cold and shivered. Night: Relapse of hæmoglobinuria with 250 c.cm. dark red acid urine. Hb + + +.

11th day: 6 A.M. to noon. Sod. bic. 6 g. Urine: 770 c.cm., slightly lighter. Hb + +. Noon: Rigor. Noon to 6 P.M.: Sod. bic. 8 g. Urine: 800 c.cm., alkaline light red colour, soapy froth, effervescing with acids. Night: Urine, 1200 c.cm., alkaline light red colour.

12th day: 6 A.M. to noon. Sod. bic. 6 g. Urine: 500 c.cm., very light red and strongly alkaline. Hb trace. Noon to 6 P.M.: Sod. bic. 3 g. Urine: 950 c.cm., normal colour. No Hb.

13th and 14th days: Sod. bic. 10 g. Urine copious and normal.

15th to 22nd days: Quinine gradually increased from 0·1 g. to 0·2 given in capsules after meals. Sod bic. in 1·0 g. capsules before meals. The urine remained alkaline, but tinnitus and the reaction of Tanret in urine proved quinine absorption.

The following points are of interest in this case:—(1) Both in the initial attack and the relapse the disappearance of hæmoglobin from the urine, which was formerly acid, followed a few hours after it showed an alkaline reaction. (2) This was effected solely by the oral administration of sodium bicarbonate (and the citrates of lemonade) in doses up to 21 g. in 24 hours. Bilious vomiting which caused rejection of the first few doses was controlled by frequent sips of this alkaline fluid. (3) The relapse on the tenth day followed a couple of 0·6 g. (10 grains) doses of quinine when the urine was acid, whereas 1·2 g. (20 grains) was taken with impunity ten days later when the urine was kept alkaline. (4) Sodium bicarbonate in large doses is easily detected in the urine by the effervescence of CO_2 caused by the addition of an acid. The hæmoglobin in such urine gives a very slight cloudy precipitate on boiling, whether previously acidified with acetic acid or not, possibly on account of the formation of alkaline ageusia over the area supplied by the chorda tympani nerve. And the loss of taste perception seemed to be permanent. A considerable number of cases of middle-ear suppuration showed a lesion of the chorda tympani; also that nerve was most frequently damaged in cases in which the middle-ear disease was of long standing and affected the attic, and was attended by cholesteatoma. In many advanced cases of middle-ear disease the integrity of the chorda tympani was fully preserved. Thus no useful deduction as to the extent of the disease in a particular case could be drawn from the integrity or from the destruction of the chorda tympani nerve. Mr. Vlasto gave the results of the testing of nine male patients in a hospital ward.

---

[1] Cooke, W. E., and Willoughby, H.: THE LANCET, Feb. 16th, p. 334. Hanschell, H. M.: Trans. Roy. Soc. Trop. Med. and Hyg., 1926, xix., 488.

Dr. JOBSON said otologists frequently learned of distortions of taste after the radical mastoid operation had been done. Several times his patients had complained of a foul taste after such operation; some said they had a metallic taste.

Mr. G. J. JENKINS said that occasionally patients with chronic suppuration complained of a burning sensation on the anterior part of the tongue, on one side. Tumours in the neighbourhood of the ear also sometimes caused aberration of taste in the tongue, a taste as of ink, or a burning sensation.

Dr. C. S. HALLPIKE read a detailed paper on the subject of

Bone Conduction.

He submitted that increased bone conduction, as exemplified by the Schwabach test, in cases of affections of the conducting mechanism of the ear, was one of the basic facts in otology. The theories of Bezold and others, which attributed the phenomenon to changes in rigidity of the ossicular chain, Dr. Hallpike regarded as unsatisfactory. He himself believed that the increase in the bone conduction was due to a screening effect upon cochlear function of the damaged middle-ear mechanism. Two lines of investigation suggested themselves. First, there was a disappearance of the increase under conditions of equal screening for the observer's cochlea. These conditions were supplied by the absolute bone conduction test. The truth of findings with this test was now definitely established. The second line of investigation was the disappearance of the increase in conditions of absolute silence, where screening effects would be inoperative.

Examination of cases of conducting deafness in absolute silence showed a tendency for the increased bone conduction found under ordinary conditions to be reduced to normal limits. In many cases of chronic deafness, cochlear loss was present, but it was latent because of the concomitant screening effect of the middle-ear damage, which tended, under ordinary circumstances, to lengthen the Schwabach response. This cochlear loss, from the point of view of prognosis and treatment, was a sign of the first importance. As shown under ordinary conditions it was latent. The absolute bone-conduction test, the logical outcome of the theory put forward, rendered it manifest. The main part of Dr. Hallpike's contribution was concerned with the consideration of sensory fields in general, and of screening effects in those fields. Dr. Hallpike described a new apparatus to show screening effects in the retina.

The PRESIDENT remarked on the fact that the Section had appointed a Committee to consider ear tests.—The paper was discussed by Mr. WATKYN-THOMAS, Mr. JENKINS, and Dr. YATES.

Mr. ALEX. R. TWEEDIE gave a demonstration of an

Apparatus for Control of Conversation Test.

By this means a person speaking into a magneto microphone would be able to note the exact point at which a person ceased to hear. It was so designed that the person being tested could, if required, repeat words spoken by the observer who was conducting the test. The receiver was quite inactive unless both switches were closed. Tests were made of the apparatus by various members.

Reviews and Notices of Books.

THE MODERN TREATMENT OF HÆMORRHOIDS.

Second edition. By JOSEPH FRANKLIN MONTAGUE, M.D., F.A.C.S., of the Rectal Clinic, University and Bellevue Hospital Medical College. London: J. B. Lippincott Company. Pp. 298. 21*s.*

IT is evident that the author's views on the treatment of hæmorrhoids have undergone no marked change since the publication of the book three years ago. Pronounced internal hæmorrhoids mostly demand operation. He uses the method of transfixion and ligature with catgut for clean cases, and the clamp and cautery for ulcerated, thrombosed, and gangrenous piles. The Whitehead operation is condemned. Dr. Montague shows a preference for local anæsthesia, and speaks strongly against the current practice of preparing cases for operation by purgation and enemata; a much less drastic preparation is suggested which he thinks leads to lessened post-operative discomfort and quicker recuperation. This plan is certainly worthy of trial.

As regards the injection treatment, the author still prefers a 20 per cent. solution of cresylic acid in glycerine and water, and places 5 per cent. quinine-urea and 10 per cent. carbolic acid in olive oil next in order of merit. He makes no particular reference to the method, advocated strongly by Albright and by Blanchard, in which high submucous injections of 5 per cent. phenol in vegetable oil are given; this solution is considered by many to be more effective and free from risk than the stronger solutions. Dr. Montague's recommendations as to dosage are very vague, amounting only to the advice that the injections should be stopped as soon as the slightest blanching of mucous membrane is seen. He practises injection into the centre of the pile mass; this is a point in technique on which there is considerable difference in opinion, but we cannot recommend anyone to follow closely the technique illustrated in Figs. 97, 99, 101, in which the needle is shown inserted into the lowest border of the pile, at the upper end of the anal canal. This is the one place, being so close to the sensitive epithelium of the anal canal, where the injection should not be made. The mucous membrane should be punctured at least an inch or more above the point shown. In Chapter 15 the results of treatment of hæmorrhoids by radium are given. The method of implanting and leaving in situ glass radon seeds proved unsatisfactory on account of the irritation caused by the presence of the foreign bodies, and Dr. Montague now advocates removable platinum-screened seeds (4 millicuries). Cessation of hæmorrhage and fibrosis are said to unfailingly follow their use, but whether this or the various electrical methods described in the following chapter will ever be found as practical as the injection method seems to us doubtful. The use of a suction-pump, here illustrated and recommended for the diagnosis of hæmorrhoids, is regarded as obsolete by most authorities. Practitioners would probably appreciate the elaboration of the chapter on the injection methods, and the supply of detailed descriptions of technique and dosage, together with some facts about recurrence-rates.

DISEASES AND DEFORMITIES OF THE SPINE AND THORAX.

By ARTHUR STEINDLER, M.D., F.A.C.S., Professor and Head of the Department of Orthopædic Surgery of Iowa State University Medical School, Iowa City. London: Henry Kimpton. 1929. Pp. 573. 52*s.* 6*d.*

THIS is an authoritative and well-balanced treatise on the subject of diseases and deformities of the spine and thorax. The opening chapter on congenital deformities of spine and thorax contains well-arranged information, and is illustrated by plates showing both the deformity in the patient and the X ray picture. This is followed by a chapter on the static antero-posterior deformities of the spine and then by one on scoliosis, which is perhaps the best in the book. The mechanics, dynamics, pathology, diagnosis, and prophylaxis of scoliosis are discussed fully and clearly, and finally the difficulties of treating this deformity are considered in detail. The advantages and disadvantages of various methods are set out impartially, and the reader is left in no doubt as to the method suitable in any particular type of case. This chapter also is well illustrated. The fourth chapter deals with fracture and dislocation deformities, and the fifth with low back pain. The author's experience and knowledge enables him to bring together the widely separated conditions associated with this symptom into an orderly classification. Tuberculosis, osteomyelitis, syphilis, chronic arthritis, and tumours of the spine make up the reminder of the book, and each subject receives the critical treatment which enables the reader to come to his own decisions and conclusions. A full bibliography is given at the end of each chapter and a valuable synopsis of the anatomy of the spine is contained in an appendix. Prof. Steindler has added to the literature of orthopædic surgery a book worthy of his reputation, and the work is well produced.

ARTIFICIAL SUNLIGHT AND ITS THERAPEUTIC USES.

Fifth edition. By FRANCIS HOWARD HUMPHRIS, M.D., F.R.C.P. London: Humphrey Milford, Oxford University Press. 1929. Pp. 346. 10*s.* 6*d.*

Dr. Humphris's handbook, now in its fifth edition, has for some years been a popular introduction to the study of actinotherapy. It is clearly written, well illustrated, and contains a useful survey of apparatus, technique, and indications for clinical guidance. An elementary exposition of actinotherapy necessitates a dogmatic presentation, and this unfortunately may easily convey the impression—to the reader not familiar with the subject—that the statements are all based on well-ascertained facts. Unfortunately, hypothesis still plays a prominent part in any attempt to explain the action of light on the living organism, and only some of the end-reactions are known to us. The indirect action of ultra-violet light, for instance, on the ductless glands, now freely quoted in text-books, still rests on scanty experimental evidence and on clinical findings which are often contradictory. It is interesting to note that Dr. Humphris mentions glycosuria as one of the main contra-indications to light treatment, whereas Pincussen and Rothman claim to have obtained clinical improvement, diminished sugar excretion, and lowered blood-sugar by light treatment in diabetes.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORY.

Edited by DAVID THOMSON, O.B.E., M.B., Ch.B. Edin., D.P.H. Camb., Hon. Director, Pickett-Thomson Research Laboratory, St. Paul's Hospital, London; and ROBERT THOMSON, M.B., Ch.B. Edin., Pathologist to the Laboratory. Vol. IV., Parts I. and II. London: Baillière, Tindall and Cox. 1929. Pp. 494. 42*s.* each volume.

THE first of the two parts which together form Vol. IV. of the publications of this laboratory, and which appeared in November, 1928, is reviewed here together with the second, which has just appeared. The subjects dealt with are the rôle of the streptococci in rheumatic fever, chorea, erythema nodosum, carditis (including endocarditis), acute and subacute arthritis, chronic arthritis, and a consideration of Rosenow's theory of elective localisation. Like their predecessors, these volumes consist almost entirely of elaborate excerpts from the already published work of others. From this point of view the publications have value, since the quotations given are very widely drawn and conveniently grouped. Their collection reflects the energy of the editors, who have provided a valuable series of references and abstracts, being mostly the ipsissima verba of the workers, and being free from that unconscious editorial distortion which may greatly detract from the value of reviews.

The authors, partly in collaboration with Dr. Warren Crowe, have now for some time been occupied in the collection and classification of a very large number of species of streptococci, and have evolved a classification depending upon a large number of properties, in particular the naked-eye appearance of colonies and the morphology of the organisms in films. They have expended an immense amount of time and energy in this work, and have provided some beautiful illustrations produced with excellent photographic technique. As regards the larger question of the meaning and value of their classification, it is the opinion of many bacteriologists that their energies are largely misapplied. The methods may be criticised from two angles. First, as to their accuracy, morphology, except in its broadest aspects, is notoriously an unsafe guide in bacteriological classification. The most potent diphtheria bacillus may appear to be a coccus; the morphology of the Pfeiffer group is extraordinarily variable; and amongst the streptococci the lack of fixity of morphological characters is extremely well marked. Small variations in the composition of media, in pH, in moisture of solid media, will cause corresponding variations in morphology, often, it is true, not of a gross type but sufficient to be significant where the finer shades of morphological difference are being relied upon. In the second place, it is pertinent to ask what is the result of this system of classification? The authors divide the organisms into five main primary groups, upon their morphological appearance upon a boiled blood medium. Each of these groups is subsequently split into subgroups, depending on lesser variations of the same nature and the microscopic characters of the organisms. As a result the number of subgroups already reaches 21, and the authors hold out the prospect of more to come. Within these 21 subgroups species are recognised as a result of fermentative reactions with ten sugars. In the end, and with sufficient perseverance, the possible result will be the recognition of many thousands of different types, each of which the authors apparently hope to perpetuate by indexing and by recording the photographic characters of each strain in seven different photographs. Their apparent aim is to produce a permanent record of as large a number of characters as it is possible to examine for each and every strain of streptococcus passing through their hands and, in the end, to achieve something akin to a Bertillon system of identification.

In assessing their work from this view-point we find that the primary classification by means of colour differences upon boiled blood media is defective, in that these functions are not correlated with hæmolysin production, nor with heat resistance, two properties which in the present position of our knowledge do seem to introduce real lines of division that have some practical meaning. Now, what is the real meaning of the differences which the authors adduce? That they are there, and may be of interest, does not of itself warrant their being used for classification. The streptococci are an almost infinitely variable group of organisms, and in a practical world we want to see the woods and not be confused by an infinity of trees. Classification, as a fine academic art, may be blamelessly pursued, but in medical bacteriology it is barren unless it has a practical meaning. The over-elaborate system devised by Dr. David and Dr. Robert Thomson, even if the factors used in it are not open to serious experimental variations, which there are reasons to doubt, tends to lead rather to confusion than to clarification of the subject. The pebbles on a sea-shore may be classified in many ways. They may be roughly designated *large*, *medium*, and *small*, and such a distinction may be of real value to the road-maker, ballast-seeker, or gardener. But if we take equal cognisance of a wealth of other properties, such as accurate weight, shape, colour, roughness or smoothness, specific gravity, chemical composition, and so on, we get a classification which will be highly elaborate and may be even scientific, but will be of little use in a work-a-day world where life is short. What we require in a sound classification of bacteria is a few main features which give indications of real use—and this the scheme outlined in these monographs fails to give.

The volumes contain also a short original paper by Dr. Warren Crowe upon the experimental production of foci of infection in rabbits, and its bearing upon osteo-arthritis. His experimental evidence goes to show that a focus of chronic infection may produce a lowering of resistance to bacterial invasion, not only locally but at a distance, and may favour the settling of organisms in sites which may otherwise escape. He also claims that certain streptococci have an innate tendency to localise in the articular ends of bone, and may be found there when absent from the heart's blood or from the shaft marrow. Under conditions of lowered resistance, due to artificial chronic infection, this "osteotropic" faculty may be relatively enhanced. Whilst generally adverse to E. C. Rosenow's elective localisation views, Dr. Crowe appears to admit such a mechanism in his own experiments. It is not clear if due regard has been paid in this work to the relative chances of foreign particles in the blood stream being localised in the more cancellous marrow of the ends or in the less complex marrow of the shaft. This might be an essential factor in the results obtained.

A SURGICAL DIAGNOSIS.

By J. LEWI DONHAUSER, A.B., M.D., F.A.C.S., Clinical Professor of Surgery, Albany Medical College (Union University). London and New York: D. Appleton and Co. 1929. Pp. 799. 42s.

THIS book is based on the author's 20 years' experience in surgical teaching, and contains information invaluable to the student working for an examination or to the practitioner confronted by a difficult surgical problem. After introductory chapters on the taking of a careful history, the examination of the patient, and the interpretation of laboratory data, chapters are devoted to the infections and to tumours. This chapter on tumours might well be expanded in future editions, and some illustrations should be added. The remainder of the work is on a regional plan, the lesions of the region under consideration being considered in turn with their ætiology, signs, and symptoms; included in each chapter are charts showing the differential diagnosis of the main regional diseases, which summarise the chief symptoms in a way that is readily grasped. A number of more detailed charts deal with the differential diagnosis of either diseases, symptoms, or signs. When seeking information on a number of the less common problems of surgical diagnosis we were not disappointed. Dr. Donhauser may well be pleased with the results of what must have been prodigious labour. He has produced a book of sound surgical teaching and attacks the problems of diagnosis in a way that is both original and satisfactory.

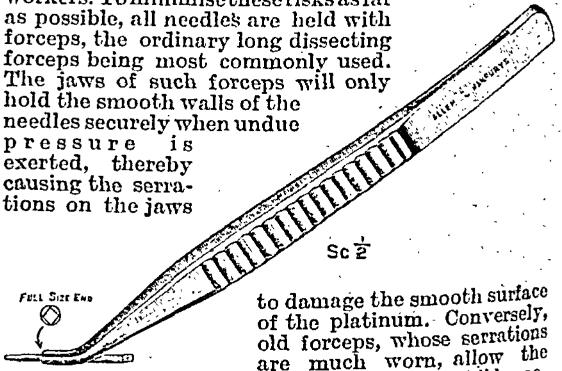
JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXVI. April–June.—Mr. J. D. R. Murray contributes a paper on eight cases of Acute Intussusception in Infants. An account of these cases was given in THE LANCET of April 20th (p. 826).—Writing on Rheumatic Fever and Tonsillitis, Dr. J. Tertius Clarke maintains that the geographical distribution of *Ceratophyllus fasciatus*, the common rat-flea of northern temperate climates, and of rheumatic fever is so similar as to make it seem possible that the insect is in some way connected with the ætiology of the disease. He finds coincidence not only of geographical and local distribution but also of temperature and humidity.—Dr. F. Parkes Weber contributes a note on Herpes Zoster and its Connexion with Arsenic and with Varicella, in which he describes cases of herpes occurring during arsenical treatment, being followed in the course of the next fortnight by varicella in other individuals with whom they had been in contact. He comes to the conclusion that arsenical herpes zoster should be regarded as ordinary herpes zoster, an unknown causative virus of herpes zoster possibly already present in the body becoming activated by the arsenic.—Dr. Angélique Panayotatou, of Alexandria, records a case in a boy, aged 2½ years, suffering from a severe attack of kala-azar who was cured by rectal injections of tartar emetic.—Mr. Macleod Yearsley contributes a paper on Intestinal Toxæmic Deafness in Children in which he maintains that there are catarrhal conditions of the upper air passages with or without middle-ear complications which refuse to clear up until the primary intestinal toxæmia has been properly treated. He records three illustrative cases in boys, aged 7, 8, and 8½ years, in whom deafness due to affection of the internal ear was much improved by treatment of chronic intestinal intoxication.—Dr. J. H. Twiston Davies and Dr. R. L. Flett report an Unusual Complication in a Vascular Nævus. The patient was a male infant, aged 3 months, who developed streptococcal infection of a large nævus on the left shoulder followed by abscesses in the right groin and hand. Death was preceded by jaundice and pneumonia. In addition to pneumonia the necropsy showed pus in the left pleural cavity, recent vegetations on the mitral and tricuspid valves, purulent perisplenitis, and perihepatitis.—The abstracts from current literature are devoted to diseases of the newborn.

New Inventions.

RADIUM FORCEPS.

THE constant handling of radium needles, particularly in the "making-up" room where they are threaded or placed on the surface of Columbia paste collars, is associated with definite dangers to the workers. To minimise these risks as far as possible, all needles are held with forceps, the ordinary long dissecting forceps being most commonly used. The jaws of such forceps will only hold the smooth walls of the needles securely when undue pressure is exerted, thereby causing the serrations on the jaws to damage the smooth surface of the platinum. Conversely, old forceps, whose serrations are much worn, allow the needles to "shoot out" immediately any pressure is applied to them, with the result that the needles may be difficult to recover, or even lost altogether. I have had made, therefore, the forceps here illustrated. They are shaped like the well-known Childe's dissecting forceps, but having angular-cut jaws they readily adjust themselves to, and firmly hold, without undue pressure, any needle from 1·75 mm. diameter to 2·2 mm. diameter.



Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W., are the makers.

THE LANCET.

VDON: SATURDAY, JUNE 29, 1929.

IMISM IN THE INDIAN MEDICAL SERVICE.

Indian Medical Service still offers a good vith interesting work, fair pay, and a fair at the end. This was the message of Colonel RD'S address to his brother officers at the linner of the Service held last week in London. likely, he said, that the Service will ever again a British Foreign Office with an Ambassador it will again provide a Governor for Bengal; hardly hope to reach the success attained by en as Sir JOHN MCNEILL and Sir JOSEPH ; but, he added, if I had to live my life over, live that life again in the service of medicine a. Colonel CRAWFORD was followed by Sir D ROGERS, who is now Medical Adviser to etary of State and who alluded to the I.M.S. greatest imperial medical service the world seen. It may be gathered that the occasion much more cheerful nature than some of the gs held since the war put the fortunes of all ian services in the melting-pot. Far-reaching have been in the air and some of them were affect the prospects of new entrants adversely. ort of the Lee Commission in 1924, however, the air, and in that year we felt justified in out the favourable significance of some of proposals, and the attractions which the still offered to newly qualified men. Subsequent ments have strengthened this impression, on seal has been set by certain additional ons now to be granted, of which an official ement is imminent. Four years ago it was that while many improvements in pay and onditions of service had been effected, there cause for misgiving. The reduction of civil gether with a difficulty in obtaining suitable and the consequent inability of the military ent to release its medical officers, often the prolonged retention in the Indian army who wished for civil work, and there was a insecurity regarding the civil administrative hich it had been proposed to throw open to tside the Service. It was also felt that nents might occur during the next few years ould affect the position adversely in various d that some guarantee of permanent employ, atively, a system of gratuities in the event of re retirement, was desirable. We understand a result of discussions which have been ng for some time these requirements have en met, and that in other ways also the ns of service have been much improved. The already been very considerably increased, reduction of civil posts was largely compen- y the fact that those relinquished were y the smaller and less desirable stations. concessions with regard to free passages are y important. Then, owing to the necessity viding for European troops and civilian ions, it has been decided to retain two-thirds total existing posts, military and civil, for ans. It has now been ruled that so long as there remains in the Service a single I.M.S. officer who was in civil employment when the scheme was published last year (that is, for more than 20 years to come) administrative posts will be filled by I.M.S. officers appointed directly by the Government of India. Furthermore, from the beginning of the present year the military department in India will be content with 22 British medical officers, instead of the 72 who have recently been required, a concession which has been rendered possible by the improvement which has taken place of recent years in recruitment. Particularly heartening is the high standard of candidates coming forward, which is shown in the excellent results obtained in the examinations at Millbank.

There is, in short, every sign of a revival in the fortunes of this ancient and distinguished Service, and not the least encouraging symptom is the tendency of officers appointed under the new rules to engage for permanent employ rather than avail themselves of the facilities now provided for early retirement with gratuities. A reference to the revised regulations for the recruitment of European officers and the improved rates of pay (as set out in our advertisement columns) will, we think, taken with all these considerations, show that the Indian Medical Service still merits the attention of that considerable section of the graduates of our great medical schools which does not feel drawn to the ordinary round of general practice at home, and may be attracted by the wider opportunities of work in India. There is no reason why some of the best men of the schools should not find the prospects as attractive as heretofore. A survey of the Indian Army list shows four names in the medical service to which the letters F.R.S. are appended, and countless higher professional qualifications bear witness to the reputation of the Service in the past. There are, of course, certain conditions of climate and family life which have to be faced before taking up residence in a country six thousand miles away and largely within the tropics, but even these have been much improved by modern transport facilities, and for anyone who is disposed to adventure India has much to offer. To those who are prepared to accept the general spirit of the reforms, work in association with Indians, on an equal footing, may be made very pleasant. It is a mistake to assume that the attitude of an Indian who happens to be placed in a high official position is necessarily hostile to Europeans serving under him, and experience has shown that efficient Englishmen of the right stamp, particularly in the more technical departments, are increasingly appreciated as their numbers diminish. We have consistently advocated the reforms which have conduced so largely to this improved position, and we welcome the dissipation of the cloud which has hung too long over medical service in India.

ANTIBODIES IN RELATION TO IMMUNITY.

VERY early in the study of bacteriology, almost as soon as it was recognised that micro-organisms could cause disease, attention was directed to the reactions resulting in the body, and elaborate theories of immunity were formulated. Such hypotheses were no doubt of value as a basis for future work, for without some conception of the nature of a problem progress is impossible. But as time went on it became more and more apparent that these hypotheses did not explain the phenomena of infection and immunity. Theory, in fact, had outgrown observation, and the recognition that this was so was followed by a tendency to belittle the practical value of immunological observations. Recent work has done much to clear away the ambiguities of the past. More careful and detailed experiments have reconciled apparently conflicting views and have established beyond reasonable doubt many of the factors which govern the antigen-antibody reactions. Nevertheless the whole subject of the natural acquirement of immunity seems to have passed beyond the comprehension of the average medical man; and even the laboratory worker, unless he is actually engaged in the study of immunology, is scarcely in a better position than the clinician to appraise the trend and value of current work, for the subject has become as complicated as it is important. A communication by Prof. W. W. C. Topley, which appears elsewhere in this issue, suggests that the complications are more apparent than real and are often enough legacies from the past. As he very clearly shows, if we confine ourselves to authentic observations and the inferences which may reasonably be drawn from them, we possess a conception of immunity which takes us a long way and is full of promise for the future.

The problems are, of course, too vast to be discussed otherwise than superficially in a single address, but Prof. Topley defines the more important conclusions which our modern knowledge seems to justify. He points out that the older idea that a bacterium, acting as a single antigen, calls forth several different antibodies, has given place to the view that whereas the bacterium may contain several antigens, each of these antigens is capable of giving rise to one, and only one, antibody. The immunological value of the different antibodies is not always the same; some may profoundly modify the infective process, while others may have little or no effect on it. It is well known, for example, that infection with the typhoid bacillus causes the appearance of agglutinating antibodies in the circulating blood. These agglutinins are of two kinds, corresponding to two different antigens contained in the bacterium; one agglutinates the flagella, the other the body of the organism. The flagellar antibodies occur in large numbers, but appear to have no effect on the infective process; the somatic antibodies are numerically far inferior but are of real immunological significance, for they are responsible for the phenomena of bacteriolysis and opsonification. The recognition of the different immunising values of different antigens explains why, in some cases, active infection may be accompanied by the appearance of antibodies in quantities in the circulating blood, while in other infections a significant degree of immunity may be established apparently without the development of antibodies which can be detected. The haphazard search for antibodies in the circulating blood is useless; we must first determine which of the various bacterial antigens is the important one, and then concentrate on the search for its specific antibody. There is good evidence to show that multiplicity of antigens is associated with a complexity of bacterial structure hitherto unsuspected. Certain antigens are associated with nucleo-proteins, others with polysaccharides, and of these the polysaccharide antigens appear to be the significant ones in the production of in vivo immunity. The actual position of these different constituents of the bacterial cell is of importance, for the first reactions between the invading microbe and the fluids and tissues of the host must take place at the surface of the bacterium. If the surface of the bacterium contains antigens which possess the property of virulence the host may produce antibodies which attach themselves to the surface of the microbe and so neutralise the specific poison. But if the superficial antigens, the flagellar antigens of the motile bacilli, for example, are of no infective importance, the immediate antibody response may immobilise the microbe while failing to protect the host.

Another interesting phenomenon to which Prof. Topley draws attention is the persistence in the tissues of immune animals of the specific infecting organisms. If an animal is artificially immunised by an appropriate vaccine it may be able to withstand a subsequent inoculation with virulent bacteria, yet these same bacteria may often be recovered from the spleen in a condition of full virulence several weeks later. And the same kind of thing may be noticed after a natural infection. In other words, antibodies do not sterilise all of the tissues, though they may be sufficiently powerful to keep clean the ordinary paths of invasion and so prevent subsequent infections. Virulent bacteria may remain latent in the tissues for long periods of time even though the animal may be apparently healthy and immune from fresh external infections; and various non-specific factors may determine a recrudescence of infection from within. The revival of latent tuberculous infections is, of course, a commonplace of clinical medicine, but that a similar process can occur in the more dramatic acute infections is less generally recognised. There are other phenomena, however, which suggest that we are still far from a complete understanding of the processes of infection. In some established infections, in malignant endocarditis for example, organisms may live and proliferate in direct contact with the blood stream though they are killed if they are transported from the heart valves to other tissues and organs of the body. The actual mechanism of immunity is still hidden though there is evidence that we are groping very near the truth. Antibodies appear to sensitise bacteria in such a way that they become more readily ingested by phagocytes or destroyed by other means. We are unable, however, to express this process of sensitisation in the more accurate terms of chemistry or physics. But this no doubt will come in time. Meanwhile, as Prof. Topley says, we are justified in claiming that our conception of antigen-antibody reactions is as authentic as many of those which are regarded as fundamental in other branches of biology.

◆

RESEARCH AND ROWDYISM.

Prof. A. V. Hill chose a good title for the attack upon the antivivisectionists which he delivered as the Stephen Paget Memorial Lecture—"The Enemies of Knowledge." For the real defence of vivisection is not that it is useful, not that it has played a considerable share in ameliorating man's material state, but that it is a means of finding out things which could not be discovered by any other method. Those who put forward the argument that vivisection should be allowed because of its practical utility to medicine do so on good grounds, but are stating only a part of what might be stated better. They may never have asked themselves what should be said if animal experimentation ceased to be of material benefit. Here Prof. Hill, in his address, which we publish elsewhere (see p. 1385), takes the line of the idealist rather than the opportunist, and supplies the fitting answer. It is idle to wonder whether knowledge is worth having or not and whether perhaps men would be better off if they did not know so much. No serious minded man with any apprehension of modern biology will waste his time on such questionings. Knowledge may be good or it may be ill, but its acquisition is the larger part of man's evolutionary destiny; in hunting after knowledge man is filling most truly his place in nature; to refuse to do so is to blaspheme.

Man has, in comparatively recent times, added the arts of kindness and gentleness to his evolutionary programme; to be unkind has become blasphemy too, and we are faced with something of a dilemma such as progress must have posed often enough before; super reptiles, for example, must have been in something of a quandary when they were faced with the advantages of being warm-blooded and the disadvantages of having to get the vastly greater amount of food which warm-bloodedness needs. And of such dilemmas there is probably no solution available at the moment when they occur, but those who are inspired with the zeal for knowledge feel that endeavour to acquire it should not be baffled. Others equally sincere may not place the same value on particular endeavour, and well-informed criticism deserves serious consideration. But ignorance, especially wilful ignorance, cannot obtain a similar reception and the facts about animal experimentation are misunderstood by many of those who sit in judgment upon the progress of science, while many more have never acquired the facts. It is the strictures of these, especially of the last class, which lead to the undesirable element of partisanship, that in London recently took the overt form of the deplorable scenes of which everyone has heard: Prof. HILL's meeting, commemorating one of the kindest and gentlest men that ever was, ended in "considerable turmoil," while the Caxton Hall meeting of the British Union for the Abolition of Vivisection scarcely began, but ended in the police-court. The acquisition of knowledge and the cultivation of kindness are both good causes; neither is helped by rowdyism.

VICTOR HORSLEY MEMORIAL LECTURE.

THE Third Victor Horsley Memorial lecture will be delivered at University College Hospital on Tuesday, July 16th, at 5 P.M., by Sir Thomas Lewis, Sir John Rose Bradford presiding. These memorial lectures were established as a result of a trust instituted in 1921 to perpetuate the name of the great physiologist and surgeon and the subscriptions rapidly reached a total of over £1000, when the money was invested in the name of a board of trustees with the responsibility of arranging for the delivery in London of a lecture triennially. The first Victor Horsley Memorial lecture was delivered in 1923 by Sir Edward Sharpey-Schafer, who dealt with the Inter-relations of Surgery and Physiology; the second was delivered in 1926 by Mr. Wilfred Trotter who took as his subject the Insulation of the Nervous System. Sir Thomas Lewis will lecture upon the Mechanism of Raynaud's Disease. The subjects of these three lectures are closely related to Horsley's life work, but the terms of the trust place no limit on the theme of the lecture, nor need the lecturer be himself either surgeon or physiologist, and thus a good opportunity is afforded for wide surveys of scientific progress.

ALEXANDRA DAY IN LONDON.—It is reported that the London collections on Alexandra Day produced £50,535, about £3000 more than last year.

Annotations.

"Ne quid nimis."

NOTIFICATION AND ACUTE RHEUMATISM.

The first annual report on the Rheumatism Scheme of the Royal Borough of Kensington is the record of an experiment of some importance in the campaign against this destructive disease. The Kensington scheme includes compulsory notification, a supervisory centre, in-patient accommodation, treatment during convalescence, and home visiting. The authors of the report consider that, in conjunction with the other activities of the public health authority, which it facilitates, notification has been of paramount importance to the scheme. Acute rheumatism for purposes of notification is the occurrence, separately or together, in a child under 16, of rheumatic pains and arthritis with pyrexia, rheumatic chorea, and rheumatic carditis. The number of cases notified was 159, of which 81 attended the centre. Of these 81 cases, 8 were definitely not rheumatic, and in 6 the diagnosis was doubtful. The mistake in four of the wrongly diagnosed cases was the confusion of habit-spasms with chorea. The result suggests that there may be a similar error of 10 per cent. in all statistical calculations based on the results of unconfirmed notification of rheumatism. The authors remark that, with the exception of tuberculosis, there is probably no common notifiable disease with a higher rate of mistaken diagnosis. Moreover, at least half of the notifications were made by practitioners well accustomed to rheumatism. It is improbable that the total of notified cases represents more than a rough guide to the incidence of rheumatism in the borough, since the local practitioners have presumably not yet all acquired the habit of notification, and some of the existing cases are attended by practitioners from outside the area, or by none at all. Nevertheless, the number is already two and a half times that of the notified cases of tuberculosis in children under 16. The percentage of patients coming from damp dwellings is 37·7, a figure very close to that given by the Medical Research Council but considerably less than that given by the British Medical Association. The figures for lighting, ventilation, and personal cleanliness show that such defects are not ætiologically important, but the authors suspect that uncleanliness of rooms is at least a contributory factor. The heaviest incidence does not correspond entirely to the flood areas and the report suggests the conclusion that dampness of site is not the important factor, unless the house is in some way defective, or that the social and hygienic conditions which accompany congestion are as important as, or even more important than, the dampness itself.

The Kensington authorities also investigated another factor which has been put forward as a possible cause of acute rheumatism. In a paper read before the Royal Society of Medicine in February of last year, Dr. J. Tertius Clarke brought evidence to show that the geographical distribution of rheumatic fever coincided with that of the common rat-flea, *Ceratophyllus fasciatus*. The Public Health Department already knew the rat-infested areas of the borough, and they were plotted on the map which showed the sources of notification. The rheumatism and the rats undoubtedly coincided to a certain extent, and a search for a third factor common to both, which would account for an indirect association between them, showed that the railways, which are the favourite breeding places of rats, are largely situated in low-lying, and therefore damp, areas. This indirect association, however, only holds good if a relation be assumed between dampness and acute rheumatism. Moreover, rats are encouraged by defective housing and untidiness; they do not seek damp surroundings, but rather surroundings in which damp is incidental. Rats and rheumatism coincide more closely in Kensington than damp and rheumatism. These interesting results certainly suggest that Dr. Clarke's theory should be investigated further. The authorities of the borough believe that the solution of the rheumatism problem lies in eradicating the conditions which constitute poverty, overcrowding, deterioration of house property, and difficulty in obtaining the necessities of life. They do not record what many other investigators have noticed—namely, that the incidence of rheumatism is considerably higher among the comparatively poor than among the very poor. This is perhaps because actual destitution is rare in the Royal borough. Nevertheless, if this observation of other workers is correct, it would further support Dr. Clarke's theory, for rats would naturally infest the dwellings of untidy and wasteful persons rather than those whose inhabitants consume every particle of food.

The second part of the report is a valuable treatise on juvenile rheumatism from the clinical aspect, by Dr. R. C. Lightwood and Dr. M. L. Davies. In the absence of a specific remedy and of a certain means of protecting the heart of the rheumatic child, the primary object of a supervisory centre is, they say, to prevent relapses by providing as good management and surroundings as possible, and to supervise the after-care of children whose hearts are already affected. The chief measures directed against recurrence are correction of unsuitable environmental conditions, attention to general health, treatment of diseased tonsils, and education of the parents. Temporary removal to a convalescent home is largely a line of least resistance and can be permanently effective only if the children return to improved surroundings and better management. Much good work is done by the Invalid Children's Aid Association, which visits the homes of all rheumatic children and gives advice and instruction to the mother. Moreover, many housing defects are remedied by the Public Health Department. It is important, when diagnosing the conditions of each child, to decide whether the disease is in an active or a quiescent stage. Active cases require thorough and sustained treatment. If the family can afford a private doctor, they are advised to call him in; if they cannot, the child is sent to a hospital. Quiescent cases are examined at appropriate intervals, and many of them, together with all children discharged from hospital, are sent to convalescent homes. The special schools for physically defective children are invaluable for some of the older children who suffer from relapsing rheumatism or for those whose hearts are too badly damaged to allow them to attend the ordinary County Council schools. It appears, from the analysis of 200 cases of rheumatic children, that the females preponderate at all ages, but especially between 11 and 13. The highest relative incidence in male children is between 5 and 8, but the highest peak is at 12 for both sexes. Heart disease was found in 17·5 per cent., none of whom improved under observation. Fifty-four per cent. had normal hearts when first inspected, but four of these subsequently developed heart trouble. The remaining 28·5 per cent. were classed as doubtful; 12 improved under observation and one deteriorated.

There appears to be no relation between the state of the heart and tonsillectomy, but the investigation showed that the tonsils had been incompletely removed in 45 out of 85 tonsillectomised children, a proportion which suggests that the guillotine operation needs much skill and experience. The fact that rheumatism began in 27 children after an incomplete operation and in only 10 after a complete one indicates that complete removal gives a certain amount of protection. Moreover, the rheumatic manifestations, according to the report, were much lighter in those children who developed the disease after complete tonsillectomy. Only two children whose tonsils had been completely removed suffered from heart disease. Dental caries does not appear to be related to rheumatism, and constipation occurred in only 11 per cent. of the children examined. The proportion of children with a history of exanthemata was much the same as that noted by other workers. The first part of the report is by Dr. James Fenton, the medical officer of health, and Dr. Lightwood; whilst the second part is, as we have said, the work of Dr. Lightwood and Dr. Davies. The whole forms a useful contribution to the current knowledge of rheumatism, and we await its successor with great interest.

THE REDUCTION OF INTUSSUSCEPTION.

THE danger of delay in the acute intussusception of children makes one chary of putting off operation in order to try other forms of treatment, and manipulation and enemas have therefore been abandoned in favour of immediate surgical interference. A method of reduction by manipulation and barium enemata under close radiological control nevertheless seems worth consideration, and the results of treatment on these lines in five acute cases in young children have lately been described by Dr. Jacob Nordentoft.[1] In three of them reduction was effected successfully. In the fourth case manipulation failed; operation revealed an ileal intussusception which had progressed further and invaginated the colon; and the child died after this had been reduced with great difficulty. In the fifth case, which was of the colo-colic variety, manipulation was a failure but operation proved successful. In all the cases the intussusception had a characteristic appearance under the X rays. At its apex the barium was held up by a concave line which embraced its head by two slender arms, whilst from the mid-point of the concavity a thin streak of barium could be seen trailing up the lumen of the invaginated gut. In the first three cases reduction was secured by external manipulation, by injection of enemas under pressure, and by inversion of the child if necessary. The actual process of reduction could be clearly watched radiologically, the whole colon and appendix gradually filling with barium, which finally flowed unhindered into the small intestine. Nordentoft draws attention to the value of X rays in the diagnosis of intussusception in doubtful cases, and points out that it rarely involves the use of an anæsthetic. The advantage of avoiding both an anæsthetic and an operation need hardly be emphasised, and the only question is whether preliminary manipulation affects the chances of the child surviving an operation should this be needed later. Nordentoft considers that sometimes it may actually make the operation less severe by bringing about a partial reduction.

THE HUNTERIAN MUSEUM.

ADDITIONS made during the year to the collections in the Museum of the Royal College of Surgeons of England will be on view in Room I from Thursday next until Saturday, July 27th. Many of them are of interest to medical men, more especially the fine series of specimens illustrating von Recklinghausen's disease. This disease, although uncommon, is of sufficient frequency to exclude it from the category of pathological curiosities, and usually comes before the practitioner in the form of multiple fibromata. The specimens illustrate the remarkable convoluted masses of enlarged nerves, and the extensive involvement, not only of the peripheral nerves, but also of the great plexuses, the vagi and other cranial nerves, and the sympathetic system; pigmentation of the skin is also well shown, and the less recognised alterations of bones and joints occurring in cases of elephantiasis due to the disease. The 30 new specimens of various diseases of the central nervous system form a series well worthy of study; and the same may be said of the numerous specimens of disease of the thyroid gland. Attractive single specimens cannot be enumerated but two, carrying a moral, should not be overlooked; one is a rubber tube encrusted with phosphates which was removed from the bladder of a woman 13 years after the operation of total hysterectomy; the other, a sarcoma in the scar resulting from removal of the toe for hallux valgus, the same knife having been used for excision of a sarcoma of the skin of the thigh. The number of new pathological and teratological specimens amounts to 156. To those who take an interest in the early history of disease the Museum offers considerable opportunity for study; no museum can show a collection illustrating the diseases and injuries of a prehistoric people so completely as the Nubian series presented by Prof. Elliot Smith, and including specimens dating from 5000 B.C. down to Roman times. From time to time opportunities have arisen to add specimens illustrating the diseases of the ancient British and thus the nucleus of a section of British Paleopathology has been formed. An addition to this department has recently been made by Dr. Wyatt Wingrave, consisting of fossil remains of the great reptilia found in the secondary deposits of the south of England: these illustrate various bone diseases, and represent the earliest traces of disease which have so far come under the eye of the geologist. Sir Arthur Keith refers in detail in his annual report as Conservator to the work done in other departments of the Museum—the physiological, osteological, odontological, laryngological, and historical departments—all of them showing evidence of progressive activity.

THE BACTERICIDAL SUBSTANCE IN MILK.

AMONG 48 reprinted papers in Vol. XLVI. of "Studies from the Rockefeller Institute for Medical Research "[1] is one by F. S. Jones on the bactericidal substance ordinarily present in cow's milk. Hesse in 1891 showed that raw milk inhibited for a time the growth of *Bacillus typhosus*, and Rosenau did a good deal of work on it in 1008. Thus it has long been known that milk delays for several hours the propagation of many kinds of bacteria and that the delaying action is less effective if the milk is heated. Some further information is now available as a result of Jones's researches. In the first place the concentration of the inhibiting substance seems to bear a definite relationship to parturition and lactation. The maximal concentration appears about the sixth day after parturition, and different sections of the udder yield milk of different bactericidal power. Whatever the substance may be it is not inactivated by heat in the sense that complement is, but it is destroyed when exposed to room temperature or a little higher. It is destroyed by alcohol, but is feebly soluble in weak alkalis and sodium chloride. It is present in whey; it passes through the coarsest Berkefeld filter; it is not adsorbed by casein, fat, kieselguhr, or kaolin, but it can be retained in unknown concentration by animal charcoal. It withstands desiccation and has been demonstrated in a commercial preparation of dried cow's milk. The exact nature of the substance thus unexpectedly brought to light is uncertain. Some of the earlier observers thought it would prove to be identical with blood alexin, but Jones's experiments on heating show that this is not so. The most probable suggestion is that it will prove to be an enzyme derived from food, possibly of the nature of the "lysozyme" found in tears.

NON-RECOVERY AFTER AVERTIN ANÆSTHESIA.

THE details of a case briefly recorded in the daily press on June 14th have now been made known,[2] and deserve attention from anæsthetists interested in avertin. An apparently healthy man of 25 was operated on for inguinal hernia and was given a dose of avertin of the strength 0·1 g. per kg. of body-weight. This is generally regarded as the safe strength to use as a routine. He was also given morphia, gr. ¼, half an hour before the avertin. Full surgical anæsthesia not being attained nitrous oxide and oxygen were used in addition. It is noted that there was cyanosis early in the operation, which passed off and he left the theatre after half an hour's operation with a good colour and no abnormal symptoms. Two and a half hours later he was reported to be rather cyanosed, but the resident medical officer who examined him stated that his condition was good. About two hours later, at midnight, he was reported to have become suddenly worse. Treatment with artificial respiration and cardiac stimulants failed, and he died without having recovered consciousness, some seven hours after operation. The necropsy revealed nothing abnormal, unless a thymus gland weighing about half an ounce is to be so regarded. No case hitherto reported is quite analogous with this, for there is no instance of an apparently perfectly healthy person failing to eliminate the proper dose of avertin. Death appears to have resulted from an increasing respiratory failure, but it is scarcely conceivable that this could have been due to mechanical obstruction in the unconscious patient being allowed to bring about asphyxia. Moreover, had this been so, the artificial respiration would surely have saved life in a patient with a sound heart. We have to suppose, therefore, that the avertin was not eliminated as it usually is, and the reason for this it is important to discover. For the treatment for such failure in detoxication injection of thyroxin has been suggested, and experiments in this direction have been and are being carried out. It is said that patients with exophthalmic goitre recover more quickly than others from the effects of avertin. It is worthy of note that in this patient morphia had been given beforehand, whilst omnopon was used in the only other case at all resembling it of which we have cognisance. As increasing cyanosis and respiratory failure seems to be the mode of death when avertin is not eliminated it is probable that extreme caution is necessary in employing respiratory depressants before the rectal injection.

PROF. REGAUD ON RADIUM.

IN his Cavendish lecture entitled the Progress and Limitation in the Cure of Malignant Diseases by Radium, delivered before the West London Medico-Chirurgical Society on Friday evening last, Prof. Claude Regaud, director of the Radio-Physiological Laboratory of the Radium Institute in Paris, made a brief survey of radium therapy (or Curie-therapy as he prefers to call it), from its first application for this purpose about 30 years ago up to the present time, and pointed out the enormous advances which have been made. Many different methods of attacking cancer by means of radium have been tried, but in general there were three methods in common use: (1) Internal radiation: by the insertion of radium into one of the body cavities. (2) Interstitial radiation: which is radiation by means of radium containers inserted actually into the tissues. (3) External radiation: where the radium applicators may be in contact with the surface of the body or supported at a distance away. To this method of radiation from a distance he attaches the name of "telecurietherapy" and considers that its use must always be limited by the scarcity and high price of radium. Much had been hoped for from internal radiation, but with the exception of the treatment of carcinoma of the cervix these hopes, said Dr. Regaud, had not been realised. He considered the interstitial method of radiation to be the most successful; a wider combination of surgery and radium therapy along these lines was a promising field of research in the treatment of malignant disease. He illustrated the various methods of treatment both by photographs of cases and by statistics of results obtained at the Paris Institute. Turning to the future Dr. Regaud thought that it was the radio-physiological side that offered scope for fruitful investigation; if means were found to increase the narrow margin of radio-sensitiveness, which lies between normal and cancerous tissues, it would constitute a momentous discovery. Existing obstacles in the path of the treatment of cancer by radium were, he said, very grave. They included the apparent lack in certain cancer cells of any sensitiveness to radium, the presence of widespread local extension, and, above all, dissemination of the disease. Radium is not a panacea for cancer: far from it! The public, and even medical men, do not always realise the serious difficulties which are met with in the use of radium. Whilst awaiting further developments in the radium treatment of cancer we must rely upon early diagnosis followed by early and proper treatment by surgery or such radiotherapeutic methods as are of proved value. False hopes must not be raised or wrong views allowed to prevail; and Dr. Regaud ended with a plea for enlightenment of the medical profession as well as of the general public through social and medical organisations.

THE BRITISH ASSOCIATION'S VISIT TO SOUTH AFRICA.

IN this its ninety-ninth year the British Association for the Advancement of Science will hold its annual meeting in South Africa, and the proceedings will open at Cape Town on July 22nd with an official welcome by the Earl of Athlone, the Governor-General. The new President, Sir Thomas Holland, F.R.S., who is soon to succeed Sir Alfred Ewing as Principal of Edinburgh University, will not deliver his presidential address on the International Relationship of Minerals until the Association reaches Johannesburg, where nearly all the remaining sessions will be held. Arrangements for the general meetings will include an address on Africa and Science by Mr. Jan Hofmeyr, President of the South African Association for the Advancement of Science; an evening discourse by Sir Ernest Rutherford, President of the Royal Society, on the Structure of the Atom; and lectures by Prof. Julian Huxley on Evolution, and by Prof. G. H. F. Nuttall, F.R.S., on Yellow Fever in Africa. At Pretoria Prof. J. H. Priestley will speak on the Growth of a Tree and Prof. A. S. Eddington, F.R.S., on the Interior of a Star. Both at Cape Town and Johannesburg there will be discussions on Science and Industry. The ordinary proceedings will, of course, be divided according to sections. The Section of Chemistry will have a presidential address from Prof. G. Barger, F.R.S., on the Relation of Organic Chemistry to Biology and will later join the Section of Physiology in a discussion on Vitamins. The Section of Zoology, over which Prof. D. M. S. Watson, F.R.S., will preside, is to hear several contributions of medical interest, including one from Dr. Annie Porter on the Hookworm Problem in South Africa and one from Dr. J. F.V. Phillips on research concerning the tsetse-fly. As usual, however, members of our profession will chiefly be found in the Sections of Physiology and Psychology. Prof. W. E. Dixon, F.R.S., President of the former, has chosen for his address the subject of Physiology as the Basis of Treatment, and among other contributors to this section will be Prof. J. S. Haldane, F.R.S., on the Dissociation of Oxyhæmoglobin, Mr. L. Mirvish on Calcium Metabolism and Internal Secretions, Dr. T. M. Mavrogordato and Dr. Haldane on the Effects of Dust Inhalation, Mrs. May Mellanby on Some Factors controlling the Structure of the Teeth and their Susceptibility to Caries, and Dr. S. Monckton Copeman, F.R.S., on Cancer and Diet. Besides the discussion on Vitamins with the Chemical Section, another meeting, on the Nature of Life, has been arranged by the Section of Physiology jointly with those of Zoology and Botany. Mr. F. C. Bartlett is the President of the Psychological Section which he will address on Experimental Method in Psychology. Dr. C. S. Myers, F.R.S., will speak to this section on a New Interpretation of Adaptation and Dr. Margaret Macfarlane on Training the Mentally Unfit, whilst a joint discussion on Psychological Tests in Relation to Education and Vocational Guidance will be held with the Section of Educational Science. The latter section will also consider the question of Education and the Poor White, introduced by Dr. E. G. Malherbe; the Teaching of Biology, by Prof. H. B. Fantham; and the Professional Education of South African Natives, by Mr. D. D. T. Jabavu. The Section of Agriculture meets on the 23rd at Cape Town and on the 31st at Pretoria, where Major Walter Elliot, M.P., will be among those taking part in its deliberations. The rest of the congress will conclude at Johannesburg on August 3rd, after which a series of tours will be made in and beyond the Union, ranging as far north as the Victoria Falls.

ERGOTAMINE TREATMENT OF GRAVES'S DISEASE.

THE treatment of hyperthyroidism with ergotamine which has found favour on the continent, is based on the inhibitory action of this drug on the sympathetic system. E. Rothlin has shown that the vaso-constrictor effect of stimulating the cervical or splanchnic sympathetic by adrenalin is hindered or annulled by the previous administration of ergotamine, and that uterine contractions produced by adrenalin in the rabbit are also inhibited. Moreover, after the administration of ergotamine experimental adrenalin hyperglycæmia is said not to occur. Dr. P. Sangiorgi has now published[1] a series of ten cases of Graves's disease which seem to have improved a good deal under subcutaneous injections of tartrate of ergotamine, this improvement being maintained for some time after the treatment was discontinued. Tachycardia was the symptom most rapidly influenced, but it also was the first to reappear when administration of ergotamine was suspended. Increase of weight in the patients, who all followed their ordinary avocations, was regarded as a practical demonstration of the behaviour of the basal metabolism under the influence of the drug, and the nervous symptoms were apparently to some extent controlled by the treatment, Sangiorgi's observations being here in agreement with those of J. Bouckaert. In none of the cases, however, did he notice any effect on the thyroid enlargement, when there was any. At first a dose of 0·25 mg. was given every morning; if this was well tolerated it was repeated in the evening. In no case did it seem advisable to exceed a dose of 0·5 mg. daily, and after 20 to 25 days administration of ergotamine was suspended for a week or two, preferably in women, at the time of the menstrual period. After the pause the treatment was then renewed for another period of 20 to 25 days. The first series was considered sufficient to establish the efficacy of the treatment, whilst the second consolidated it. Sometimes, if necessary, after a longer pause a further course of treatment was begun. The general conclusion to be drawn from Sangiorgi's observations if they can be confirmed, is that although ergotamine tartrate is not curative, in the full sense, it may nevertheless have its uses in appropriate cases of Graves's disease. It has also been employed for treating migraine.[2]

LADIES' NIGHT AT THE ROYAL SOCIETY.

THE distraction of a set piece shown at specified times during the evening was absent from the second of the two annual demonstrations of scientific fireworks held at Burlington House this year, and the guests, spared from anxiety lest they should miss the chief item of the evening's entertainment, could examine exhibits, sample refreshments, and greet their friends at leisure. The three occupations offered were equally popular, but since two of them could be happily combined, there was time not only to look carefully at most of the 33 exhibits, but also to supplement the descriptions in the catalogue ("supplied by the exhibitors, who alone are responsible for their accuracy") by cross-examining the long-suffering authors of these simplified statements. Some of them, with the best will, could not at this stage add much to the written word. The exact nature of the resin or balsam, which, with nine times its weight of neutral animal fat, made up the cosmetic found in the tomb of Tut-ankh-Amen will never be disclosed. The very small organism (diameter 0·1 μ) recently discovered by the method of dark-ground illumination with ultra-violet light by Mr. J. E. Barnard, has not yet been named, nor its properties investigated. Still less could Miss M. A. Tazelaar and Prof. Julian Huxley explain the curious influence of temperature gradients on development. By means of a simple apparatus, developing frog's eggs can be subjected to a temperature gradient in any direction required. When the gradient passes from side to side asymmetrical tadpoles may be produced. Cold at the future head end alters the type of gastrulation and may lead to double-tailed monsters. The continuation of normal development outside the body was one of the most attractive demonstrations, shown by Miss Honor Fell, D.Sc., with Dr. R. Robison. At the Strangeways Research Laboratory at Cambridge she has cultivated in vitro the femurs removed from fowl embryos 5½ days and 6 days old. These isolated femurs have a remarkable capacity for self-differentiation. When removed from the body and cultivated in a watch-glass containing suitable culture-medium they may increase to more than three times their original length and at the same time undergo a remarkably normal anatomical and histological development, including ossification. They continue growing for three weeks, after which no further development takes place. As in normal development, the femurs cultivated in vitro form enlarged cartilage cells and osteoblasts and synthesise a phosphatase which may effect calcification by liberating inorganic phosphate from phosphoric esters. When three-day embryonic limb-buds are cultivated they differentiate to form small-celled cartilage; but no enlarged cartilage cells or osteoblasts are formed, nor is phosphatase synthesised. In the annual report of the Lister Institute of Preventive Medicine, which we summarise on page 1373, these results are mentioned as providing strong evidence of the truth of Dr. Robison's earlier conclusion that phosphatase is secreted by the hypertrophic cartilage cells and osteoblasts, but not by small-celled cartilage which never ossifies. The extension of experiments of this kind and of those designed to establish the action of X rays and radium on normal and malignant cells, will soon settle the doubt whether tissue culture represents merely an interesting phenomenon or whether the technique can be developed to yield results fruitful in other sciences.

SKIN IMMUNISATION IN TUBERCULOSIS.

As a mechanical method of protection it is obvious that the skin stands facile princeps in the first line of defence against infection. Long ago Robert Koch showed, in the classical experiment known as "Koch's phenomenon," that, once the body had been sensitised by a primary infection with the tubercle bacillus, the skin acquired the power of holding up at the site of inoculation a second dose of bacilli. But the actual value of the skin as an immunising agent has, on the whole, been inferred rather than demonstrated. More recently Prof. A. Besredka showed that vaccines of living organisms, such as staphylococci, applied in a wet compress to the shaved skin of the guinea-pig acted as an immunising agent against subsequent infection, and we have called attention to the significance of this observation. It would indeed be astonishing if the skin, with its blood capillaries under such efficient vasomotor control, did not exhibit immunising powers, but when we come to examine step by step the mechanism of this immunisation, it is by no means easy to determine precisely of what properties this bacterial resistance consists. Phagocytosis is not difficult to demonstrate, but the humoral side of the question is less open to direct experimentation. Dr. P. Woringer, of Strasbourg, in a recent article[1] reviews the evidence for a specific cutaneous immunisation against tuberculosis, based largely on the work of A. Marfan and J. Paraf. Meanwhile remedies based upon the action of the skin as an immunising factor continue to be introduced in clinical medicine, and whatever may be the theoretical explanation of their action there would appear to be good reason for their continued trial.

Prof. A. Wolff-Eisner, of Berlin, in introducing[2] yet another tuberculin into medicine bases his treatment on the belief that these immunological properties of the skin have been hitherto much neglected. Reasoning from the tuberculides he suggests that in cutaneous tuberculosis two immunological reactions take place, first a bacteriolysis of the tubercle bacillus in the skin, and, second, a fixation of the tubercle toxin in the skin which prevents its harmful effect as a circulating toxin (*Winkelriedfunktion*). Santuben, which is a tuberculin ointment manufactured under his control, is claimed to have been used in 16,000 cases during an experimental period before the preparation was put on the market. The ointment is rubbed into the skin for ten seconds once a week. After 24 to 48 hours a slight reddening or swelling should appear at the site of inunction, which remains visible for 3 to 5 days. If the reaction is not obtained a larger inunction is made on the next occasion. Marked erythema is considered to be an overdose and should be avoided. As an adjuvant of this treatment a tablet preparation of guaiacol and silica is administered by mouth, the former for its antiseptic properties, the latter for its supposed effect in promoting the formation of fibrous tissue. After using the remedy in his various institutions of the University of Berlin for 20 years, Wolff-Eisner has obtained a large experience and believes that he can achieve valuable results by cutaneous immunisation in many forms of early tuberculous disease.

THE CENTENARY OF KING'S COLLEGE.

On June 21st, 1828, at a meeting held in the Freemasons' Tavern, with the Duke of Wellington in the chair, a college was inaugurated for the purpose of giving instruction in the various branches of literature and science, and the doctrines and duties of Christianity as the same are inculcated by the United Church of England and Ireland. King's College, London, obtained its Charter a year later, and the centenary of the granting of this Charter is being celebrated this week. On Tuesday last the Duke and Duchess of York opened the proceedings in the College, and on Wednesday the Archbishop of Canterbury dedicated the chapel and opened the library and new wing of the Hostel in Vincent-square. During the hundred years that have intervened King's College has set up faculties in many branches of literature and science, and these have contained an astonishing number of names of world-wide repute. Those of Wheatstone, Adams, Clerk-Maxwell, and Daniell are household words in the basic sciences on which medicine is built up, while the College is hallowed to the student of medicine by the memory of Joseph Lister and more recently of David Ferrier. It is very seemly that one of the Colleges of the University of London should lie within the precincts of the City, and now that the question of a central university site has been decided once and for all there is a wide feeling of satisfaction, we believe, that King's College should continue to occupy part of William Chambers's famous palace. Many of those who parked their cars on Tuesday by permission in the quadrangle of Somerset House, the home of the Board of Inland Revenue, may with the eye of faith have seen the whole edifice tenanted by University students, and some other place found for the servants of the Treasury. One could hope that the bleak stretch of London south of the Thames might acquire some university building of its own, to bring the southern boroughs into more intimate contact with the academic life of a great city. Central London, however, has become progressively less suited for school-children and students' residence. King's College School moved out to Wimbledon Common in 1898, ten years later the hospital nearby was transferred with its attendant school of medicine to Brixton, and the social science department has found a permanent home on Campden Hill. These moves left unchanged the question of accommodation for the students attending the College, the number of whom has doubled since the war, while there are at present over a hundred visiting students from the Dominions and continental countries. The three College hostels in Bayswater, Denmark Hill, and Westminster have long outgrown their accommodation. The last-named of these, lying centrally in Vincent-square and overlooking a first-class playing-field (not, of course, its own), becomes with the new additions one of the best equipped institutions of the kind. The increased number of students has led to the need of larger College buildings, and they can only be partly met by the superstructure over Aldwych Station. The proposal to rebuild the south-west block of the College, with new buildings for anatomy upon the roof, will make it possible to bring together the various departments of the faculty of medical sciences hitherto separated. The estimated cost of all these changes is £125,000, and the money must be found.

THE NERVOUS ELEMENT IN CHRONIC CONSTIPATION.

CHRONIC constipation is well called by the Germans a Kulturkrankheit, and is indeed so widespread and in many eyes so serious as to be in danger of taking its place as a definite disease. Perhaps half the patients that a doctor sees describe themselves as constipated and the most far-reaching ills are commonly attributed to this condition alone. All this has a basis of truth, for constipation is undoubtedly the cause of much ill-health; on the other hand, it is very often only a result or symptom of an underlying disturbance. Since the conception of intestinal toxæmia is pretty familiar to the public the fear of constipation looms large in the minds of many and gives rise to much anxiety. The consequent nervous factors in chronic constipation have lately been studied by Dr. Lewent[1] of the University Hydro-Therapeutic Station in Berlin, who finds, like other physicians, that the commonest symptoms complained of are headache, anorexia, lassitude, insomnia, whilst flatulence and abdominal pain are comparatively rare. The great majority of her patients have been women at about the climacteric, and usually the condition has been attributed to "endocrine" disturbance, the cases falling into a large group which she terms the "endogenous" or neuropathic constipation. She recognises also a smaller "exogenous" group largely composed of what would usually be called atonic cases.

A broad division into these two types, "endogenous" and "exogenous," has perhaps as much value in practice as the customary division into spastic, atonic, and dyschezic types. The endogenous group includes that difficult patient, the bowel hypochrondriac, in whom it is often hard to determine how far the symptoms are those of neurosis and how far the result of intestinal toxæmia. The term "intestinal toxæmia" is certainly much abused, and for a large proportion of those who have habitual constipation it is actually less harmful to be constipated than to pass loose stools. In fact it is not definitely known if constipation alone is ever a cause of increased absorption of toxins from the intestine, and everyone is aware that in phlegmatic people an action of the bowel once a week is compatible with perfect health. It will be remembered that Alvarez has shown that many of the symptoms of constipation—irritability, nausea, headache, and so forth—can be caused by mere mechanical distension of the rectum, as, for example, by stuffing it with cotton-wool. Laboratory experiments so far furnish little proof of true intoxication in chronic constipation, for the products of protein putrefaction (indol, skatol, phenol) when given by the mouth or by injection have usually failed to reproduce the symptoms. By giving large doses of such nitrogenous products by mouth Power and Sherwin[2] have produced typical symptoms in man, which leads them to suggest that stasis of the colon may bring about failure of the intestinal wall to detoxicate bodies of this kind, and thus lead to their absorption into the blood unchanged. But their excretion, as judged by the degree of indicanuria, is notoriously unreliable as a guide to intestinal putrefaction, a fact which has led to the suggestion of several alternative tests, including a proposal for the estimation of tyrosin recently made in our own columns.[3]

The whole question cannot be satisfactorily answered at present. It is important, however, that in every case of constipation the relation of cause to effect should be borne in mind; that the relative harmlessness of delayed excretion of solid fæces, as compared to the dangers of fluid motions following the abuse of purgatives, should be remembered; and that reassurance of the patient should never be neglected in treatment.

Lord Donoughmore, treasurer of the Thank Offering Fund for the King's Recovery, organised by King Edward's Hospital Fund for London and the National Radium Fund, has received an anonymous contribution from "Grateful" of 1000 guineas as a tribute to the work of the voluntary hospitals in forwarding the progress of medicine.

THE late Lord Revelstoke has bequeathed £100,000 to King Edward's Hospital Fund, £50,000 to Guy's Hospital, and £25,000 to St. Mary's Hospital Medical School.

ON Thursday, July 18th, at noon, H.R.H. the Prince of Wales will formally open the school buildings of the London School of Hygiene and Tropical Medicine, the new School of the University of London which owes its building to the generosity of the Rockefeller Foundation.

MANCHESTER MEDICAL SOCIETY.—The annual meeting of this Society was held on May 1st in the Medical School of the University, with Dr. R. W. Marsden, the President, in the chair. In connexion with the visit of the British Medical Association to Manchester this year, Dr. Charles Horace Mayo and Dr. William James Mayo, of the Mayo Clinic, Rochester, U.S.A., were elected honorary members of the Society.

IRISH MEDICAL ASSOCIATION.—The annual meeting of this Association was summoned to be held at the Royal College of Surgeons in Ireland on June 12th. A quorum failed to attend within half an hour of the time fixed for the meeting, and the meeting stood adjourned for a week at the same hour and place. On the second occasion those present were able to constitute a quorum, and to proceed with the business. Mr. P. E. Hayden was elected unanimously as President, and Dr. E. Byrne, of Slane, as Vice-President. The President delivered a brief address in which he pointed out the advantages attached to membership of the Association. The report of the Council, which was adopted, stated that at the end of last year there were 409 members, being an increase of 19 during the year.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXXV.

THE INTERPRETATION OF MENTAL TESTS.

II.*—THE SIGNIFICANCE OF ACCEPTED TESTS.

Mental Tests.

THE systematic testing of the mentality of children for evidence of subnormality and supernormality and for purposes of vocational guidance has become a routine practice in modern educational systems, but anything like a complete test can only be carried out by those who have had experience both in the use of tests and in interpretation of results. The general practitioner, in examining a case of suspected subnormality, may, however, with the use of a few simple tests, obtain sufficient to guide him to a diagnosis not utterly inconsistent with facts, or at least to guard him from giving a prognosis absurdly optimistic. Those given here will not occupy an undue amount of time, and do not require special apparatus.

Binet-Simon Tests.

(*a*) A few tests taken from the Binet-Simon scale serve by their simplicity as a good starting point. If a child of 3 cannot give his full name, know whether he is a boy or a girl, name simple objects shown—*e.g.*, penny, key, knife (closed)—point to his eyes, nose and mouth when asked, and name a few objects in a simple picture he is not up to normal standard. At 4 he should be able to say of two lines which is the longer, the question being repeated with the lines reversed in position (a point of much importance). At 5 he should be able to carry out three simple orders in succession, at 6 should distinguish right and left, and at 7 should repeat the weekdays, and then give the name of the day before any day mentioned to him.

Simple Counting Tests.

(*b*) (1) In order to give confidence to the child, see if he can count consecutively "1, 2, 3, &c.," and how far. It is a purely parrot-like procedure, and has no significance.

(2) Ask him to count aloud different numbers of fingers or pence, using his finger. He should be able to count 4 at 4 years and 13 at 6 years. This process often reveals an utter inability to grasp numbers.

(3) Hold up 2, 3, 4 or more fingers or show pennies and find if he can give the correct answer without counting—that is, find the span of his grasp of numbers. A child of 4 should grasp 4. A failure to grasp more than 2 or 3 at 7 years is very serious.

(4) Simple calculations in addition and subtraction are easily given; the latter always gives the greater difficulty, particularly to the subnormal. The defective's relative inability to deal with abstract number may soon be apparent, so that all calculations have to be done attached mentally to pennies or apples, or in the worst event, can only be done with concrete aids. At 5 years of age there should be the beginnings at least of abstract calculation—*e.g.*, 5 + 2, 4 − 2. There is always a real danger of being too favourably impressed with successes in very simple calculations.

(5) Another useful test is the repetition after the examiner of series of digits: 3 should be repeated at 4 years, 4 at 5, 5 at 6, and 6 at 9. More difficult and of great value for diagnosis is repetition of the digits backwards—3 at 7 years, 4 at 9.

Drawing Tests.

(*c*) A few simple drawing tests may be rapidly carried out. The child may be asked to copy certain lines and simple geometrical forms imitatively after the examiner. A vertical stroke should be imitated at 2, a horizontal before 3, a circle about 3. These imitative performances are always possible much earlier than a copy from an already prepared diagram. A child will not copy a circle from a model until nearly four years, a cross about 4, a square between 4 and 5, a triangle about 5, a diamond at 6. A child who cannot do these at 7—except the diamond—is certainly subnormal, while a child of that age who could not do any or only a few strokes would be an idiot or an imbecile.

Consideration of Results.

Those who desire to carry out a more complete examination will find material for their purpose in the various scales of tests now available—the linguistic Binet type, preferably in the revised forms prepared by Prof. Cyril Burt, Prof. L. M. Terman, or Dr. E. O. Lewis, and the more practical types represented by the Porteus mazes and other performance tests, involving the handling of concrete material. Detailed description of these is beyond the scope of this article. What the examiner is concerned with is the contribution they make to an understanding of the mentality of the examinee. A "mental age" is calculated from the results, and this when expressed as a percentage of the real age gives an Intelligence Quotient (I.Q.), a quantity which remains fairly constant throughout at least the school ages in any one child. As a rough approximation it is true to say that a child with I.Q. below 50 (or even 55) is either an idiot or an imbecile, and will never be able to make his own living or manage his own affairs, and that a child of I.Q. of 50 to 70–75 is feeble-minded and will always suffer from his limitations to such a degree as to be more or less inefficient except under careful supervision.

A bare statement of percentage, however, conveys little knowledge, and the examiner should always endeavour to assess the significance of individual tests. Success in tests of mechanical memory (repetition of digits or sentences), simple school knowledge (naming coins, days, months) should not weigh so heavily in the balance in the child's favour as success in tests which involve rearrangement of ideas, comparisons and abstractions; examples of these are the expression in words of differences and similarities of objects, rearrangement of mixed sentences, repetitions of digits backwards, detection of absurdities, definition of abstract terms. It is in this capacity to form, to compare, to utilise, and to reason about ideas that the higher and therefore the less easily recognisable types of feeble-minded are conspicuously lacking, in contrast to their nearer approach to normality in the elementary processes of perception and memory. Performance tests also, whether the threading of mazes, the fitting of form-boards, the arrangement of blocks of varying sizes and shapes in a given space, the reconstruction of pictures—to instance only a few types—involve an element of arranging and planning, working, however, with concrete material instead of ideas. Some intelligences, both normal and subnormal, are more apt in dealing with the concrete and the mechanical; performance tests are therefore a necessary supplement to the linguistic ones.

It is in so far, then, as these tests reveal something of the mental make-up of the individual that they are of value. But, in estimating future prospects more than intelligence must be taken into account. In the feeble-minded, success or otherwise in after-life will largely depend on temperament; only a fairly well-balanced, stable type can overcome the limitation of intelligence. It is with this group that the examining doctor has much difficulty. In many respects they present the aspect of normality (superficially, at least). They may be brought to the doctor only because a school medical officer has ordered their attendance at a special school, and as it is only special teaching that holds out any hope to these children of making good in after-life, the family doctor will be wise to advise in this direction.

---

* Part I. appeared last week.

Sometimes the trouble for which the practitioner is consulted is not so much lack of intelligence as abnormality of behaviour. Symptoms may occur very early. The child of 5 may be already a thief, impulsive, and even violent to a degree, a truant from school, and generally a nuisance. A family doctor may be able to estimate how far this condition has been contributed to by home circumstances and training. Defect of intelligence must be considered as a possible factor and should be tested, but frequently the defect is one of character only. In such cases diagnosis should be deferred. Modern psychology has shown that many children reckoned as having a defect in character—moral defect, that is—are really the victims of subconscious factors. A change of environment, partly for observation and partly for treatment, is desirable, and prognosis should always be very cautious. Where, however, there is a definite history of instability of character from an early age, with offences of many types, and a general disregard of moral codes, moral defect or mental defect of a temperamental type is certainly a probable diagnosis.

EARLY ADOLESCENCE.

At this period, or slightly earlier, just before the child is about to leave school, consultation of the family doctor is not uncommon, for it is often only when the child reaches this stage of life that the parent begins to realise that his child, if feeble-minded, is not as others are, or if he has already to some degree realised this, to suspect that the condition is threatening to remain permanent. His school teachers will probably have given persistently bad reports of progress, and the parent will be growingly aware of a marked lack of capacity and common sense, a lack of initiative and effort, a forgetfulness, a weakness of character, an indisposition to mix with his fellows, a too persistent reliance on his elders.

Reasoning Tests.

In the examination of cases at this age, the evidence of tests is at times singularly negative. Only recently the writer had to certify a lad of 17 who had not come under special attention in his school years as a possible defective, who, on intelligence tests, was almost 12 years in mental age; was certainly backward in reading and very backward in arithmetic, but who, in appearance, bearing, and attitude to the examiner, was obviously a weakling in character, a fact confirmed by his mother's statements. He had committed under influence a sordid crime into which he had simply drifted through his sheer weakness. Even the most advanced tests of the Binet scale only involve a very elementary amount of reasoning and fail to assess types such as this, who, with some mechanical intelligence, lack that reasoning ability which is essential both to the sensible management of one's own affairs and to the adequate control of conduct. Prof. Burt's Reasoning Tests are of much value here. A simple example, adapted to a 7-year mentality, is, "Kate is cleverer than May; May is cleverer than Jane: who is the cleverest." A common type of problem is one in which a variety of alternatives are presented and a choice required. At 10 years, for example, a problem of medical diagnosis is given, the patient being a girl. "If she has a rash, it may be chicken-pox, measles, or scarlet fever; if she has been ailing with a cold or cough, she may develop whooping-cough, measles or mumps. She has been sneezing and coughing for some days, and now spots are appearing on her face and arms. What is probably the matter with her?" Ballard's Absurdities Tests are also useful. "A soldier on the march complained that every man in the regiment was out of step except himself." "The moon is more useful than the sun, for it gives us light in the night when we really need it, while the sun gives us light in the day when we don't need it." It is only exceptionally that tests of this type require to be given; and even the most intelligent of feeble-minded adolescents never get beyond the 10-year level, and usually remain considerably below it.

Apart from tests, the practitioner will usually obtain a fairly solid basis for an opinion from a careful and searching questionaire on the lines already indicated, but especially relating to behaviour and habits now; the fact that he has had work, possibly several jobs, and has lost each through incapacity, will, of course, be very significant. His ability to read and understand a simple passage, and his ability to count may readily be put to the test. He may be questioned about his school or any work he has done, about streets, buildings, mills and factories in the town or district, about places he has visited, and what he has seen there.

By these and similar methods the practitioner will be able to form some idea of his subject's probable ability to make a living on his own or look after himself sensibly, which are the parent's chief interest in the examination. A happy solution, temporary at least, in some of these cases, may be achieved when the parent himself or a friend is able to give the child or youth some simple occupation in which he can be supervised. Where home circumstances are good and the youth's behaviour is not objectionable, institutional care can at least be postponed until circumstances alter. The worst cases, and those of unstable type whose behaviour is uncontrolled and vicious, should have institutional care, but this, up to the present, is in most parts of the country utterly inadequate to requirements.

Manchester Education Committee.

DONATIONS AND BEQUESTS.—Mr. Fred Kershaw, of Starcliffe House, Great Lever, Bolton, on his wife's decease, left £2000 to Chetham's Hospital, Manchester, in memory of his nephews who were killed in the war; £1000 to Bolton Infirmary, in memory of his brother, who was also killed in the war; and £1000 to St. Dunstan's Hostel for Blinded Sailors and Soldiers. Of the ultimate residue he left half to the Bolton Infirmary for the acquisition or purchase of radium; one-eighth to the Cancer Research Fund of the Manchester Royal Infirmary; and one-eighth to the Cancer Hospital, Fulham-road, London.—Mr. David Beattie Ritchie, of West Cumberland-street, Glasgow, left—subject to two life interests—£2000 to Glasgow Royal Cancer Hospital for the promotion and advancement of medical and surgical science relating to the treatment of the disease and of the efficient instruction of students and nurses to cope with the disease; the ultimate residue of the property to Glasgow Royal Infirmary, the Western Infirmary, Glasgow, and the Victoria Infirmary, Glasgow.—About £16,650 passes to charitable objects under the will of Miss Isabella Salmond, the oldest resident of Kirkcaldy, including £3000 to Edinburgh Royal Infirmary and £2000 to Kirkcaldy Hospital.—Mr. Frederick Richard Dixon-Nuttall, J.P., of Ingleholme, Eccleston Park, Prescot, Lancs, left, among other bequests, £2500 each to St. Helens Hospital and the Endowment Fund of the Providence Free Hospital, St. Helens.—Mr. William Jones, of Walter-road, Swansea, left £1000 to the Swansea General and Eye Hospital, to endow a bed in his name; and £250 to Swansea and South Wales Institute for the Blind; and Mr. William George Ayliffe, of Highcliffe, Wotton, Glos, £1000 to Gloucester Royal Infirmary.—Mr. Thomas Ledbrook, of Enham Lodge, Leamington, Warwickshire, left the bulk of £58,000 to charity, including £1000 to Dr. Barnardo's Homes, £1000 for a Warwick cot in Lord Mayor Treloar's Cripple Hospital and College, £500 to the Children's Aid Society, and, after bequests to relatives, all other property equally between St. Dunstan's Hostel, Regent's Park, London, N.W., for Blinded Sailors and Soldiers, the Warneford (Leamington) and Warwickshire General Hospital, and the Royal Midland Counties' Home for Incurables, Leamington.

PERSONAL AND IMPERSONAL FACTORS IN SCHOOL INFECTIONS.

By G. B. PAGE, M.D. EDIN., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, COUNTY OF ROXBURGH.

IT is generally agreed that transference of infection is to a large extent a personal matter, the infecting agent being passed directly from one individual to another by droplet infection and contact. No doubt there are exceptions—for instance, protozoal infections that require an intermediate host, but the personal element, direct or by carrier, is paramount for infectious diseases of school-children in this country. For this reason the attention of teachers has been directed to the detection of illness at an early stage and to the necessity of excluding these cases and sometimes their contacts. It is recognised as almost equally important that convalescents should not be readmitted to school until the appropriate period has elapsed, the period in each case being fixed as the result of experience. This provision sometimes brings officialdom into conflict with the parents and the family practitioner, who forgets that the former must legislate for numbers and not for individuals. Thus it has been argued that measles ceases to be infectious after a fortnight and that the common period of exclusion (three weeks) is too long, provided that the child has no obvious catarrhal condition. As a matter of fact, few children convalescent from measles are physically fit to return to school at the end of a fortnight; and who is to judge catarrhs in the numerous cases that have never been attended by a doctor?

In this county head teachers are provided with printed notes, which give in clear language the early symptoms of the common infections and the action to be taken in suspected cases, convalescents, and contacts. Teachers are not asked to make a diagnosis—they are merely asked to exclude sick children from school and to report, on forms provided for the purpose, any infectious trouble which occurs in the school or which may threaten it from without—e.g., a case in the family of a scholar. Teachers are not asked to bother whether a disease is "notifiable" or not, the two main points being that a sick child has no place in school and that any disease liable to spread from one person to another should be reported. Much useful information comes to hand in this way, especially concerning non-notifiable infectious diseases. When a disease is actually prevalent, other returns are called for, but the early intimation and prompt action by the teacher are the points upon which stress is laid.

Attention has been focused on the personal factor in another way: by abandoning, to a large extent, so-called disinfection. It was formerly the custom to carry out "routine" disinfection during the three holiday periods in all schools. This meant that janitors and other more or less uninstructed persons sprayed the schools with formalin and various disinfectants, irrespective of the cleanliness of the building. So great is the public faith in disinfectants, no matter how applied, that this ritual not only gave signal satisfaction but engendered complete confidence and, indeed, was frequently demanded in the face of an outbreak as an effective and necessary preventive measure. For some time past this fetish has been replaced by a higher standard of cleanliness at all times, and in particular by a process akin to the domestic "spring cleaning" at each holiday period. It is probably immaterial whether the school cleaner adds disinfectant to her scrubbing-bucket or not, beyond the fact that most disinfectants leave behind them that coal-tar odour upon which the public has been taught to rely by years of skilful advertisement. It is the cleaning that matters.

The two important points recognised to-day in the prevention of school infections are the exclusion of the sick or potentially sick and a high standard of cleanliness. Actual disinfection by the sanitary staff, and the destruction of books and other articles, may still be thought desirable in certain instances. This is a matter for the judgment of the medical officer and not a routine procedure. As pointed out in a recent circular of the Scottish Board of Health (now Health Department for Scotland) these and similar measures should go a long way towards avoiding the wasteful and inconvenient method of school closure. In fact the Board went so far as to say that closure should never be required in urban areas and rarely in rural districts, where admittedly the school is the chief meeting place of the younger members of the community.

Inanimate Objects and the Spread of School Infections.

It is evident that common drinking-cups might convey diphtheria and that a sucked penholder might convey scarlet fever or exchanged caps ringworm; beyond these occasional and accidental sources of mischief, do book, desks, and other things in daily use convey infections at all frequently? It is not practicable to demonstrate the presence or absence of specific disease germs on these articles, even during an epidemic, but it is possible to examine bacteriologically things used in school and to obtain some idea of the flora they may carry.

For the purpose of this investigation substances were chosen which come into intimate contact with children and, in the case of younger children, doubtless with their mouths. The substances examined were plasticine and glitter-wax, both used for modelling, and sand from a large sand tray used chiefly for geography lessons. The sand originally came from the sea-shore in the north-east of Scotland. Glitter-wax is used for the same purpose as plasticine, but is hard and rather brittle until warmed by the hand. Samples of these substances were collected in sterile containers and examined for micro-organisms, particularly staphylococci, streptococci, and members of the *Bacillus coli* group. The result was largely negative, or the inquiry would have been pushed further. Various culture media suitable for the purpose were used, and I am greatly indebted to Dr. A. Nimmo Smith, lecturer in bacteriology in the School of Medicine of the Royal Colleges, Edinburgh, for carrying out the work.

1. An unused sample of plasticine proved to be sterile.

2. A sample of plasticine that had been in use from three to four months gave the following:—

Surface Results.

Agar plate.	Broth.	Bile-salt-lactose-peptone water.
Six colonies of *Staphylococcus albus*. Seven colonies of *Sarcina lutea*. One colony of a Gram-negative bacillus not fermenting glucose, lactose, or mannite.	No strepto-cocci.	No *B. coli*.

Centre: No growth.

3. A sample of plasticine that had been in use for five or six months in another school also appeared to be free from pathogenic organisms. Cultures from the surface gave a growth of a large Gram-positive coccus of the *Micrococcus tetragenus* type. No streptococci, *B. coli*, or other bacteria were found. Cultures from the centre yielded a pure growth of *B. subtilis*.

4. An unused sample of glitter-wax proved to be sterile.

5. A sample of glitter-wax that had been in use for four months gave the results shown in the following table.

The spore-bearing and almost universally present *B. subtilis* was the only organism grown from the centre of samples 3 and 5 after they had been flamed.

(1) *Surface;* (2) *Centre.*

	Agar plate.	Broth.	Bile-salt-lactose-peptone water.
(1)	*Staph. aureus.* *Staph. albus.* Gram-neg. bacilli, one of the chromogenic bacilli. Growth scanty; staph. not hæmolytic.	*B. subtilis.* No streptococci.	Neg. for *B. coli.*
(2)	No growth.	*B. subtilis.* No streptococci.	,,

6. A sample of sand that had been in use for about four months was treated as follows: (*a*) A small portion was placed in broth and a plate-culture made on agar from the broth after 48 hours' incubation. The plate showed *Bacillus subtilis*, Gram-negative bacilli, and Gram-positive diplococci. No streptococci or staphylococci were found. (*b*) A small portion was placed in McConkey's bile-salt-lactose-peptone water. The culture showed slight acid, but no gas after four days, and on plating out on McConkey's medium there was a growth of three types of lactose-fermenting colonies: (1) a Gram-negative bacillus growing in translucent non-mucoid colonies, (2) a Gram-negative bacillus growing in heavy mucoid colonies, and (3) a Gram-positive diplococcus which was not examined further.

Further fermentation tests with the two Gram-negative bacilli gave the following results:—

—	No. 1.	No. 2.
Motility	Motile.	Motile.
Glucose	Acid and gas.	Acid and gas.
Lactose	,, ,,	,, ,,
Saccharose	Nil.	,, ,,
Dulcite	,,	Nil.
Mannite	Acid and gas.*	Acid and gas.*
Adonite and Inosite ..	Nil.	Nil.
Litmus milk	Acid and clot.	Acid.
Indol	Nil.	Nil.
Gelatin	No liquefaction.	No liquefaction.

* Both are apparently atypical forms of *B. coli.*

This investigation, so far as it goes, confirms the view that inanimate objects do not commonly harbour the germs of disease. With the exception of the sand, the substances examined showed a reasonable degree of bacteriological purity, and even from the sand no actually pathogenic organism was isolated. Of course, any article used in schools might carry infection temporarily, and it is realised that some organisms, such as tubercle bacilli, may exist for indefinite periods in collections of dust and dirt. Furthermore, particular cultural methods applicable to certain organisms might occasionally reveal their presence, although many of those associated with disease do not seem to exist for any great length of time apart from living creatures and organic matter.

A higher standard of cleanliness creates an environment unfavourable to pathogenic organisms, so it may be concluded that this and other common-sense measures (such as individual supplies of books, pens, and plasticine) go far to render the impersonal factor in school infection negligible.

Except in certain circumstances disinfection of schools is probably unnecessary and useless, and the so-called disinfection sometimes practised is "eye-wash," calculated to give the public a false sense of security. The personal factor is the one that really matters, calling for constant vigilance on the part of teachers and officials, together with the enlightened coöperation of the parents.

ROYAL SANITARY INSTITUTE.—As we have already announced, the fortieth congress of this Institute will be held at Sheffield from July 13th to 20th. Next year the corresponding congress will be held at Margate from June 21st to 28th.

GENERAL ELECTION, 1929.

HOW THE UNIVERSITIES VOTED.

BY ALFRED J. GRAY, M.A., B.Sc.,
ASSISTANT SECRETARY, PROPORTIONAL REPRESENTATION SOCIETY.

IN the General Election which has just gone by a large proportion of the medical profession will have voted for a University representative as well as in their own constituency. The system of voting in the two cases has been different and it may be of interest to recall how these differences have arisen. In 1917 an all-party Conference, including members of both Houses of Parliament, was appointed, under the chairmanship of the Speaker, to make agreed recommendations for the Reform Bill then in prospect. From this Conference issued adult suffrage for men and partial adult suffrage for women, now extended to universal adult suffrage. Certain amendments in the method of election were also proposed with a view to ensuring a closer relation between political opinion in the country and its representation in Parliament. It was unanimously recommended that the principle of proportional representation should be applied in the large cities and in thickly populated industrial districts (amounting to some one-third of the present membership of the House of Commons), and in Universities returning two or more members. Further, a majority decision was given in favour of the alternative vote system for the remaining constituencies.

The need for some reform of this nature has been emphasised by the general elections since 1918, notably by the election just held, where more than half the contested seats for the House of Commons were won on a minority vote. But in 1918, Parliament was not prepared to accept any important alterations of the electoral method. The only change made was to adopt proportional representation for University constituencies returning two or more members. These constituencies are now four in number: Oxford, Cambridge, the other English Universities (except London) in one combined constituency, and the Scottish Universities. In 1918, Dublin University likewise elected two members to the House of Commons by proportional representation. Since the formation of the Irish Free State in 1921, Dublin University no longer sends members to the House of Commons, but it still elects its representatives to the Irish Dáil by proportional representation.

One-Member Universities.

Universities in Great Britain include, in addition to those mentioned, the University of London and the University of Wales, each electing one member to the House of Commons. Their experience in the general election may be very briefly described. In each case there were three candidates, and in each case the sitting member improved his position, notably so in the case of Dr. Graham Little of London University, who, in Sir John Gilbert and Mr. W. T. Layton, was faced with two strong opponents. The comparative figures for London University in the two elections in 1924 and 1929 are given below:—

1924.

Dr. Graham Little	(Ind.)	.. 3202	Elected.
Sir J. R. Bradford	(Con.)	.. 2813	
Prof. A. F. Pollard	(Lib.)	.. 1539	
Dr. F. G. Bushnell	(Lab.)	.. 1087	

1929.

Dr. Graham Little	(Ind.)	.. 5869	Elected.
W. T. Layton	(Lib.)	.. 2923	
Sir John Gilbert	(Con.)	.. 2179	

Proportional Representation in the Two- and Three-Member University Constituencies.

The results in the Universities using the proportional representation system may first be examined in their broad outlines, as shown in the following statement.

Combined Scottish Universities.

	Votes.	*Seats.*
Con. ..	15,714 ..	2
Lib. ..	6,698 ..	1
Lab. ..	2,691 ..	–
Total	25,103 ..	3

Quota which ensures election (one more than one-fourth of the votes)—6276.

Combined English Universities.

	Votes.	*Seats.*
Con. ..	4,441 ..	1
Lib. ..	2,231 ..	–
Ind. ..	3,331 ..	1
Total	10,003 ..	2

Quota which ensures election (one more than one-third of the votes)—3335.

Oxford University.

	Votes.	*Seats.*
Con. ..	8,186 ..	2
Lib. ..	3,277 ..	–
Total	11,463 ..	2

Quota which ensures election (one more than one-third of the votes)—3822.

Cambridge University.

	Votes.	*Seats.*
Con. ..	11,425 ..	2
Lib. ..	3,099 ..	–
Lab. ..	1,463 ..	–
Total	15,987 ..	2

Quota which ensures election (one more than one-third of the votes)—5330.

It will be observed that within the somewhat narrow conditions imposed, the result in each case reflects as nearly as possible the political opinion of those voting. In the Scottish Universities, returning three members, the substantial Liberal minority secured one seat, as it has done consistently since P.R. was introduced in 1918. This may be contrasted with the results which prevailed in the interval between the last two Reform Acts, 1884 and 1918. During this whole period, when elections went by majority, the representation of academic opinion in Scotland was purely Conservative. The union of all the Scottish Universities, the addition of one member to their representation, and the introduction of proportional representation, gave the Liberal minority the opportunity of making its views heard at Westminster. In view of the prominent place occupied by the Faculty of Medicine in Scottish Universities, it was fitting that two of the candidates should have been members of the medical profession. Sir George Berry, ex-President of the Royal College of Surgeons, Edinburgh, has been elected continuously since 1918. Dr. James Kerr, a new candidate whose public work in the field of school hygiene is well known, was nominated by the Labour Party.

The Combined English Universities, like the Combined Scottish Universities, have, at each election since 1918, secured a varied representation. Up to 1924, a Conservative and a Liberal were elected. In 1929 the Liberal was displaced by a strong Independent in the person of Miss Eleanor Rathbone, who thereby enjoys the distinction of being the first woman returned by a University in Great Britain. Not only so, she was placed at the head of the count on first preference votes, the Conservative vote being divided between two candidates.

In Oxford and Cambridge the majority party outnumbers the minority, or minorities, by more than two to one, so that even under proportional representation both seats properly fall to the majority party.

Second Preferences at Oxford.

The election at Oxford University may be described in somewhat greater detail as some misunderstanding with regard to it has been publicly expressed. The position of candidates on the first count was as follows:—

Lord Hugh Cecil	(Con.)	.. 6,012
Prof. Gilbert Murray	(Lib.)	.. 3,277
Prof. Sir Chas. Oman	(Con.)	.. 2,174
Total		.. 11,463

Under proportional representation elections are determined not by a majority, but by a quota of votes, this depending on the number of votes cast and the number of seats to be filled. In an election of two representatives, the quota is one more than one-third of the votes, the minimum number which can be obtained by two candidates and not by three. In an election of three representatives, the quota is one more than one-fourth of the votes, the minimum number which can be obtained by three candidates and not by four; and so on.

In Oxford the quota was 3822 votes, and Lord Hugh Cecil was elected at the first count with 2190 votes to spare. In order to transfer this surplus fairly as between the other two candidates, regard was had to the next preferences of all the voters who originally supported Lord Hugh Cecil. Of Lord Hugh Cecil's supporters, eight out of every nine, in round numbers, gave a second preference for Sir Charles Oman, the second Conservative candidate. The exact figures of the votes transferred were, 1938 to Sir Charles Oman and 252 to Prof. Gilbert Murray, placing the candidates as follows:—

*Lord Hugh Cecil	(Con.)	.. 3822
†Prof. Sir Chas. Oman	(Con.)	.. 4112
Prof. Gilbert Murray	(Lib.)	.. 3529

*Elected 1st. †Elected 2nd.

The Conservative voters were thus enabled by the proportional representation system to distribute themselves, as it were automatically, in the most advantageous way. Both the Conservative candidates were now supported by a larger group of voters than was obtained by Prof. Gilbert Murray, and were therefore elected.

It has been said, in reference to this election, that but for the operation of proportional representation, Prof. Gilbert Murray would have been elected. This view is mistaken. Had the election been contested under the method formerly used in the Universities, and which still prevails in a few two-member boroughs, each voter would have had two votes (not one, as under proportional representation) and the great majority of the Conservative voters, 8000 in round numbers, would have supported both Lord Hugh Cecil and Sir Charles Oman. The result would have shown Cecil and Oman at the top of the poll with 8000 votes apiece, and Murray with some 3500, or possibly slightly more.

General Effect of P.R. on University Representation.

It will be seen that the general effect of proportional representation in the Universities has been to broaden the basis of representation. Minorities, which under a purely majority system, would have been in a hopeless position, have been given a fighting chance, and in two of the Universities have succeeded in returning representatives. This result is greatly to the advantage of University representation, which is thereby freed from the charge, to which it was formerly open, of being practically a preserve of one political party.

THE LISTER INSTITUTE OF PREVENTIVE MEDICINE.

RESEARCHES IN PROGRESS DURING 1928–29.

THE annual report for 1928, after noting changes in the personnel of the council and the staff, acknowledges the generosity of other organisations concerned with the promotion of research in giving financial support to individual workers and their assistants. For example, the Medical Research Council furnish the salaries of the staff of the National Collection of Type Cultures, of Prof. Korenchevsky, who is working on the endocrines, and of Miss E. M. Hume, Dr. T. Lumsden and his research assistant, Miss Kohn-Speyer, are endeavouring to work out a method of vaccine treatment for implanted and spontaneous malignant tumours, and are continuing tissue culture experiments, under a grant from the British Empire Cancer campaign.

An account follows of the experiments in progress in each of the six departments of the Institute. Since many of the workers in various departments are concerning themselves with different aspects of the same subject, independently or in coöperation, the range of activity of the Institute is wide. Among the investigations of topical interest is that on

Vaccinia. Methods of Modifying Vaccine Virus.

Prof. J. C. G. Ledingham with Dr. Douglas McClean has demonstrated the possibility of propagating vaccine virus from dermis to dermis of the rabbit by intracutaneous inoculation. In the course of such passage the virus appears to acquire a greatly increased capacity for proliferation in the dermis and a correspondingly diminished capacity for proliferation in the shaved skin. The dermal virus is free from contaminating bacteria and has been cultivated successfully through four generations in vitro by Dr. G. H. Eagles and Dr. McClean, who used the technique of Carrel and Rivers for the culture of the tissues of chick embryo. An increase to 5,000,000 times the amount of virus in the original inoculum occurred.

Considerable irregularity in multiplication of the virus is observed, and that the virus had not changed its character became apparent when lesions before and after cultivation were compared by scarification and intradermal inoculation of the skin of rabbits; moreover, virus propagated in vitro is neutralised by antivaccinal serum from an immune rabbit. Unlike calf lymph, it deteriorates rapidly, even when kept at a temperature of 0°–2° C. There is evidence that changes in oxidation-reduction potential are important factors in this deterioration which cannot as yet be prevented.

During the past winter generalised lesions in the skin and various viscera have been observed among rabbits inoculated with vaccinia at the Institute. All these animals, however, suffered from snuffles, and organisms of the Pasteurella group were isolated from them. Certain of the stock rabbits at the time also showed symptoms of active pasteurellosis. Dr. Ledingham, who is working with Dr. Mary Barrett on this problem, suggests that the generalised lesions following the intravenous inoculation of highly virulent virus, which have been reported by other observers, may be due to activation of latent pasteurellosis in the rabbits by vaccinia and not to the unaided action of the virus itself.

Dr. Ledingham has also studied the "elementary bodies" in vaccine virus which were first described by Paschen in 1906. These bodies ($0{\cdot}2\,\mu$ in diameter) may or may not represent the actual virus, but in any case they deserve more attention than has yet been given them, particularly in view of the fact that the virus in vaccine lymph is held back by bacterial filters.

In the department for the study and preparation of anti-variolous vaccine Dr. A. B. Green has continued his attempts to raise the virulence of the vaccine virus in vitro. Initial experiments have been made in an endeavour to ascertain whether vaccine virus other than a dried preparation can be kept at a high stage of potency at ordinary temperature.

In the course of experimental work on foot-and-mouth disease for the Research Committee of the Ministry of Agriculture, Mrs. Y. M. Gibbs (formerly Mrs. Burbury) has tried the effect of inoculating guinea-pigs with mixed foot-and-mouth disease and vaccinia viruses. It was found that both or one of these diseases might develop unaltered. It was easy to detect foot-and-mouth virus when mixed with vaccinia virus by the generalised vesicles produced by foot-and-mouth virus, but not by vaccinia. The results of these experiments depended largely on whether the part of the skin inoculated was more susceptible to one or the other virus.

An arrangement has been made for the examination (histological and experimental) of any material that may become available from cases of post-vaccinal and other forms of encephalitis by Dr. E. Weston Hurst and Dr. R. W. Fairbrother. These workers are primarily concerned, however, with the investigation of a filterable virus, for they have been appointed under a special grant to embark on research on poliomyelitis in conjunction with five other selected institutes in Europe and America. Mr. Milbank, of New York, has provided £2000 annually for three years to each selected institute towards the cost of this work. Dr. S. Flexner, of the Rockefeller Institute, has generously sent a supply of potent virus.

The histology of the experimental disease in monkeys has been reinvestigated with the aid of improved methods in neuropathological technique.

There is divergence of opinion as to the nature of the cellular reaction, both in monkeys and in the human disease, and most authors believe the lesion to be a primary interstitial inflammation with secondary involvement and destruction of the nerve-cells. The newer silver-impregnation methods devised by Del Rio Hortega have revealed new types of cell in the nervous system; among these the microglia has now been found to play an important rôle in the cellular response to infection with the virus of poliomyelitis. The application of the oxidase reaction has shown that polymorphonuclear leucocytes play a greater part than has been generally believed. Dr. Hurst and Dr. Fairbrother's studies have already shown clearly that the nerve cell destruction is to be regarded as a primary event and not due to the interstitial changes.

In connexion with ætiology their results indicate that coccal organisms are not ætiologically connected with the disease but are most probably air-borne contaminants, though it is possible that organisms belonging to the nasopharyngeal flora may occasionally gain access to the blood stream in the course of the disease. The relationship of the so-called "globoid" bodies to the disease is now being examined.

Attempts made to reproduce poliomyelitis in rabbits so far have failed. Samples of serum from poliomyelitis convalescents, obtained from different sources, have been found to possess neutralising properties; monkeys intracerebrally inoculated with mixtures of serum and virus have remained well. However, no immunity was acquired, since all succumbed to a later inoculation of virus. An investigation into the path of spread of virus in the experimental animal is said to be well advanced.

Experiments in Nutrition.

The water-soluble B vitamins are now definitely established as (1) antineuritic, anti-beri-beri, more heat-labile vitamin B_1; (2) anti-dermatitis, anti-pellagra, more heat-stable vitamin B_2. Miss H. Chick, D.Sc., and Miss M. H. Roscoe have continued their efforts to isolate vitamin B_2 from yeast. Some samples containing vitamin B_2 free from vitamin B_1 have been obtained by the process used (the addition of lead acetate to an extract of washed yeast cells made with acetic acid), but this result was not constant and seems to depend on the relative amounts of the two vitamins present in the original yeast. The properties of vitamins B_1 and B_2 have been studied and differentiated, and their distribution in natural foodstuffs worked out quantitatively by biological methods based on growth response in rats.

Mr. W. R. Aykroyd and Miss Roscoe have made a systematic assay of vitamin B_2 in wheat and maize grains and their constituent parts. These two cereals were chosen because a striking discrepancy in their content of vitamin B_2 might explain the connexion between pellagra and the consumption of maize. Unfortunately for that interpretation, the germ and bran of wheat proved to be fair sources of vitamin B_2 and the immunity to pellagra of people using wheaten bread would seem, therefore, to be due to other constituents in the diet commonly consumed by such populations.

The cereals were found to be poor sources of B_2 compared with yeast and many foods of animal origin, as, for example, liver, egg-white, milk, meat-muscle, and to a less degree, egg-yolk. The results obtained correspond with the relative values of these foods for the prevention and cure of pellagra observed by Goldberger and his colleagues in the United States and thus support their views of its ætiology. Apart from yeast, which contains both factors, the distribution of B_2 seems to be very different from that of B_1.

Rats on a diet devoid of B vitamins will frequently maintain fair health with subnormal growth if allowed to eat their own dried fæces. It has been suggested that these vitamins may be synthesised by the activity of bacteria inhabiting the lower part of the alimentary tract.

Miss E. M. Hume and Miss H. Henderson Smith have completed the biological examination of irradiated zymosterol in conjunction with Mrs. I. Smedley-MacLean, D.Sc., who has discovered this new sterol, and more recently still another unsaturated sterol in yeast. The specificity of ergosterol, in acting as pro-vitamin D, however, remains unchallenged. Experiments to investigate the possible synthesis of ergosterol in the animal body and the occurrence and nature of vitamin A and its relation to carotene are being devised.

Dr. H. Schütze and Dr. Zilva are studying the influence of a diet deficient in fat-soluble vitamins on the development of sensitivity to tuberculin in rats infected with tuberculosis.

Experimental researches on the antiscorbutic principle (vitamin C) are being conducted by Dr. S. S. Zilva for the British Empire Marketing Board.

He is continuing the chemical investigation of the antiscorbutic factor in lemon-juice and is devoting further attention to the study of the cause of the spontaneous inactivation of the vitamin.

Dr. Zilva, Mr. E. Hoyle, and Miss M. F. Bracewell, working on the variation of the antiscorbutic factor in apples, found that the variation in activity is more dependent on the variety of the apple than on its origin. Baking a cooking apple in its skin did not destroy its antiscorbutic activity. Gas storage seems to be less favourable than cold storage to the preservation of the antiscorbutic activity of the apple.

Dr. Zilva, Miss Soames, and Miss Perry have commenced an investigation into the limitations in the accuracy of some of the methods of assay of the vitamins, notably to Hojer's test for vitamin C.

Biological Action of Light.

Sir Charles Martin has tried to determine what proportion of the total radiant energy of sunlight is absorbed by the skin and various fabrics and converted into heat. This can only be indirectly found by ascertaining the proportion scattered and turned back. The absorption through the skin of a number of Europeans with fair and dusky skins was determined and also that of Indians and a negro. The proportion absorbed varied from 65 per cent. in the very fair to 87 per cent. in the negro.

The total solar energy impinging upon the surface of a man of average size is about 4000 calories per minute when the air is clear and the altitude of the sun is 45°. If three-quarters of this is absorbed, this supplement to the heat normally formed in the body at rest would increase the rate of heating fourfold. It is, therefore, understandable how well-browned children at an Alpine sanatorium can run about naked on the snow without becoming cold, although the temperature of the air may be some degrees below freezing point, as long as they are in the sun and there is no wind.

The permeability of the epidermis to radiation capable of activating ergosterol is being investigated by Dr. N. S. Lucas. His observations indicate that the transparency to ultra-violet light of keratin, chitin, and epidermis, which is smaller than that of other proteins, is due to the high content of cystin and aromatic groupings in the former.

The colony of tropical monkeys (marmosets) irradiated with ultra-violet rays continue to thrive and breed, casualties being due to special causes. It is hoped in the immediate future to compare the breeding capacity of marmosets fed on vitamin D with that of those in which the vitamin has been produced by direct irradiation. The squirrel monkeys have not continued to thrive. It is now clear that they require more energetic antirachitic treatment than do the marmosets.

A pneumococcal infection among guinea-pigs being bred for use in the department for the study and preparation of antitoxic sera still persists, but to a diminished extent. On the assumption that the higher incidence of this infection during the early months of the year might be attributable to lack of sunlight, one-half of the breeding stock was regularly irradiated by means of a mercury-vapour lamp, the other half serving as a control. The experiment lasted for one year. No benefit accrued from the light treatment; as it happened, the control stock appeared to give better results both as regards general health and fertility. The improvement in the stock as a whole is probably ascribable to changes in diet, and to selection for breeding purposes of the progeny of animals with a "clean" breeding history, and presumably with a natural resistance to infection with this strain of pneumococcus.

The Experimental Production of Pneumococcal Endocarditis.

Evidence has been obtained by Dr. G. F. Petrie that an infective endocarditis can be readily induced in immune rabbits by intravenous injections of living cultures of a virulent strain of pneumococcus, provided that, in addition, they are subjected to recurring losses of blood by cardiac puncture.

An obvious possible explanation for the occurrence of endocarditis after this procedure is that the slight trauma occasioned by puncturing the heart may facilitate an infective focus, which forms the starting-point of a vegetative endocarditis. The experimental technique was, therefore, modified by substituting for cardiac puncture repeated withdrawals of blood from the jugular vein. Although in a number of rabbits thus treated an amount of blood equal to the total blood volume has been removed, signs of cardiac disease have not so far appeared. On the other hand, a rabbit rendered anæmic by a series of sub-lethal intravenous injections of an anti-rabbit-red-cell serum developed a typical mitral endocarditis which ended fatally. This animal was treated in exactly the same way as those just mentioned except that blood-letting was not practised. From the heart-blood of this rabbit an avirulent variant of the original strain of pneumococcus was isolated.

The experiments suggest that the injurious action of anti-red-cell serum on the vascular endothelium, as well as upon the red cells, predisposed to the infective process. A fresh series of experiments on similar lines has been begun to test the correctness of the theory, which, if confirmed, may throw light upon the pathogenesis of infective endocarditis in man.

MEDICINE AND THE LAW.

Charge of Negligence against a Practitioner.

FOREIGN observers are often laudatory and sometimes critical of the English jury system. If they collect curious instances, they will not omit the recent case of Shewry *v.* Maybury in which twelve laymen were asked to pass judgment upon the propriety of a medical practitioner's diagnosis and treatment of the state of health of an infant child more than eight years ago. The infant's father brought an action against Dr. L. Maybury of Hampshire-terrace, Southsea, complaining that the latter wrongly diagnosed the child to be suffering from congenital syphilis in August, 1920, and unnecessarily and improperly injected a preparation known as "N.A.B." into the longitudinal sinus channel of the head with the result that the child had convulsive fits and is now an incurable mentally defective epileptic. Dr. Maybury in reply admitted that he injected N.A.B., but denied that he was guilty of any negligence or want of skill and said that his treatment was in accordance with the best medical practice. Thus the twelve laymen were asked to perform the seeming miracle of deciding what was the proper treatment in August, 1920, of a child then 14 days old. In this task they were, of course, assisted by the evidence of medical experts, by the arguments of learned counsel, and by the impartial summing up of the judge. But it need occasion no surprise to find that their answers to a string of specific questions failed to furnish a clear reply. Asked whether the condition of the infant plaintiff was caused by Dr. Maybury's treatment, they failed to agree. This being the crucial question, it would seem that the plaintiff failed to establish his case and is left at liberty to bring his action afresh before a fresh jury. But the position is complicated by further questions and answers. Asked if Dr. Maybury believed that the infant had congenital syphilis, the jury answered, "Yes." Asked if Dr. Maybury was negligent in diagnosing that the infant was suffering from congenital syphilis, they answered

"Yes." Asked if he was negligent in deciding on the method of treatment, they answered, "No." Asked if he was negligent in the way in which he administered the treatment, they answered, "Yes, in his general treatment." What the total effect of these answers may be, and whether they furnish ground on which it can be definitely said that the plaintiff has either succeeded or failed—these are matters reserved for further discussion by counsel before the Lord Chief Justice at some future date. It may perhaps be added here that the point was sought to be made against Dr. Maybury that he had not warned the midwife of the child's condition and that consequently she might have contracted the disease and given it to her next patient. It is impossible to know what considerations influence a jury's individual or collective wisdom; but, if such a point had any influence, it would appear that Dr. Maybury's omission to warn the midwife—if he did so omit—was a matter which did not aggrieve the infant or its father so much as the midwife and her future patients. The broad principles applicable to these actions for negligence against medical practitioners are first that the burden of proof is on the plaintiff, and secondly, that, before a doctor can be found to have been negligent, he must have fallen below the ordinary standard of his profession; it does not matter that some other doctor might have done something better nor is it the question whether he has made a mistake. "The jury," as Lord Hewart once said in another case, "should not exact the highest or a very high standard, nor should they be content with a very low standard."

The plaintiff's case was opened to the jury as that of a poor little innocent child blasted at its birth by an incompetent doctor needlessly performing a most hazardous operation. Every mother who read the opening day's proceedings must have thought Dr. Maybury a fiend incarnate. Medical witnesses in support of the plaintiff's claim suggested that the child was suffering from a postnatal condition, and stated that an injection of a solution of arsenic into the brain cells must be immediately destructive, and that it was wrong to treat a child of 14 days with arsenic. Injection of a drug into the sinus vein, it was said, was easy but mistake was easier; the operation had fallen into disrepute because of the possibility of mistake. Medical witnesses for the defence gave evidence which one would suppose no jury could reject. Dr. Maybury said the child was sickly from birth, did not thrive, was feeble and constantly crying; after about a week it developed "snuffles" and a characteristic rash and had jaundice. On those symptoms he diagnosed syphilis; his assistant, Dr. Eberle, agreed with the diagnosis and gave evidence to that effect. Dr. George Riddoch, who was also called, had seen the child in hospital in 1924; he did not believe its condition was due to injections of N.A.B.; the child was apparently becoming worse. Dr. J. J. Abraham, D.S.O., said that in 1920 the injection of N.A.B. into the longitudinal sinus vein was considered the best method of treating congenital syphilis in an infant. He had himself treated 100 to 150 children in that way; he knew of no case of ill-results; it was not a difficult operation; it was incorrect to say that N.A.B. injections were no longer given, or that injection should not be made in the case of an infant 14 days old. If Dr. Maybury's diagnosis were wrong, the injections would not harm the child; he himself used N.A.B. as a tonic; N.A.B. could not destroy the brain if it came into contact therewith; if there had been a deep-seated injury in 1920 from mechanical means, the child could not have survived. Mr. A. L. Abel, F.R.C.S., gave confirmatory evidence; he had examined the child last March and found it a severe but typical case of Little's disease, a congenital ailment. Dr. R. C. MacPherson, medical superintendent of St. Mary's Hospital, Portsmouth, said the child was an imbecile, a typical case of Little's disease with advanced mental symptoms and becoming progressively worse. Dr. F. M. R. Walshe also said the child was a characteristic severe case of Little's disease, with "brutish" features and a rather small head; the child was its mother's first-born child; there had been precipitate birth, a feature of Little's disease. Without going further into the evidence, enough has been said to indicate the obstacles which a jury would have had to surmount before they could have held Dr. Maybury to have been negligent. One might go further and ask whether, if a practitioner is to be found guilty of negligence in the face of such evidence and in respect of an incident more than eight years old, any practitioner could be safe from the hazards of litigation.

Colonel Kynaston and the General Medical Council.

On June 19th a motion was submitted in the High Court on behalf of Col. J. W. Kynaston for a rule *nisi* for a writ of mandamus directed to the General Medical Council. He asked that the Court should call upon the Council to delete his name from the Medical Register at his own request and to erase from the Register all record of the fact that his name had been deleted for professional misconduct. As is probably known, a writ of mandamus is a method of remedying some defect of justice; it takes the form of a command from the High Court to some lesser tribunal or to some body, requiring some particular step to be taken which lies within the functions of that tribunal or body and which is both of the nature of a public duty and consonant with right and justice. If an aggrieved person has no other obvious remedy, he can sometimes have recourse to a mandamus. If, contrary to the famous phrase in Magna Charta, there has been a selling or a denying of justice, a mandamus may issue to put matters right. Col. Kynaston was granted his rule *nisi*, a preliminary step to further argument—this time with the General Medical Council represented—and a considered decision. The point is interesting. Col. Kynaston, if his position is correctly understood from the reports of the recent proceedings, says in effect: "I am perfectly entitled to practise (subject to certain recognised statutory disabilities) without having my name upon the Medical Register: I can decide whether I will be a registered or unregistered practitioner: on a certain date I elected to practise in future as an unregistered practitioner: after I had made that election, the General Medical Council had no right to strike off my name on some other ground." If the writ of mandamus is to issue, remarked the Lord Chief Justice, you must allege that something was done which is wrong in law. It was wrong, replied Col. Kynaston's counsel, to hear evidence about charges after application had been made voluntarily for the removal of the name. Lord Hewart's next question went to the root of the matter. "Do you say," he asked, "that it is contrary to law or natural justice that, where a man, having offended, voluntarily applies to have his name removed, the Council may not say, 'Before we decide whether your name shall be removed at your request, we will look at the circumstances and see whether we shall not remove it in a somewhat different spirit'?" The answer on Col. Kynaston's behalf was that the General Medical Council had no inherent disciplinary power; they had purported to usurp a semblance of discipline by stretching the words "infamous conduct" to mean anything of which they disapproved. At this point, it would seem, Col. Kynaston's advisers were on the fringe of reopening the merits of the Council's decision in their client's case. This line the law-courts have hitherto refused to follow. A practitioner's name may be struck off the Register in the first place if he has been convicted of felony or misdemeanour, or in the second place if he has been deemed guilty of infamous conduct in a professional respect. Chief Justice Cockburn laid down the rule in La Mert's case that the High Court had no more power to review the General Medical Council's decision on a question of "infamous conduct" than to reopen the question whether a practitioner had been rightly convicted of felony or misdemeanour. Lord Justice Lopes quoted this opinion with approval

40 years ago in H. A. Allbutt's case,[1] and the principle thus established has never since been doubted. Mandamus will not be granted to compel the Council to restore a name to the Register if the Council has properly exercised its quasi-judicial discretion in examining a charge of "infamous conduct." Col. Kynaston, therefore, it seems, though he can ask public opinion to declare that he has been unfairly treated, cannot ask the law-courts to reopen the merits of the Council's decision. The High Court has granted him his rule *nisi*, "at his peril," as Lord Hewart observed. If we set the facts and arguments in Col. Kynaston' case entirely aside (since they are subject to judicial consideration) and view the matter in the most general and impersonal way, we see an important issue. The preamble to the Medical Act signifies the expediency in the public interest of the existence and maintenance of a register of qualified medical practitioners. Parliament has entrusted the General Medical Council with a certain authority to preserve professional standards. Is it, or is it not, important that the Register should have some permanent character in the sense that its value should not be vitiated by abrupt and possibly capricious withdrawals? Is it, or is it not, important that, once the Council is seized of an issue relating to professional conduct, its jurisdiction should not be ousted and stultified by the voluntary withdrawal of the practitioner's name from the Register? These are the problems which it may be hoped that the High Court's decision will solve.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Social Insurance Law.

THE Confederation of French Medical Syndicates has now held its general meeting, the delegates representing 17,000 practitioners, and of course the main subject of discussion was the new social insurance law. Let me briefly recall the history of this measure, at which the French Parliament has been working—if one may so describe it—for nearly ten years. Both Chambers have studied it by means of various commissions, and last year a first text was approved both by deputies and senators. A complementary text, called the "rule for administration," has since been added which is intended to settle all the smaller points that the general law has not touched upon. The whole Act is supposed to come into force on April 1st of next year, by which time the offices are to have everything prepared.

Now let us see what has been happening to the medical profession during this period. Some years ago, just when Parliament was deciding to complete the drafting of the law, the medical profession split into two parts—the old Union of Syndicates and a new Federation of Syndicates. This was the worst thing that could have happened, just when difficult negotiations with the Government were beginning, and it was only last year that the two rival associations united under the title of the "Confédération des syndicats médicaux de France." By that time the Act was already passed, though the "rule for administration" had not yet been considered.

One last explanation is necessary. The new law was voted in haste two years ago just before the general election, and with the electorate in mind. The Government promised at the time that it would come back for revision and modification after the election, but nothing of the sort has been attempted in the two years that have passed since then. The meeting of the delegates of the syndicates was thus faced with a well-defined situation, and strong in its new unity decided on a full campaign for revision of the law. The unanimity of the delegates has shown that the law cannot be accepted in its present form, in which professional discretion, the free choice of doctor and various other items have not been considered in accordance with the wishes of medical men in this country. A fund for the campaign has been started, and every member of the profession in France is asked to send 100 francs.

It is interesting to see that laymen who were somewhat hostile to the profession on this particular question some months ago are now beginning to change their attitude. It was noticeable, for instance, that many newspapers gave the text of the paper voted by the Confederation—a thing they would not have done two years ago. And the Government itself is not quite so confident as it was about getting the law to work next April.

Experimental Syringomyelia.

Dr. Levaditi, of the Pasteur Institute, has succeeded in inoculating syringomyelia into foxes with a filterable virus coming from an epidemic disease isolated from foxes in the United States by Dr. Green. He has shown at a meeting of the Academy of Medicine the slides of the syringomyelic cavities produced in the medulla of the animals, and he thinks it can be inferred that some human cases may be due to infectious disease.

The International Reunion for Neurology, lately held in Paris, was mainly occupied with the study of dystonies, reports being read on Torsion Spasms by Dr. Wimmer, of Copenhagen, and on Spasmodic Wry-neck by Prof. Barré, of Strasbourg. Prof. Wagner-Jauregg, of Vienna, gave a lecture on his method of treating general paralysis with malaria.

The Society of Surgeons of Paris celebrated its twentieth anniversary some days ago. It was started in 1909 for the benefit of surgeons who could not gain admission to the old Société de Chirurgie, which is almost reserved for men belonging to the regular staff of the official hospitals.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

New Chairs in Sydney University.

GREAT interest has been shown in the contemplated appointment of professors of medicine, surgery, and bacteriology of Sydney University. On Oct. 9th, 1928, Mr. George Bosch, of Sydney, bequeathed to the University a large sum to establish full-time professorships of medicine, surgery, and bacteriology and to endow a department of bacteriology with proper buildings and equipment. The deed of gift provides for the payment of extra remuneration to enable appointees to chairs of medicine and surgery to devote the whole of their time to the duties of their chairs, without the right of private or consulting practice or commercial enterprise associated with the practice of medicine. The donor expressed an earnest desire that the professors so appointed should also act as directors of studies in clinical medicine and clinical surgery, and also direct clinical research. Similarly, the professor of bacteriology must devote the whole of his time to the duties of his chair. It is further provided that, if it should be decided that full-time chairs of medicine and surgery are not in the best interests of the medical faculty, part-time chairs may be re-established at salaries now existing and the extra remuneration not so paid may be devoted to the teaching of research. A committee of the University Senate has been appointed to examine the whole position, and is it not expected that any appointments will be made before six or twelve months.

The Pacific Science Congress.

The following official representatives of the Commonwealth Government and of the National Research Council are attending the Fourth Pacific Science Congress which is being held at Batavia on May 16th: Mr. E. C. Andrews (New South Wales Government Geologist), Mr. G. H. Halligan, Dr. I. M. Mackerras, follows :—Small-pox, 269 under treatment, 10 under observation (last week 301 and 14 respectively), scarlet fever, 1351 ; diphtheria, 1540 ; enteric fever, 12 ; measles, 142 ; whooping-cough, 539 ; puerperal fever, 28 (plus 9 babies) ; encephalitis lethargica, 121 ; "other diseases," 42. At St. Margaret's Hospital there were 22 babies (plus 10 mothers) with ophthalmia neonatorum.

---

[1] See THE LANCET, 1887, i., 707; and ii., 1085, 1119.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (1) from enteric fever, 56 (6) from measles, 9 (2) from scarlet fever, 33 (8) from whooping-cough, 19 (3) from diphtheria, 45 (15) from diarrhœa and enteritis under two years, and 33 (9) from influenza. The figures in parentheses are those for London itself.

Liverpool reported 14 deaths from measles, Sunderland 10, and Salford 4. Liverpool also reported 7 deaths from whooping-cough ; no other great town more than 2. Diarrhœa claimed 4 victims in Manchester, 3 each in Liverpool and Leeds. Birmingham reported 4 deaths from influenza. One death from small-pox provisionally assigned to Brighton C.B. should have been reported in the return for the week ended April 20th.

The number of stillbirths reported during the week was 273 (corresponding to a rate of 38 per 1000 births), including 43 in London.

Obituary.

ERNEST MORTON WYCHE, M.R.C.S. ENG., D.P.H.,

SCHOOL MEDICAL OFFICER, CITY OF NOTTINGHAM.

Dr. E. M. Wyche died on June 13th at his residence in Nottingham in his sixtieth year after a very brief illness. He was educated at Oundle School and the London Hospital, and obtained his M.R.C.S. L.R.C.P. in 1893, and after holding various appointments the D.P.H. Lond. in 1898. For 18 months he served as surgeon on a cable-laying ship, and then went into general practice in Cambridgeshire, but on the inception of the School Medical Service in 1908 he was appointed to South Essex, where he had to do pioneer work in a large rural area. In August, 1914, he was appointed senior school medical officer to the City of Nottingham. The service was still in its infancy and Dr. Wyche devoted himself to extension of the work as rapidly as the difficulties of the war allowed. Careful not to encroach on the work of the general practitioner and the hospitals, he attempted to supply those forms of treatment which were otherwise difficult to secure. The expansion of the service after the war soon brought about the necessity for a bigger central clinic, and he was instructed to work with the city architect in adapting a large building to his needs. The new clinic was opened in November, 1926, and is a lasting testimony to his foresight and ingenuity. He was justly proud of the tonsil and adenoids theatre and wards and of the dental department.

We are indebted to one of his intimate colleagues for the following estimate of Dr. Wyche's work. "He followed closely scientific research on the health of young people, and he was always to the forefront in securing for the children of Nottingham the benefits of new advances. A keen enthusiast on the importance of fresh air, he was instrumental in establishing one of the finest open-air schools in the country. He was quick to realise the value of ultra-violet therapy for the ailing child, and his committee was one of the first to instal this treatment. His detailed organising ability, applied to every aspect of school medical work, was especially shown in his scheme for the ascertainment of mentally defective and dull and backward children. A man who avoided personal publicity, he was loved by all who came in contact with him from the youngest of his patients to the highest officials in the town. The members of his staff feel his death most keenly. They have lost not only a respected chief, but also a sympathetic friend."

Dr. Wyche leaves a widow, a son, and a daughter.

"Audi alteram partem."

THE ESTABLISHMENT OF NORMAL STANDARDS.

To the Editor of THE LANCET.

SIR,—The article by Dr. Lindsey Batten in your issue of June 15th, together with the leading article which it inspired, draws attention to a defect in our outlook that leads to repeated error, illustrated by Dr. Batten's list of old and new "abnormalities" beginning with those aged friends, the retroflexed uterus, the sagging colon and the movable kidney. I was privileged to watch that change of surgical opinion which led to the maxim "never tell a neurotic patient she has a movable kidney," but the maxim was formulated only after much good surgery had been wasted and, to use Dr. Batten's words, "the whole unedifying story repeats itself with a new 'abnormality' and there is no sign that the field is exhausted," for our refinements of technique ensure that an abnormality can be discovered in every neurotic patient. I have before me a report upon a woman, with a history of hysteria going back for years, in which are described elaborate investigations, including the use of the ureteric catheter and duodenal tube, which led to a diagnosis of visceral "trouble" and an outline of treatment winding up with the inevitable course of vaccines. Two surgical operations had previously failed to remove her symptoms, and the excision of a painful scar was now recommended. The evidence of disease was worthless, but to the lay reader of the report the imposing appearance of scientific method concealed the lack of scientific thinking. The patient is now doomed to invalidity.

Such a history is common, but it is doubtful whether the situation would be met by the establishment of physiological standards (which would be left behind by every improvement in mechanical diagnosis). I wonder how medical orators of the future will describe our methods, which involve teaching the student endless refinements of mechanism whilst, in spite of the fact that psychoneurotic complaints are a most serious cause of invalidity, he is left with no clinical instruction in their diagnosis except the pernicious maxim "if you can't find an organic disease you must think of a functional nervous disorder." As we see, modern methods can find an organic disease in anyone. If a candidate at a qualifying examination were asked to examine a patient for the presence or absence of a psychoneurosis he would rightly complain that he had never been taught how to do it ; yet it is safe to deduce that the majority of patients in whom these "abnormalities" are discovered are suffering from psychoneurotic symptoms which, as in the case cited above, are ignored in our keenness for the latest delicacies of mechanical diagnosis. The establishment of standards of mental or "nervous" fitness would be an interesting matter for discussion, but it is plain that we are not ready for it.

I am, Sir, yours faithfully,

Loughton, Essex, June 18th, 1929. MILLAIS CULPIN.

THE PROBLEM OF NEPHRITIS.

To the Editor of THE LANCET.

SIR,—In a description of a case of nephritis which appears in your issue of June 8th (p. 1196) Dr. E. Wordley expresses the opinion that no class of disease would repay better than nephritis a long-continued study over many years. The importance of this remark cannot be too much emphasised though, strange to say, I have not seen this view advanced by any of the able specialists who write on renal subjects. If the various conditions that come under the heading of albuminuria can be properly sifted in the hospital ward or in the laboratory nothing more need be said, as this is being done at present, but if the collaboration of the general practitioner is required no time should be lost in arousing and guiding the research flair which is probably to be found in the family doctor just as much as in the other ranks of the profession.

It is vexatious and humiliating to be brought face to face with cases such as the following and not to be able to give a definite opinion.

A young woman suffered from nephrosis in winter of 1927–1928; has been recently a candidate for Civil Service examination when the urine was quite clear. A young man with brilliant prospects had an attack of nephrosis in March, 1928; albumen persisted for about nine months when the urine became free; after an influenzal attack a recurrence took place and persisted for some time. The urine is now clear.

These are the problems which are continually meeting every practitioner, and it is an opprobrium to medicine that no serious effort is being made to tackle them. Does law or engineering allow itself to be baffled by comparatively simple problems?

I am, Sir, yours faithfully,
Belfast, June 18th, 1929. R. M. FRASER, M.D.

VACCINAL REACTION.

To the Editor of THE LANCET.

SIR,—I recently vaccinated 88 Europeans on a ship bound from India to England. The vaccinations were performed on four consecutive days, and five days after the last was performed the whole group of cases was inspected either by another medical man who was travelling on board the ship or by myself, or (as a rule) by both of us. The vaccine appeared to have taken in 64 cases, or 73 per cent. of the total, and this percentage of successful vaccinations surprised me, because: (1) All the 88 persons had been in countries (chiefly India) where small-pox is an endemic disease. In the 87 cases in which the period of residence in such countries was ascertained its average length proved to be nine years. (2) The average number of previous vaccinations, as stated by the subjects themselves, was 4·7. (3) Two patients had had small-pox some years previously. One of these, who had had it as a child, was among the "takes"; the other, who had had it as an adult, was not. I considered a "take" as something definitely more than the inflammatory lesion to be expected from vaccination with (say) aseptic normal saline.

Nobody would say that on board ship is a place of ideal surgical surroundings, but the other doctor on board considered that I could acquit myself of causing sepsis and that the clinical character of the lesions supported me. The vaccine was from a continental source.

I am, Sir, yours faithfully,
London, June 20th, 1929. G. PRATT BROOKS.

THE "PHYSIOTHERAPY CLINIC" AND THE PRACTITIONER.

To the Editor of THE LANCET.

SIR,—If I may still return to Dr. Matthew Ray's letter in your issue of April 20th it is to bring to your notice, as likely to be of interest, the Comely Bank Clinic, Ltd., Orford-road, Walthamstow, which is run on lines which meet all the objections he raises. The Clinic is a private limited company run by a board which, with one exception (a solicitor), consists of local medical men. This Clinic employs a specialist who attends at the Clinic two days in the week and at other times when necessary. The specialist alone is entirely responsible for treatment, which is carried out by the staff of fully trained and certificated persons under his direction. The doctor sends, or, if he prefers it, brings his patient to see the specialist at the Clinic. No charge is made for the consultation unless the case is considered unsuitable for treatment by electrical or physical methods when the modest fee of 10*s.* 6*d.* is requested.

In this way specialist treatment is secured without the specialist rate of fees, the treatment is carried out by fully trained and certificated persons under specialist direction, and there is no fear of the doctor being deprived of his patient, as the patient never comes into contact with any local practitioner. At the end of the treatment the specialist communicates to the doctor who sent the patient the results obtained and returns the patient to him.

I am, Sir, yours faithfully,
A. POTTINGER ELDRED,
Chairman of Board of Directors,
June 18th, 1929. Comely Bank Clinic, Ltd.

PRESENTATION TO SIR RONALD ROSS.

WHETHER or not the general public is mindful of the immense service rendered to medical science by Sir Ronald Ross, there is ample proof that his colleagues have never forgotten it. Last week two separate societies—one chiefly concerned with the advance of clinical medicine in highly civilised communities and the other with tropical hygiene in its widest aspects—summoned their members together for the purpose of presenting him with tokens of admiration and esteem.

At a meeting of the Royal Society of Tropical Medicine and Hygiene, the newly installed President of the Society, Dr. G. Carmichael Low, handed the Manson Medal to Sir Ronald Ross, who received a great ovation from the large assembly. The President in a brief address recalled the famous researches which had elucidated the whole life-cycle of the malaria parasite. When Sir Ronald began work in India in 1889 he was attracted to the study of malaria, a main cause of death to the people of that country. While in England on leave in 1894 he met Manson and learnt from him the hypothesis—Manson's great induction—that there were stages in Laveran's parasite the purport of which was to infect mosquitoes which sucked the patient's blood. Struck by this idea and stimulated by his talks with Manson, Sir Ronald, on returning to India in 1895, started on the researches, now of world renown, which were ultimately to make clear the true history of the malaria parasite in its passage from man to man. The story of the difficulties, disheartening disappointments, and trying work in a tropical climate, crowned finally by complete success, were to be found in Sir Ronald Ross's memoirs. No one reading this account could fail to appreciate the energy, perseverance, and ability of the man who carried them out. A remarkable feature of the work was that it completely elucidated the whole life-cycle of the malaria parasite, and that it had stood unaltered to the present day. Sir Ronald Ross was the Society's first Vice-President under Manson's presidency, and himself held the chair from 1909–1911. His work had brought him many deserved honours; among them the Manson Medal would surely rank high, for it associated his name with that of an old friend who had encouraged and helped him in trying times. After Sir Patrick Manson's death the Society had founded the Manson Medal to be awarded for distinguished meritorious work in tropical medicine. It would be strange indeed if this medal did not carry the name of Ross as a recipient, for the two names of Manson and Ross would go down together to posterity as the conquerors of malaria.

On the same evening, at a meeting of the West London Medico-Chirurgical Society, Dr. Harold Sanguinetti, who was in the chair, presented to Sir Ronald the Triennial Gold Medal of the Society. Dr. Sanguinetti pointed out that, though the discovery made by Ross was all-important to medical science, it was certainly not a money-making one for the discoverer, who would have done better for himself in the worldly sense if he had discovered a new boot polish. Malaria was not, as was supposed by some people, only a disease of the East. At one time it

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, July 1st.—2.30 to 5 P.M., Medical, Surgical and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

THURSDAY, July 4th.—4.30 P.M., Sir Thomas Carey Evans: Stone in the Bladder with special reference to Treatment by Litholapaxy.

Appointments.

LING, W. H. G. M., F.R.C.S. Edin., has been appointed Hon. Surgeon to the Keighley and District Victoria Hospital.

SMITH, D. S., M.B., Ch.B. Glasg., Certifying Surgeon under the Factory and Workshop Acts for Lesmahagow, Lanark.

STEVEN, ALICE, M.B., Ch.B. Edin., and HOLT, H. M., M.B., B.S. Lond., M.B., Ch.B. Leeds, D.P.H., Asst. Medical Officers of Health, Hull.

King's College Hospital: LIVINGSTONE, G. H., L.R.C.P. Lond., M.R.C.S., and TAYLOR, I., L.R.C.P. Lond., M.R.C.S., Senior Casualty Officers; HALL, V. F., L.R.C.P. Lond., M.R.C.S., House Anæsthetist; HALER, D. H., L.S.A., Resident Assistant Clinical Pathologist; HOSKIN, E. M., L.R.C.P., M.R.C.S., Radiologist; CUMINGS, J. H., M.B., B.S., CUBITT, A. W., M.B., B.Ch., and EASTON, J. H., L.R.C.P., Lond., M.R.C.S., House Physicians; REES, H. L., L.R.C.P., Lond., M.R.C.S., FERRABY, G. S., L.R.C.P. Lond., M.R.C.S., and THORNTON, J. W., L.R.C.P. Lond., M.R.C.S., House Surgeons; MAY, K. S., L.R.C.P. Lond., M.R.C.S., Urological Dept.; ORME, C. R. L., L.R.C.P. Lond., M.R.C.S., Orthopædic Dept.; MACBETH, R. G., M.B., B.Ch., Aural and Throat Depts.; PLAYFAIR, P. H. L., L.R.C.P. Lond., M.R.C.S., and KNOX, H. N., L.R.C.P. Lond., M.R.C.S., Obstetrical and Gynæcological Depts. *Non-Resident Appointments.*—LYLE, T. K., L.R.C.P. Lond., M.R.C.S., House Surgeon to Ophthalmological Dept.; PARER, A. J., L.R.C.P. Lond., M.R.C.S., Junior House Anæsthetist; and NICOLL, D. A., L.R.C.P. Lond., M.R.C.S., Junior House Surgeon to Aural and Throat Depts.

Queen Charlotte's Maternity Hospital: JENNINGS, D. R., F.R.C.S. Edin., Senior R.M.O.; DOLEMAN, F. T., M.R.C.S., L.R.C.P. Lond., Asst. R.M.O.

Victoria Memorial Jewish Hospital: BLAIN, I., F.R.C.S. Edin., Hon. Surgeon; LAMBERT, V. F., F.R.C.S. Edin., Hon. Ear, Nose, and Throat Surgeon; HUNTER, J. W. A., M.B., Ch.B. Edin., Hon. Gynæcologist; and BROCKBANK, W., B.Chir. Camb., M.R.C.P. Lond., Hon. Physician.

Vacancies.

For further information refer to the advertisement columns.

Accrington Victoria Hospital.—H.S. £150.

Birmingham, Dudley-road Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham General Hospital.—Res. Surg. Reg., &c. £100–£140.

Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.

Bombay Goculdas Tejpal Hospital.—Hon. Surgeon.

Bristol City Mental Hospital.—Third Asst. M.O. £350.

Cardiff, Welsh National School of Medicine.—Jun. Asst. in Med. Unit. £500. Jun. Asst. in Surg. Unit. £350. Also Asst. Lecturer in Pathology. £500.

Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Asst. S. Two Chief Clin. Assts. Also Res. H.S. At rate of £75.

Children's Hospital, Balaam-street, Plaistow, E.—H.P. At rate of £50.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—Asst. Laryngologist.

Croydon Mental Hospital, Upper Warlingham.—Second Asst. M.O. £350.

Dreadnought Hospital, Greenwich.—Asst. Radiologist. 50 gns.

Durham County Sanatorium, Holywood Hall, Wolsingham. Locum. 9 gns. per week.

East Suffolk Administrative County.—Asst. County M.O. £625. Also Asst. County M.O.H. £600.

Edinburgh Cogarburn Certified Institution.—Medical Superint dent.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate £120.

Gateshead County Borough, Mental Hospital, Stannington.—A M.O. £400.

Glasgow, Hawkhead Asylum.—Asst. M.O. £275.

Gloucester, Gloucestershire Royal Infirmary.—H.P. At r of £150.

Golden-square, Throat, Nose and Ear Hospital, W.—Hon. Asst.

Grange-over-Sands, Westmorland Sanatorium, Meathop.—M Supt. £800.

Great Yarmouth General Hospital.—Jun. H.S. £100.

Harrogate Infirmary.—Jun. H.S. £100.

Hellingley, East Sussex County Mental Hospital.—Res. Loc Tenens M.O. 7 guineas per week.

Hospital for Consumption, &c., Brompton, S.W.—H.P. At r of £50.

Hosp. for Sick Children, Great Ormond-st., W.C.—Part-time J Cas. O. At rate of £150. Also Res. M.O. for Country Bran Hospital, Tadworth Court, Tadworth, Surrey. At r of £250.

Hull Royal Infirmary.—2nd Res. H.S., Res. H.S. to Ophth De &c. Each at rate of £150. Also Res. Cas. H.O. At r of £130.

Ilford Emergency Hospital.—Jun. H.S. £100.

Indian Medical Service.—Recruitment of European Officers.

Inverness, Northern Infirmary.—Sen. H.S. Also H.P. and J H.S. At rate of £120 and £100 respectively.

Jewish Maternity Hospital, Underwood-street, E.—Res. M.O. rate of £50.

Kensington Tuberculosis Dispensary, 119, *Ladbroke-grove, W.*—Temporary Tuber. O. 35 gns.

Kidderminster and District General Hospital.—H.S. £150.

London Homœopathic Hospital, Great Ormond-street, W.C. Asst. Surgeon, Surgeon to Mechano-Therapy and Ort pædic Dept. Also Anæsthetist. £50.

Lowestoft and North Suffolk Hospital.—H.S. £120.

Macclesfield General Infirmary.—Res. H.S. £180.

Manchester, Ancoats Hospital—Res. M.O. £150. Also As Pathologist. £200.

Manchester Northern Hospital for Women, &c., Cheetham H road.—Jun. H.S. £100.

Manchester, St. Mary's Hospitals.—Four H.S's. Each at r of £50.

M.A.B. Tuberculosis Service.—Consulting Laryngologist. rate of 200 guineas.

Middlesex County Council.—Tuberculosis M.O. £750.

Miller General Hospital, Greenwich-road, S.E.—Pathologist. £6

Newcastle-upon-Tyne, City Hospital for Infectious Diseases. Res. Med. Asst. £350.

Northern Hospital, Winchmore Hill, N.—Jun. Asst. M.O. £5

Nottingham General Hospital.—Res. Surgeon. £250.

Oldham Royal Infirmary.—Three H.S.'s to Special Depts. Ea at rate of £175.

Portsmouth, St. Mary's Hospital, Institution, &c.—3rd Asst. R M.O. £250.

Preston, Royal Infirmary.—H.S. £150.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Asst. to Ear, Nose and Throat Dept.

Princess Louise Kensington Hospital for Children, N. Kensington. H.S. At rate of £75–£100.

Queen Mary's Hospital for the East End, E.—Hon. M.O. Electro-Therapeutic Dept. Hon. S. for Orthopædic De Hon. P. for Skin Dept. Anæsthetist. 50 guineas. A Cas. O. £150.

Reading Royal Berkshire Hospital.—H.P. At rate of £150.

Rotherham Hospital.—Sen. H.S. £200.

Royal Army Medical Corps.—25 Commissions.

Royal Dental Hospital, 32, Leicester-square, W.C.—Hon. Anæsthetist.

Royal London Ophthalmic Hospital, City-road, E.C.—Two O patient Officers. Each £100.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Albans, Napsbury Mental Hospital.—Jun. Asst. M.O. £4

St. Bartholomew's Hospital.—Asst. Physician and Asst. [illegible] of the Medical Professorial Clinic.

St. John's Hospital, Lewisham, S.E.—Two Res. House Each at rate of £100.

Sheffield Children's Hospital.—Jun. H.S. £100.

Sheffield Royal Infirmary.—Surg. Reg. £200. Also [illegible] H.S., Ophth. H.S., and Asst. Ophth. H.S. [illegible]ch at [illegible]

Shrewsbury, Royal Salop Infirmary.—Res. [illegible] Res. H.P. At rate of £160.

Sleaford, Kesteven Mental Hospital.—[illegible]

Southampton, Royal South Hants and [illegible] H.P. At rate of £130.

Stockport Infirmary.—H.S. Also H.[illegible]

Stoke-on-Trent, North Staffordshire [illegible] £150. Also H.S. to O[illegible] rate of £150.

Swansea County Borough.—Asst. M.[illegible]

Victoria Hospital for Children, Tite-[illegible] At rate of £100.

Swansea Hospital.—H.S. £150.

asey, Victoria Central Hospital.—Jun. H.S. At rate of £100.

ford, Herts, Peace Memorial Hospital.—Res. M.O. At rate of £150.

London Hospital, Hammersmith, W.—Director to Venereal Dis. Dept. £700. Also Aural and Ophth. H.S. and Res. Asst. Cas. O. At rate of £100.

esden General Hospital, N.W.—Res. H.S. At rate of £100. Also Refraction Assistant. 50 gns.

olwich and District War Memorial Hospital, Shooters-hill, S.E. H.P. and H.S. Each at rate of £125.

cester General Infirmary.—General Secretary.

exham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

rk County Hosp.—H.S. Also Res. Anæsthetist. Each £150.

e Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Croston (Lancs), and at Kirkcowan (Wigtown).

irths, Marriages, and Deaths.

BIRTHS.

AKE.—On June 20th, at "Bradesfield," Brundall, Norfolk, the wife of Dr. Eliot Blake, of a son.

AZARUS.—On June 13th, at Lancaster-road, Swiss Cottage, the wife of Mr. Arthur Lazarus, F.R.C.S., of Melbourne, Australia, of a son.

MARRIAGES.

OWN—TAYLOR.—On June 18th, at St. Cuthbert's Parish Church, Edinburgh, James Godfrey Lyon Brown, O.B.E., M.B., Ch.B., Northampton, to Annie Hair, youngest daughter of the late Charles Taylor and Mrs. Taylor, of Woodlands, Markinch, Fife.

VANS—DAVIES.—On June 15th, at St. Columba's, Pont-street, S.W., Dr. Horace Evans, to Helen Aldwyth, daughter of the late Mr. T. J. Davies and Mrs. Davies, of Devonshire-terrace, Hyde Park, W.

ALLINSON—PERKIN.—On June 18th, at St. Luke's Church, Matfield, Hugh Mallinson, M.A., M.R.C.S., L.R.C.P., to Betty, only daughter of the late Mr. F. R. Perkin and of Mrs. Perkin, of Meads, Eastbourne.

UCKLOW—GROVES.—On June 17th, at St. Mary's Church, Lymm, Cheshire, Stuart Leslie Mucklow, M.B., Ch.B., D.M.R.E., to Alexandra Winifred Groves, B.Sc., Ch.B., fourth daughter of Colonel and Mrs. John E. G. Groves, of Dean's Green Hall, Lymm, Cheshire.

HOMAS—WARDLE.—On June 12th, at Leeds Parish Church, Harold Hugh Thomas, L.D.S., of Leeds, to Gretta Mary Wardle, M.D.

HOMPSON—HODGE.—On June 15th at St. John's, Cheetham, Edward Roland Thompson, M.B., Ch.B., to Hilda Mary Hodge, of Farnworth, near Bolton.

ITMAS—COLE.—On June 15th, at Hampstead, Oscar Titmas, L.D.S., of Welbeck-street, W. to Madeline Yvonne, daughter of Mr. A. C. Cole and Mrs. Cole, of Ellerton Lodge, Finchley, N.

UCKER—HOBBS.—On June 21st, at the Church of the Sacred Heart, Bournemouth, P. A. Tucker, L.D.S.R.C.S., of Hereford House, Bournemouth, to Dorothy Mary, elder daughter of Major and Mrs. H. Hobbs, of Bournemouth and Calcutta.

DEATHS.

OWER.—On June 17th, 1929, David Bower, M.D., Springfield House, Bedford, aged 75.

ORLEY.—On June 20th, at Mill Hill, Thomas Simmons Morley, M.D. Lond., of Richmond Park-road, Bournemouth, and late of Barton-on-Humber, aged 76.

ORRIS.—On June 18th, the result of an accident, Barbara Edith May Morris, M.R.C.S., L.R.C.P., only daughter of Mr. and Mrs. E. W. Morris.

B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ENEMIES OF KNOWLEDGE.

Being the Third Stephen Paget Memorial Lecture delivered at the annual general meeting of the Research Defence Society on June 12th, 1929,

BY PROF. A. V. HILL, O.B.E., SC.D., F.R.S.

THERE is a limit beyond which abuse, misstatement, intolerance, and destructiveness must not be allowed to go. I hold no special brief for the medical profession, I realise that doctors, like the rest of us, have their failings, I am aware that privilege and vested interest may make some of them—sometimes—as selfish and intolerant as any. I tell them this at intervals, and admit, as greatly to their credit, that in spite of my abuse they continue to treat me with great friendliness and consideration; perhaps they do not take it too seriously. Gratitude, however, for that friendliness is not the reason why I stand here to-day, to defend them and their colleagues in the laboratories. Rather is it a sense of urgent necessity. When the beneficent work of the Medical Research Council is publicly denounced by a presumably responsible priest, when the use of radium, in the treatment of cancer, is openly described an an imposture by a qualified medical man who claims to have investigated it, and found it worthless forty years ago (9 years before it was discovered !), when the public is implored not to subscribe to hospitals lest its money be spent in torturing rabbits and guinea-pigs, when the greatest of human quests—the search for knowledge for the alleviation of suffering—is held up to obloquy by persons incapable of understanding or appreciating the beginning of what it means, then it is time for a counter-attack to be made. To change the metaphor, diagnosis is a necessary preliminary to cure. Instead of answering preposterous falsehoods merely by denial—a certain amount of mud always sticks, however innocent the victim pelted—one should inquire into the motives and mentality of those who make them. Stephen Paget would have approved of the title of this lecture. His fighting spirit and his generous heart often led him to join battle with those who attempted to hinder the advance of knowledge, and the improvement of medicine and surgery, for the gratification of their own sense of superior wisdom and goodness. I do not propose, however, to-day to discuss only the fantastic opposition of the anti-vivisectionists. Their attitude of mind is only one aspect of a general phenomenon well known throughout history, a mild form of mental disorder, if you will, but one which has expressed itself from time to time in various hideous forms; in cruelty and persecution, in hatred and malice, in the perpetual treachery of hindering mankind in his slow and pathetic efforts to climb the ladder of civilisation.

There are not many who realise the facts of man's gradual evolution; the majority are still inclined to imagine that Adam arrived full-grown a few thousand years ago, with a complete university education and a degree in zoology, in the Garden of Eden, and undertook forthwith the task of naming and classifying the other creatures whom God created for his special needs and satisfaction. Not many properly appreciate, and in some quarters it is almost blasphemy to do so, that in the course of a half million years mankind by a slow and painful process of trial and error has gradually risen from his original low estate. Nature's experiments in living things have been proceeding for hundreds of millions of years: by these experiments creatures of the most varied type had been evolved, to meet the absolute necessities of life, namely growth, maintenance, and reproduction. Finally a type of animal appeared, man's distant ancestor, so designed and constructed that he could become civilised. In an essay in the New Encyclopædia Britannica, "Civilisation," by J. H. Robinson, which some of you may have read, the matter is expressed in a vivid and arresting form. Picture the five hundred thousand years of man's developing culture as compressed into a single lifetime. On this scale mankind needed 49 years to learn enough to desert his primitive hunting habits and to settle down in villages. Half through the fiftieth year a few of the villagers discovered and began to practice the art of writing. The achievements of the Greeks on this scale were in March of this year: Christianity has prevailed since the middle of April: the printing process was invented a fortnight ago: we have been using steam for less than a week, motor cars for a day, wireless for a few hours. Whither is mankind going, on this strange progress? What are the methods of advance? are they inevitable? or can they now be influenced by conscious adjustment on his part? Have we in fact any responsibility in the matter?

Knowledge Makes Civilisation.

There are superior people who affect to despise the degree of civilisation, the modicum of knowledge, the extent of social organisation which have been as yet attained. They would have us abandon scientific research and engineering development as things unworthy of man's high spiritual estate. Such highbrows and unbelievers are useful, not for what they themselves bring to the common fund, but because it is good, even for the best of causes, to have to bear the brunt of criticism. I would not make "Progress" into a false god. Most reasonable people, however, neither believing in magic on the one hand, nor in the inevitability of progress on the other, see in the achievements of mankind, won by patient toil and eager searching, by failure as well as success, by disaster as well as triumph, in sorrow as well as in joy, by courage as well as skill, something to be treated with respect and reverence, something sacred, as we have come to regard human life itself to be. The advance of knowledge is a real and living thing, something worth working for, worth fighting for. That is why we are here to-day. It is true that we are all very stupid and unseeing still—some of us perhaps more stupid than others. We are very far yet from any Utopia, moral, mental, or material; but that the general progress of knowledge has improved man's lot and character and outlook in the last half million years, and that it can continue to improve them in the fifty million that lie before him, is a general proposition that not many will dare to deny. After all, it is knowledge which makes civilisation, *knowledge tempered by reasonable sentiment*, *controlled by decent emotion.* It is knowledge which makes the difference between man and animal: my spaniel Ben is a tangle of emotions, sentimental beyond belief, credulous to the last degree, ready to chase any imaginary cat or squirrel, believing in spooks and probably in "ectoplasm," a very pleasant and interesting companion, but utterly incapable of reaching any great height by his own unaided effort. The capacity for knowledge, for understanding himself and his environment, is man's essential characteristic and his alone: and to deny him the exercise of this fundamental gift would be an unpardonable, an almost unthinkable offence. There is indeed no danger, to-day, of anyone attempting to do so: all governments pay at least lip-service to education and research. The danger arises in the special applications, not in the general proposition—namely, when any specific individual piece of knowledge comes in conflict with vested interests, or tribal prejudices, or inherent conversatism, or even natural stupidity. It is against such prejudices that the fight has continually to be waged. We cannot hold our position by standing still—civilisation must either go forward or go back, and to go forward on some paths, back on others, will probably lead to confusion and disaster. Stephen Paget founded this society "to promote national health and efficiency, to bring about a better understanding of the value of medical and surgical studies, and to expose the false statements which are made against them": and in fulfilling this purpose it is necessary to combat one particular aspect of the spirit of reaction, namely the emotional opposition to the use of animals for experiment. Since, however, anti-vivisection is only a passing phase (one hopes) in the varying follies of mankind, while the fanatical desire to obstruct the advance of knowledge, for one or other cause, is apparently—judging from history—a permanent factor in man's mental constitution, I feel that a Society like ours must view the matter occasionally from the broader aspect and stand, as its name implies, for the defence of research in whatever form that research is undertaken.

"*Anti*"-*Bodies.*

There are many "anti"-bodies, apart from those which save us from disease. Some of them are good, most of them are bad. I cannot bring myself to object to anti-aircraft guns, and there is probably much to say for the anti-saloon league. Anti-dazzle, anti-fire, anti-germ, anti-vibration, anti-waste, and anti-slavery (to quote the telephone directory), all sound beneficent enough. In anti-prohibition, however, anti-socialist, anti-communist, and anti-vaccination we begin to tread on the dangerous ground of propaganda: while in London the anti-mind is revealed, in its highest form, in four separate and independent anti-vivisection societies, all fighting against one another in the same great cause. This anti-mind is no new phenomenon. In my recent researches I came upon an Anti-Rail-Road Journal dated 1835. The Editor claims, as Dr. Hadwen would, that he is "fighting only on the side of truth," "on behalf of some of the most valuable, but least defended interests." This journal contains "an exposure of the Railway System," and it is interesting to record that the list of those who subscribed to a pamphlet "Rail-Road Impositions Detected" is headed by the Provost and Fellows of Eton College, followed by fifteen canal companies, three steam waggon companies, several public houses, and a representative of Messrs. Pickford, carriers. The high ideals professed, and the flowery language employed, by the anti-rail-road enthusiasts of 1835 are so
similar to those of anti-vivisection to-day that the
grounds for the hope that the future of both may be the

It is strange and sad that man, for all his desire for
ledge, his sacrifice and his effort in its pursuit, shou
tormented by this mistrust of what he has been able to
Folly and hatred exist, often in the same mind, side by
with wisdom and goodwill. There is no thesis so ridic
no cause so unworthy, but that some body of zealots w
found ready, in season and out of season, to supp
Cults and movements, rooted in superstition and cred
rear their heads in our midst. There are not many w
not believe in some kind of magic. There is no self-
prophet, no soothsayer or fortune-teller, no food fadd
purveyor of patent medicines or electrical "rejuvena
who cannot, given a little plausibility, secure a follo
How are we to distinguish such cults and movements

but alas, not all people are reasonable or educated;
it is difficult or impossible to give any short defini
which will include wisdom and omit folly. After
nobody has yet supplied—or is likely to supply—a
factory definition of life itself, though most people
recognise a living thing when they see it. True kno
ledge is consistent with itself and ultimately with hum
nature: false prophets can be safely trusted to cut
other's throats: strange cults and movements to neutral
each other's efforts. One must not take these things
seriously. The presence in our midst of weird and wond
ful societies designed to save us from premature burial,
convince us that the world is flat, that "spirits" can
photographed, or even that black is white, adds greatly to
gaiety and interest of life: I for one would treat them kin
and let them have their say. The case, however, is differ
when a lunatic ceases to be harmless and begins to interf
with other people's liberties: we are no longer amused,
shut him up. Individual freedom from molestation is
hard-won basis of modern civilisation. If an individu
offends too grievously in such matters, society retorts
restricting his liberties. So it is with the advance of kno
ledge: freedom of thought and research is the basis of hum
progress: only when these interfere with other peopl
liberties and rights must a check be applied. I have
quarrel with those who choose to believe, as a lady o
wrote me, that "the Almighty never intended that
animal should profit at the expense of another." I may h
that whales, devouring millions of shrimps daily and digesti

of view. After all such beliefs add colour to the world.
situation changes, however, if she tries to interfere with
liberties of my friends and me. If by telling lies and spre
ing calumnies, if by petty persecution in private or malicio
prosecution in the police-courts, if by attempting to forwa
legislation forbidding the use of snails, lobsters and frogs
research, she provides a wanton hindrance to the advance
knowledge, then the matter ceases to be a joke and must
taken seriously; and if, to forward her thesis, she does
hesitate to stop subscriptions to hospitals and to hinder th
work on behalf of suffering fellow-men, then my blood beg
to boil, as Stephen Paget's used to do, and tolerance becom
impossible.

The Psychology of Persecution.

Persecution, the desire to injure or to kill those wh
opinions are different from one's own, is a very old factor
human history. You can see it brutally displayed, oft
under the cloak of religion, in the Old Testament, as well as
later times. You can see it in schools and colleges. F
quently enough it is for non-conformity to some establish
custom, for upsetting some ancient prejudice. The tribe
bound together by certain rites and rituals, by cert
traditional beliefs, and anything which diminishes
authority of these artificial restraints and bonds is held
weaken the tribe and so to justify the persecution of
offender. This faith in established custom is an essent
factor if mankind is to maintain advance already secur
and not to slip back, in times of stress, into barbarism.
must not underrate—however radical our own outlook—
value of conservatism as an attitude of mind, the love
things which they know and have experienced as the ba
of the outlook of common men. Equally, however, we mu
realise that necessary as a brake may be to prevent us fr
slipping down hill, or to stop us when we are going too fa
we can never go forward at all with nothing but a set
brakes, however efficient. And yet in the past (as indeed
the present) mankind has been singularly intolerant of, a
cruel to, those who sought a new point of view and usua
has invoked the name of God to justify the persecuti
I admit—to its credit—that the Anti-Rail-Road Jour
avoided calling upon the Almighty to bear witness to
the purity of its motives; the anti-vivisectionists ha

same compunction. The authorities of Rome and Catholics throughout Europe, many of them people uine *religious instinct* and purity of life, exulted in the ry of 7000 Huguenots on St. Bartholomew's Day in Even in those days the barefaced *massacre of 7000* would have been regarded as discreditable, unless the of God had been invoked. Persecution, torture and were common penalties till quite recently for those with religious beliefs one did not agree: and many things, ing astronomy, could be interpreted as religion.

psychology of persecution is not hard to understand. Barnes, now Bishop of Birmingham, wrote in 1913:

> hen a man of real piety sees the ideas which he venerates , objects which he believes to be holy scorned, he burns a righteous indignation which no mean motive of personal or revenge can kindle. The strength of his conviction with it not only a presage of victory, based on the belief will defend the right, but also the martyr's contempt of is a righteous cause. It is thus that there is no adversary midable as a man sure that he is fighting the battle of the of Hosts, no antagonist so relentless in pursuing opponents who is convinced that it is his duty to make them an able sacrifice to his God.
>
> first sight this intolerance seems to be a noble and fair flower ing from the cultivation of all that is best in the human . Of course even men filled with such fire admit that the for persecution is dangerous: all recognise that a love of and a joy in destruction are among the lower passions of kind, and inferior men animated by such passions are usually instruments by which the righteous secure the conquest of Apart from all ethical considerations the verdict of history ns intolerance as both stupid and criminal. Persecution ever mild a form is usually both a mistake and a crime. It stake because it so rarely succeeds: it is a crime because in of virtue you unchain the baser passions of mankind. success of intolerance is always momentary; its ultimate remains to hamper and distress those who inherit the which it bequeaths.

It is not, however, only in theological matters that intolerance is so rife. In matters of natural knowledge also gives us many examples, though usually here too ligion is invoked as an excuse for intolerance. Vesalius, an atomist, was inspecting with the consent of his kinsman, body of a Spanish nobleman recently dead: the heart a feeble palpitation when divided by the knife. Vesalius denounced to the Inquisition and driven from Italy and before his return. Servetus, also a physician and atomist, was burnt at Geneva for his controversial tings, though it must be admitted that these were usually a theological rather than a scientific character: science theology, however, were harder to separate in those days. uno, the great Italian philosopher of the Renaissance, was soned for seven years by the Inquisition and finally burnt the stake. In 1610 Galileo's propositions that the sun is centre of the world and that the earth rotates daily characterised by a commission of inquiry as "absurd philosophy and formally heretical because expressly trary to holy scripture." By command of the Pope he admonished not to "hold, teach, or defend" the condemned doctrine. His great book, published 10 years later in 32, reaffirmed the Copernican principles of the universe and sed him, in spite of his seventy years, to be summoned to me. Examined under the menace of torture he was ndemned to a period of incarceration and, as a penance, to ite once a week for three years the seven penitential psalms. ey had a sense of humour in those days; I am sure that . Coleridge would condemn Lord Knutsford to some worse nalty than that. After all, do not his friends (or are they . Hadwen's?) pray for our deaths, in general and in ticular, as we have their own written testimony to show; ich is a mean advantage to take if they think that their ayers have any effect. Stephen Paget's death indeed was imed by the anti-vivisectionists as a direct consequence of eir prayers: a postcard to that effect was received by this ciety. No doubt mine will be in due course. The quisition at any rate was more honest: they burnt you if ey could and took the responsibility; they did not try to mmit murder, by proxy, via the Almighty, without risk, oral or material, to themselves. In more recent times than alileo's, the bitterness and folly evoked by the controversy er evolution still linger: there must have been many, ladstone perhaps among them, and certainly several nglican bishops, who would gladly have burned Mr. Darwin d Professor Huxley at the stake, had not that procedure en out of date. There are probably respectable churchers still who would, without regret, offer Dr. Barnes as a crifice in the same great cause of anti-evolution. And yet, -day, to the mass of thinking people, it is perfectly inconivable that Gladstone was right and Huxley was wrong, and at evolution is not a fact, whatever its mechanism may have en.

Religion as a Cloak for Intolerance.

It is strange how often religion, or what is alleged to be ligion, is made the basis of intolerance. To pass from the blime to the ridiculous, even a parish magazine may be used as the vehicle for anti-vivisection propaganda. In the *Parish Paper* of the Church of St. Jude-on-the-Hill (Hampstead Garden Suburb) of May 24th, 1929, the Rev. B. G. Bourchier permitted himself to ask "intelligent people" to take the opportunity of the General Election, now past, to put an end to "the waste of public money" involved in medical research. He protested there against the expenditure of £148,000 during the last financial year by the Medical Research Council. Those of us who know the admirable use to which that money is put, in promoting medical knowledge and therewith the health and happiness of the community, would wish a formal protest to be made against such propaganda in such a place. The reverend gentleman is entitled to hold whatever private opinions he chooses about the personal characters and abilities of those engaged in medical research; the use, however, of his authority and position in the national church as a means of hindering the work of an organisation which is serving mankind at least as well as he is, is a disgrace which the authorities of that church would do well to note. It is as though the Medical Research Council were to permit an attack upon the Church of England and its priests to be launched by one of its junior workers in the pages of a report! It may be said that this is an isolated case. Unfortunately not. In the *British Weekly*, a nonconformist newspaper with an enormous circulation, in the issue of May 16th, 1929, there is a large advertisment by the British Union for Abolition of Vivisection in which it is asked, "Will God allow the interests of Humanity to be served by the violation of His law of compassion? Is His blessing likely to rest upon such barbarities as (1) baking animals in ovens and watching through glass doors to see how long they take to die, (2) tying dogs' limbs over their backs and placing them in plaster-of-Paris and keeping them thus up to 6 weeks, etc."? A woman doctor whom I know, provoked by this advertisement, wrote to the British Union and asked what evidence they had for these alleged atrocities. In reply to her letter a visitor came to see her, who gave the name of Grace Hawkins. Members of the Research Defence Society may remember that in our Journal of the spring quarter of this year there was some amusing correspondence reproduced from the *Hampstead Gazette*. A letter headed "Alleged Animal's Hell," signed by this same Grace Hawkins, had pointed out that "being an artist" she did not wish to defend the ugly headquarters of the Medical Research Association (sic) at Hampstead, but that she desired to call attention to the immeasurably greater ugliness of the work carried on within it. "Within this animals' hell vivisectors of both sexes (what is the implication of this?) perform their experiments upon the quivering bodies of live animals and agonised cries of these helpless victims sometimes penetrate into houses near by, causing great distress of mind": in fact, so great apparently is the distress that "some of the residents and visitors have left the district." These statements were challenged by our secretary, but Grace Hawkins gave as her reason for refusing to publish the facts her reluctance to draw others into the controversy. Anyhow she visited my friend in reference to the advertisement in the *British Weekly*. When asked what was her evidence for the alleged atrocities she said that the first of them was committed by Claude Bernard. It took some time to make her admit, without prejudice to the question of whether he had really performed the experiment, that Bernard was dead these many years, that he had worked in France and not in this country, and at a time when standards of kindness to animals were much lower than they are to-day. Her only defence was finally "how do we know that such things are not going on in England now?" The evidence for No. 2, the tying of dogs' limbs over their backs, etc., was apparently obtained from an anti-vivisection journal! The evidence for No. 3 came from *John Bull*. Grace Hawkins, getting little change out of my friend, remarked that she had always found that women doctors were "harder than men because they are afraid of appearing sentimental." When she left, the lady on whom she had called, wishing to end the interview as pleasantly as possible, thanked Grace Hawkins for troubling to come to explain her point of view, shook her hand and said goodbye with a smile: Grace Hawkins drew herself up dramatically and cried: "Don't smile, don't smile, your smile will haunt me. Oh, sister, may God soften your heart." What can be done with these people except laugh at their eccentricities?

Please do not imagine that I am attacking religion. Among scientists and medical men, among philosophers and thinkers, there are many who view the world from a genuine religious standpoint. Indeed, if religion be regarded as an affair of the spirit, and not as a formal acknowledgment of ecclesiastical authority, scientists and philosophers are probably among the most religious people in the community. They, at any rate, recognise some authority in Nature outside themselves, by whatever name they may call it. They do not parade their religion so openly, and they do not call on God so often to justify, or to hide, their follies and misdeeds. They are perhaps less confident that their particular faith is right.

They know how difficult the problems are. Between true science, however, and true religion there is no conflict. The battle is between science and reason on the one hand, and religion used as a cloak for intolerance and stupidity on the other. It is necessary to say this clearly, for in answer to my protests against this misuse of religion I have no doubt that, under a smoke-screen of abuse, our opponents will trail a red-herring across our path (they will mix their metaphors too) and assert, with pious hands raised to heaven, that I am attacking religion. Well, I am not. I have been attacked before now for not attacking religion.

Libel and Slander.

Perhaps, however, it is a good thing that science and scientific men should be continually suspect by the community whom they serve ; it prevents, to use the lingo of advertisement, "that pontifical feeling" ; it is good for them to be on their defence and not to have their results too readily accepted. Whether it is equally good for the community to discredit its scientists I doubt, but that is another matter. Criticism and hostility, above all, bind them together into a brotherhood. It may not be commonly known, but it is nevertheless a fact, that the Physiological Society was founded 53 years ago, as the direct result of anti-vivisectionist agitation, for the mutual benefit and protection of physiologists. This is one of the great services which that agitation has rendered to mankind. The Physiological Society was the elder sister of the American Physiological Society : its influence on the promotion of physiological knowledge by experiment and thereby indirectly on medicine, has been world-wide. University College is the proud possessor of a Bayliss Fund, which is used to assist physiological research : it represents the proceeds of an action for libel brought by Sir W. M. Bayliss against Mr. Stephen Coleridge ; another contribution by anti-vivisection to medical research. There are not many such good deeds to relate.

I wish I had time to tell you of some of the follies of anti-vivisection which I have been privileged to witness. One I must mention, for it involves Stephen Paget, the founder of our Society. Lord Cromer came to speak to the Cambridge Branch. Sir George Darwin was in the chair. Stephen Paget of course was there. Two old ladies, breathless and with their bonnets all awry, arrived in the hall. I watched them nudging and encouraging each other. At last, when questions were invited, one of them got up and demanded : "Mr. Chairman, is it true that at the Pasteur Institute they make dogs mad by poking them with red hot pokers ?" A difficult question to answer. We shall probably have just such questions to-day. After the meeting Paget and I were talking on the steps outside : he, if I remember right, was smoking a cigarette and blowing the smoke to the sky. The two old ladies rushed up to us and began upraiding him : he turned his face upwards to the heaven (his friends may remember that his face was no common one, and I shall never forget the picture) : he inhaled more deeply from the cigarette : he waited patiently for a pause in the abuse : deep from his inside, his face still upwards to heaven, came a voice—"Madam, I advise you to be very careful in the statements that you make." No more. The old ladies took up the cudgels again and belaboured him—again a pause—a voice still deeper from his inside, his face still upwards to the sky : "Madam, I advise you to be *extremely* careful in the statements that you make." The old ladies could bear it no longer : gathering up their skirts they fled across the square and we saw them no more : I fear they are still anti-vivisectionists.

Perhaps, however, the greatest experience of all was when my colleague, Prof. Lovatt Evans, was accused of stealing dogs for use in his laboratory and I, attempting to draw off some of the enemy's fire, dared to write to the *Times*, pointing out that 40,000 dogs per annum are uselessly destroyed in London alone, with the connivance of the anti-vivisectionists, and that if we could have some, say 1 per cent., of these, there would be no chance of our buying stolen ones. The argument was so obviously pertinent and the result, from the anti-vivisection standpoint, so undesirable that—as I hoped—a flood of abuse descended upon me, much of which was unfit for publication, though it pleased, if not edified, our medical students when it was exposed on the screen. Shortly afterwards my colleague, Professor Verney, was prosecuted for stealing a dog, and a similar flood of obscene abuse descended upon him and upon Sir Gregory Foster, Provost of University College. A month or two later I was reproached by the "English Branch of the World League against Vivisection and for the Protection of Animals," for having tortured my son during my Christmas Lectures at the Royal Institution ! To a foreigner these sound like fairy stories, but they are literally true.

The Path of Progress.

In all lands there are scientific workers : their problems are necessarily the same : their methods are the same : their ultimate appeal to Nature as an arbiter between their theories cannot be different. We are, or we should be—in physi indeed I have good reason to know we are—a great bro hood unbroken by frontiers and national hatreds. It not so for a time after the War, and it is still not so in other branches of science. Only three years ago a scie man of high standing told me, apparently with deep fe that he would rather hinder the progress of knowledge associate with German professors ! If there is one thi the world which should be international it is the purs knowledge, and such a point of view infuriates one no but more than the calumnies of anti-vivisectionists. more common and more dangerous and it is not mitigat any obvious and inherent absurdity. It is a negation of common human factor in civilisation.

There is one last type of intolerance to which I should this is the intolerance of scientific theory. Very often, admitted facts, a theory is based which represents no whole truth but only one aspect of the truth. Beca process follows the laws of conduction of heat it does *follow that it is conduction of heat—other processes* the same laws. Many theories which will explain a li number of facts may prove right when the number of fa increased. Let us admit that evolution is a fact: inconceivable otherwise in face of the evidence. The th of natural selection was put forward to explain the adm facts of evolution. To some that theory has become a do just as hard and unbending as those of religious ortho Science too is apt to have its "Thirty-nine Articles." an attitude of dogmatism is dangerous. To suppose theories are facts, to be intolerant of those who do not b one's theories while admitting one's facts, is to hinder pro from within just as effectively as others can hinder it without. The attitude of the dictator had better be altog avoided. Continual scepticism, both of other peo theories, but more particularly of one's own, is needed are, however slowly, to progress. Such scepticism make us unpleasant people to live with, but it ensures whatever little progress we may achieve is upwards and down.

Conclusion.

One last word. It is possible to hold strong opinions still to be tolerant. We must have theories, and we believe them very implicitly, if we are to progress. A sl accumulation of facts will gradually overwhelm the hun brain, if no means of ordering them be available. We m however, continually reflect upon the possibility that a all we may be wrong. So long as we do nothing unfai other people and *their* theories, so long as we do not inte with *their* liberties in the pursuit of their lawful business, own strong beliefs, our own stupidity and ignorance, may forgiven. Inside the front page of a recent book on phys astronomy a friend of mine has pasted a cartoon of a yo lady talking to an old fisherman : "What did you thin she says, "of last night's wireless lecture on the atom "Never heard such a pack of lies in my life." That, howe is not the same thing as intolerance ; no old fisherman wo wish to burn, to imprison, or even to pray for the death Professor Eddington and Sir James Jeans. I do not m care if the Countess of X, or her friends in the Governme take the same cheerful view that the results of medical resea are a "pack of lies." That is her business, and after all, I bably have the same contempt for many of her sacred beli I am content to leave the decision between us in such matter the public intelligence. What I do protest against, and wo fight against with all my strength, are calumnies and pe cution, and attempts at legal interference with our libert wantonly intended to hinder the advance of knowledge national and political hatreds which prevent coöperation in greatest of human quests ; or theories, however well ground which their owners cannot conceive as being otherwise t true. In such matters, after all, modesty, friendlin humanity, judgment, balanced by a reasonable sense humour are, as in other things, the basis of human welfare

AMBULANCE AEROPLANES.

The demonstration of ambulance aeroplanes during the ternational Congress of Sanitary Aviation, to which our aris correspondent recently referred, was instructive in negative as well as a positive way. Very few countries st ambulance aeroplanes—an omission which will doubtless made good in a few years, when the authorities concerned alise what scope there is for useful give-and-take in this ld. In Britain, as Air Vice-Marshal David Munro reminded e Congress, not much use has been made as yet of aeroplane nbulances for transporting urgent cases to hospital. The asons for this are manifold. One is, that communication road or rail is for the most part good and rapid, and stances are not great. Another is, as Dr. Munro had admit, that weather conditions are often bad, particularly regard to visibility. Nevertheless, he was satisfied that oner or later aeroplanes would be used for transporting e sick from remote places such as the Scottish islands, here both the population and the opportunity of medical lp is scanty. Unfortunately, such services are costly and meone must pay for them. Outside Britain aero-transport already in use in Australia and in Mesopotamia; in e latter it is the ordinary method of evacuating the sick means of R.A.F. aeroplanes transformed to carry retchers. The French, however, were the first to utilise ch specially constructed air ambulances, and Dr. Munro pressed his admiration at the success of such aerial transrt in military operations in Morocco and Syria.

Poland.

Sanitary aviation in Poland begun in 1924 with the nversion of an army aeroplane of the Albatros C.X. pe into an ambulance aeroplane, capable of carrying e lying case in addition to the pilot. In 1928, in Warsaw, committee was created for the promotion of sanitary iation. The Polish National Red Cross Society has underken the task of organising sanitary aviation. At the esent time there is a network of stations available for the bulance aeroplane, the Warsaw station, with a radius action of 200 kilometres, possessing ambulance aeroplanes the Hanriot and Bréguet types. Other stations, with adius of only 80 kilometres, are provided with Hanriot oplanes. This service is at present limited to patients o are badly injured or very ill. In an appeal for the vices of an ambulance aeroplane, the diagnosis of the plaint and the name of the doctor responsible must stated. In doubtful cases the chief medical officer the station concerned decides whether an aeroplane to be sent or not, catastrophes or unseen accidents epted. Telephone calls for an ambulance aeroplane are given precedence, even before official communications. According to the statistics of five stations compiled in March, 1929, 41 persons had been carried a total distance of 8260 kilometres. The station of Cracow was called on in 1928 for the services of an ambulance aeroplane 19 times, the distances to be traversed ranging from 30 to 160 kilometres. Some appeals had to be refused either because the distances were too great or the hour of the day too late. There were no landing accidents, although these landings were impromptu. In the winter skis were used in the place of wheels.

Map of the eastern provinces of Siam showing air lines in use or proposed (dotted). A white cross denotes an aerodrome with ambulance planes, a black ringed circle a landing ground in being, a black dot one under construction. Scale about 200 km. to the inch.

Siam.

In the north-eastern part of Siam lack of highways and the rainy season render automobile traffic most difficult. The time taken to travel 200 kilometres by the ordinary means of transport—the bullock cart—is about ten days. The Government has, accordingly, provided this part of Siam with a regional, central aeroplane station and various subsidiary stations. Sick persons desiring medical treatment in Bankok can hire ambulance aeroplanes at the rate of one tical per kilometre, no charge being made to poor patients. Before the introduction of an Air Mail Service in the north-eastern province, drugs and medical supplies took long to reach their destination and were liable to suffer mishap during terrestrial transport. As early as June, 1921, the Department of Public Health employed an ambulance aeroplane to convey doctors and medical supplies to a distant area where a serious epidemic had broken out. The success of this venture, which saved many lives, induced the authorities to arrange for the conveyance by the Air Mail Service of medical requisites for combating epidemic disease in human beings and domestic animals. It is reported that, since this arrangement was made, the serious outbreaks which used to occur have ceased. The ambulance aeroplanes in use are adaptations of the Bréguet type fitted with a 300 h.p. Renault engine. With a speed of 120 to 160 kilometres per hour, these aeroplanes, which carry two lying or four sitting cases, can remain in the air for three to four hours. There are now ten ambulance aeroplanes attached to the different air stations.

Sweden.

A Swedish ambulance aeroplane which had flown from Malmö to Paris attracted much attention at the Congress, and the thoughtful and generous provision of literature on the subject enabled delegates to pocket for future use some of the information they did not assimilate at the time. A trial flight impressed one with the comfort and warmth of the interior, and with the smoothness with which the aeroplane landed. The Swedish Red Cross Society started as early as 1923 to develop sanitary aviation, beginning with a French Bréguet aeroplane, a biplane fitted with a 12-cylinder Renault engine. The actual transport of patients by air began in the summer of 1924, and no accident has happened, although since then, from one station alone, that of Boden in the north of Sweden, as many as 126 patients have been transported, including those suffering from enteric fever (15), pulmonary tuberculosis (14), appendicitis, with or without peritonitis (17), and 16 obstetric cases. The Bréguet failing to wear well in the rough climatic conditions of the North, a Junker aeroplane was obtained, with a radius of action of 500 kilometres. Provided with floats and skis, and made entirely of duraluminium, the interior is heated by air which has passed over the exhaust tubing. The cost was kr. 85,000. This aeroplane has been stationed at Boden since 1926. For more than a year, a society (Luftfartsförbundet) has existed in Sweden with the object of promoting aerial navigation, and one of its aims is to develop sanitary *aviation. In December, 1928,* it presented the Swedish Red Cross with kr. 60,000 for the purchase of an ambulance aeroplane to be stationed south of Boden. It has also given kr. *50,000 for another aeroplane to be stationed* near Stockholm. When Goteborg and Karlskrona are similarly *provided*, Sweden will be served with ambulance aeroplanes within reach of every part of the country.

THE DANGERS OF LIFE IN THE TROPICS.

THE experiences of one who has not only travelled widely in the *tropics* but has worked there as an active investigator of local diseases can hardly fail to be of interest. Dr. Torrance describes his African and Asian journeys and supplies maps to show the routes taken. In Africa, he passed from Angola to Mombassa in the middle *south, and* in the middle north, from Kenya to Gambia; while in Asia he sampled Burma, Annam, Siam, Malay States, Sumatra, and Borneo. His book is addressed rather to the laity than to the medical profession, and he *deserves congratulation* on the simplicity and freedom from technicalities of his accounts of tropical diseases such as malaria, yellow fever, trypanosomiasis, relapsing fever, dengue, *and cholera.* He gives the history of the curative measures adopted for each at different times. These medical details are *interwoven* with tales of big game, native dances and other adventures, some of which are exciting enough. Those *who like swatting* flies will appreciate his notes on "man-handling the mosquito." The first chapter, in defence of the big jungle beasts, points the moral that, dangerous as these may be, they are no more dangerous than the insect perils that beset all travellers in the tropics. A useful table of the important tropical forces, their transmitter, geogra *distribution,* and diagnosis completes a book which meditating a sojourn in the tropics, might well read they start.

SYNTHETIC SUBSTITUTES FOR NATURA PRODUCTS.

IN the course of an address on the Changing Found of Materia Medica, delivered in Dublin on June 2 the annual meeting of the British Pharmaceutica ference, Mr. R. R. Bennett, the chairman, commen substitution of synthetic for *natural drugs. He* p out that among the achievements of recent years ha the replacement of the active *principles of certain* r products by identical substances synthetically pr at a cost which compares *favourably* with that natural article. The price of synthetic thyroxin that of the natural product obtained from the thyroid The replacement of natural ephedrine by the sy product has been attempted, but the latter does not the same *therapeutic activity as the natural* al Both in the animal and the vegetable world Nature her syntheses within a very small range of temp and with very mild reagents. Fusions with alkali, ment with powerful dehydrating agents, *and seale* reactions under pressure are unknown to her. The sy of the laboratory are invariably performed in a which would destroy the apparatus in which natur ducts are formed. Nature also possesses the se optical activity and leaves to Art the synth optically inactive forms only; but most of these o inactive forms can now be resolved. Mr. Bennett mented on the number of drugs possessing valuable cinal properties which are obtained solely by sy chemical processes. The great advances in sy chemistry were remarkable in view of the fact that century ago a sharp distinction was drawn betwe inorganic and the organic world. The discovery that substances, previously supposed peculiar to the tis living beings, could be prepared in the laboratory h a profound influence on pharmacy and during the that elapsed between. The centenary of the synth urea by Wöhler in 1828 has recently been commem Wöhler by heating potassium cyanate with amn carbonate produced the substance urea which pre had been known only as an important constituent o Between the synthesis of urea and that of thyroxi numbers of organic compounds of immense importan been synthesised.

A DIRECTORY OF BRITISH CHEMICAL

A DIRECTORY of British chemicals[1] last issued in 19 now been revised and brought fully up to date, the in being that an edition shall appear every second ye contains a full list of members of 117 firms and 13 a associations with a classified list of British chemicals note of their uses. The catalogue is printed in five lan other than English, the products being classified alp cally in tabular form from Acenaphthene down to Zin salts in English; the name of the product in other lan follows an alphabetical key table in each language, it easy for foreigners to find their way about the cat At the end is a list of proprietary and trade names, which Tartar is included as a "tar preparation for
